Part IV Cross-section and Panel Data Applications

Part V Microeconometrics

Part VI Applications of Econometrics to Economic Policy

Part VII Applications to Financial Econometrics

Part VIII Growth Development Econometrics

Part IX Spatial Econometrics

Part X Applied Econometrics and Computing

Notes on Contributors

Luc Anselin is Foundation Professor of Geographical Sciences and Director of the School of Geographical Sciences and Urban Planning at Arizona State University, USA.

Aninyda Banerjee is Professor of Econometrics at the University of Birmingham, UK.

Gunnar Bårdsen is Professor of Economics at the Norwegian University of Science and Technology, Norway.

Thorsten Beck is Professor of Economics and Chair at the European Banking Center, Tilburg University and Research Fellow, CEPR.

Colin Cameron is Professor of Economics at the University of California, Davis, USA.

Fabio Canova is ICREA Research Professor in Social Science at Universitat Pompeu Fabra, Barcelona, Spain.

Joe Cardinale is a Manager, Economics at Air Products and Chemicals, Inc., USA.

Michael P. Clements is Professor of Economics at Warwick University, UK.

John DiNardo is Professor of Economics and Public Policy at the University of Michigan, Ann Arbor, USA.

George Dotsis is Lecturer in Finance at the Essex Business School, University of Essex, UK.

Steven N. Durlauf is Professor of Economics at the University of Wisconsin-Madison, USA.

Juan Carlos Escanciano is Assistant Professor of Economics at Indiana University, Bloomington, USA.

Carlo A. Favero is Professor of Economics at IGIER-Bocconi University, Italy.

Julie Le Gallo is Professor of Economics and Econometrics at the Université de Franche-Comté, France.

Luis A. Gil-Alana is Professor of Econometrics at the University of Navarra, Spain.

William Greene is Professor of Economics at the Stern School of Business, New York, USA.

Stephen G. Hall is Professor of Economics at University of Leicester, UK.

David I. Harvey is Reader in Econometrics at the School of Economics, University of Nottingham, UK.

David F. Hendry is Professor of Economics and Fellow, Nuffield College, Oxford University, UK.

Brian Henry is Visiting Fellow at the National Institute of Economic and Social Research, NIESR, UK.

Javier Hualde is Ramon y Cajal Research Fellow in Economics at the Public University of Navarra, Spain.

David Jacho-Chávez is Assistant Professor of Economics at Indiana University, Bloomington, USA.

Paul A. Johnson is Professor of Economics at Vassar College, New York State, USA.

Andrew M. Jones is Professor of Economics at the University of York, UK.

Katarina Juselius is Professor of Empirical Time Series Econometrics at the University of Copenhagen, Denmark.

Ignacio N. Lobato is Professor of Econometrics at the Instituto Tecnológico Autónomo de México, Mexico.

Nancy Lozano-Gracia is Postdoctoral Research Associate in the GeoDa Center for Geospatial Analysis and Computation at Arizona State University, USA.

Raphael N. Markellos is Assistant Professor of Quantitative Finance at the Athens University of Economics and Business (AUEB), Greece.

Bruce D. McCullough is Professor of Decision Sciences and Economics at Drexel University, Philadelphia, USA.

Terence C. Mills is Professor of Applied Statistics and Econometrics at Loughborough University, UK.

James Mitchell is Research Fellow at the National Institute of Economic and Social Research, UK.

Ragnar Nymoen is Professor of Economics at University of Oslo, Norway.

Marius Ooms is Associate Professor of Econometrics at the VU University, Amsterdam, The Netherlands.

Kerry Patterson is Professor of Econometrics at the University of Reading, UK.

Efthymios G. Pavlidis is Lecturer in Economics at the Lancaster University Management School, Lancaster University, UK.

Ivan Paya is Senior Lecturer in Economics at the Lancaster University Management School, Lancaster University, UK.

David A. Peel is Professor in Economics at the Lancaster University Management School, Lancaster University, UK.

D. Stephen G. Pollock is Professor of Economics at the University of Leicester, UK.

Tommaso Proietti is Professor of Economic Statistics at the University of Rome 'Tor Vergata', Italy.

Sergio Rey is Professor of Geographical Sciences at Arizona State University, USA.

Larry W. Taylor is Professor of Economics at the College of Business and Economics, Lehigh University, Pennsylvania, USA.

Jonathan R.W. Temple is Professor of Economics at Bristol University, UK.

Pravin Trivedi is Professor of Economics at Indiana University, Bloomington, USA.

Ruey S. Tsay is Professor of Econometrics and Statistics at the University of Chicago Booth School of Business, USA.

Martin Wagner is Senior Economist at the Institute for Advanced Studies in Vienna, Austria.

Editors' Introduction

Terence C. Mills and Kerry Patterson

The *Palgrave Handbook of Econometrics* was conceived to provide an understanding of major developments in econometrics, both in theory and in application. Over the last twenty-five years or so, econometrics has grown in a way that few could have contemplated, and it became clear to us, as to others, that no single person could have command either of the range of technical knowledge that underpins theoretical econometric developments or the extent of the application of econometrics. In short, econometrics is not, as it used to be considered, a set of techniques that is applied to a previously well-defined problem in economics; it is not a matter of finding the "best" estimator from a field of candidates, applying that estimator and reporting the results. The development of economics is now inextricably entwined with the development of econometrics.

The first Nobel Prize in Economics was awarded to Ragnar Frisch and Jan Tinbergen, both of whom made significant contributions to what we now recognize as applied econometrics. More recently, Nobel Prizes in Economics have been awarded to Clive Granger, Robert Engle, James Heckman and Daniel McFadden, who have all made major contributions to applied econometrics. It is thus clear that the discipline has recognized the influential role of econometrics, both theoretical and applied, in advancing economic knowledge.

The aim of this volume is to make major developments in applied econometrics accessible to those outside their particular field of specialization. The response to Volume 1 was universally encouraging and it has become clear that we were fortunate to be able to provide a source of reference for others for many years to come. We hope that this high standard is continued and achieved here. Typically, applied econometrics, unlike theoretical econometrics, has always been rather poorly served for textbooks, making it difficult for both undergraduate and postgraduate students to get a real "feel" for how econometrics is actually done. To some degree, the econometric textbook market has responded, so that now the leading textbooks include many examples; even so, these examples typically are of an illustrative nature, focusing on simple points, simply exposited, rather than on the complexity that is revealed in practice. Thus our hope is that this volume will provide a genuine entry into the detailed considerations that have to be

made when combining economics and econometrics in order to carry out serious empirical research.

As in the case of Volume 1, the chapters here have been specially commissioned from acknowledged experts in their fields; further, each of the chapters has been reviewed by the editors, one or more of the associate editors and a referee. Thus, the process is akin to submission to a journal; however, whilst ensuring the highest standards in the evaluation process, the chapters have been conceived of as part of a whole rather than as a set of unrelated contributions. It has not, however, been our intention to provide just a series of surveys or overviews of some areas of applied econometrics, although the survey element is directly or indirectly served in part here. By its very nature, this volume is about econometrics as it is applied and, to succeed in its aim, the contributions, conceived as a whole, have to meet this goal.

We have organized the chapters of this volume of the *Handbook* into ten parts. The parts are certainly not watertight, but serve as a useful initial organization of the central themes. Part I contains three chapters under the general heading of "The Methodology and Philosophy of Applied Econometrics." The lead chapter is by David Hendry, who has been making path-breaking contributions in theoretical and applied econometrics for some forty years or so. It is difficult to conceive how econometrics would have developed without David's many contributions. This chapter first places the role of applied econometrics in an historical context and then develops a theory of applied econometrics. As might be expected, the key issues are confronted head-on.

In introducing the first volume we noted that the "growth in econometrics is to be welcomed, for it indicates the vitality and importance of the subject. Indeed, this growth and, arguably, the dominance over the last ten or twenty years of econometric developments in taking economics forward, is a notable change from the situation faced by the subject some twenty-five years or so ago." Yet in Chapter 1, Hendry notes that, next to data measurement, collection and preparation, on the one hand, and teaching, on the other, "Applied Econometrics" does not have a high credibility in the profession. Indeed, whilst courses in theoretical econometrics or econometric techniques are de rigueur for a good undergraduate or Masters degree, courses in applied econometrics have no such general status.

The intricacies, possibly even alchemy (Hendry, 1980), surrounding the mix of techniques and data seem to defy systematization; perhaps they should be kept out of the gaze of querulous students, who may – indeed should – be satisfied with illustrative examples! Often to an undergraduate or Masters student undertaking a project, applied econometrics is the application of econometrics to data, no more, no less, with some relief if the results are at all plausible. Yet, in contrast, leading journals, for example, the *Journal of Econometrics*, the *Journal of Applied Econometrics* and the *Journal of Business and Economic Statistics*, and leading topic journals, such as the *Journal of Monetary Economics*, all publish applied econometric articles having substance and longevity in their impact and which serve to change the direction of the development of econometric theory (for a famous example, see Nelson and Plosser, 1982). To some, applying econometrics seems unsystematic

and so empirical results are open to question; however, as Hendry shows, it is possible to formalize a theory of applied econometrics which provides a coherent basis for empirical work. Chapter 1 is a masterful and accessible synthesis and extension of Hendry's previous ideas and is likely to become compulsory reading for courses in econometrics, both theory and applied; moreover, it is completed by two applications using the Autometrics software (Doornik, 2007). The first application extends the work of Magnus and Morgan (1999) on US food expenditure, which was itself an update of a key study by Tobin (1950) estimating a demand function for food. This application shows the Autometrics algorithm at work in a simple context. The second application extends the context to a multiple equation setting relating industrial output, the number of bankruptcies and patents, and real equity prices. These examples illustrate the previously outlined theory of applied econometrics combined with the power of the Autometrics software.

In Chapter 2, Fabio Canova addresses the question of how much structure there should be in empirical models. This has long been a key issue in econometrics, and some old questions, particularly those of identification and the meaning of structure, resurface here in a modern context. The last twenty years or so have seen two key developments in macroeconometrics. One has been the development of dynamic stochastic general equilibrium (DSGE) models. Initially, such models were calibrated rather than estimated, with the emphasis on "strong" theory in their specification; however, as Canova documents, more recently likelihood-based estimation has become the dominant practice. The other key development has been that of extending the (simple) vector autoregression (VAR) to the structural VAR (SVAR) model. Although both approaches involve some structure, DSGE models, under the presumption that the model is correct, rely more on an underlying theory than do SVARs. So which should be used to analyze a particular set of problems? As Canova notes: "When addressing an empirical problem with a finite amount of data, one has ... to take a stand on how much theory one wants to use to structure the available data prior to estimation." Canova takes the reader through the advantages and shortcomings of these methodologies; he provides guidance on what to do, and what not to do, and outlines a methodology that combines elements of both approaches.

In Chapter 3, John DiNardo addresses some philosophical issues that are at the heart of statistics and econometrics, but which rarely surface in econometric textbooks. As econometricians, we are, for example, used to working within a probabilistic framework, but we rarely consider issues related to what probability actually is. To some degree, we have been prepared to accept the axiomatic or measure theoretic approach to probability, due to Kolgomorov, and this has provided us with a consistent framework that most are happy to work within. Nevertheless, there is one well-known exception to this unanimity: when it comes to the assignment and interpretation of probability measures and, in particular, the interpretation of some key conditional probabilities; this is whether one adopts a Bayesian or non-Bayesian perspective. In part, the debate that DiNardo discusses relates to the role of the Bayesian approach, but it is more than this; it concerns metastatistics and philosophy, because, in a sense, it relates to a discussion of the

theory of theories. This chapter is deliberately thought-provoking and certainly controversial – two characteristics that we wish to encourage in a *Handbook* that aims to be more than just an overview. For balance, the reader can consult Volume 1 of the *Handbook*, which contains two chapters devoted to the Bayesian analysis of econometric models (see Poirier and Tobias, 2006, and Strachan *et al*., 2006). The reader is likely to find familiar concepts here, such as probability and testing, but only as part of a development that takes them into potentially unfamiliar areas. DiNardo's discussion of these issues is wide-ranging, with illustrations taken from gambling and practical examples taken as much from science, especially medicine, as economics. One example from the latter is the much-researched question of the causal effect of union status on wages: put simply, do unions raise wages and, if so, by how much? This example serves as an effective setting in which to raise issues and to show that differences in approach can lead to differences in results.

For some, the proof of the pudding in econometrics is the ability to forecast accurately, and to address some key issues concerning this aspect of econometrics Part II contains two chapters on forecasting. The first, Chapter 4, by Michael Clements and David Harvey, recognizes that quite often several forecasts are available and, rather than considering a selection strategy that removes all but the best on some criterion, it is often more fruitful to consider different ways of combining forecasts, as suggested in the seminal paper by Bates and Granger (1969). In an intuitive sense, one forecast may be better than another, but there could still be some information in the less accurate forecast that is not contained in the more accurate forecast. This is a principle that is finding wider application; for example, in some circumstances, as in unit root testing, there is more than one test available and, indeed, there may be one uniformly powerful test, yet there is still potential merit in combining tests.

In the forecasting context, Clements and Harvey argue that the focus for multiple forecasts should not be on testing the null of equal accuracy, but on testing for encompassing. Thus it is not a question of choosing forecast A over forecast B, but of whether the combination of forecasts A and B is better than either individual forecast. Of course, this may be of little comfort from a structuralist point of view if, for example, the two forecasts come from different underlying models; but it is preferable when the loss function rewards good fit in some sense. Bates and Granger (1969) suggested a simple linear combination of two unbiased forecasts, with weights depending on the relative accuracy of the individual forecasts, and derived the classic result that, even if the forecasts are equally accurate in a mean squared error loss sense, then there will still be a gain in using the linear combination unless the forecasts are perfectly correlated, at least theoretically. Clements and Harvey develop from this base model, covering such issues as biased forecasts, nonlinear combinations, and density or distribution forecasts. The concept of forecast encompassing, which is not unique in practice, is then considered in detail, including complications arising from integrated variables, non-normal errors, serially correlated forecast errors, ARCH errors, the uncertainty implied by model estimation, and the difficulty of achieving tests with the correct actual size. A number of recent developments are examined, including the concept of conditional forecast

evaluation (Giacomini and White, 2006), evaluating quantile forecasts, and relaxing the forecast loss function away from the traditional symmetric squared error. In short, this chapter provides a clear, critical and accessible evaluation of a rapidly developing area of the econometrics literature.

Chapter 5 is by Stephen Hall and James Mitchell, who focus on density forecasting. There has been a great deal of policy interest in forecasting key macroeconomic variables such as output growth and inflation, some of which has been institutionally enshrined by granting central banks independence in inflation targeting. In turn, there has been a movement away from simply reporting point forecasts of inflation and GDP growth in favor of a fan chart representation of the distribution of forecasts. A density forecast gives much more information than a simple point forecast, which is included as just one realization on the outcome axis. As a corollary, forecast evaluation should also include techniques that evaluate the accuracy, in some well-defined sense, of the density forecast. However, given that generally we will only be able to observe one outcome (or event) per period, some thought needs to be given to how the distributional aspect of the forecast is evaluated. Hall and Mitchell discuss a number of possibilities and also consider methods of evaluating competing density forecasts. A further aspect of density forecasting is the ability of the underlying model to generate time variation in the forecast densities. If the underlying model is a VAR, or can be approximated by a VAR, then, subject to some qualifications, the only aspect of the forecast density which is able to exhibit time variation is the mean; consequently, models have been developed that allow more general time variation in the density through, for example, ARCH and GARCH errors and time-varying parameters. This chapter also links in with the previous chapter by considering combinations of density forecasts. There are two central possibilities: the linear opinion pool is a weighted linear combination of the component densities, whereas the logarithmic opinion pool is a multiplicative combination. Hall and Mitchell consider the problem of determining the weights in such combinations and suggest that predictive accuracy improves when the weights reflect shifts in volatility, a characteristic of note for the last decade or so in a number of economies.

Part III contains four chapters under the general heading of "Time Series Applications." A key area in which the concept of a time series is relevant is in characterizing and determining trends and cycles. Chapter 6, by Stephen Pollock, is a tour de force on modeling trends and cycles, and on the possibilities and pitfalls inherent in the different approaches. In the simplest of models, cyclical fluctuations are purely sinusoidal and the trend is exponential; although simple, this is a good base from which to understand the nature of developments that relax these specifications. Such developments include the view that economic time series evolve through the accumulation of stochastic shocks, as in an integrated Weiner process. The special and familiar cases of the Beveridge–Nelson decomposition, the Hodrick–Prescott filter, the Butterworth filter and the unifying place of Weiner–Kolgomorov filtering are all covered with admirable clarity. Other considerations include the complications caused by the limited data that is often available in economic applications, contrary to the convenient assumptions of theory. In an

appealing turn of phrase, Pollock refers to obtaining a decomposition of components based on the periodogram "where components often reside within strictly limited frequency bands which are separated by dead spaces where the spectral ordinates are virtually zeros." The existence of these "spectral dead spaces" is key to a practical decomposition of an economic time series, however achieved. In practice, trend fitting requires judgment and a clear sense of what it is that the trend is capturing. Other critical issues covered in this chapter include the importance of structural breaks, a topic that has been influential elsewhere (for example, in questioning the results of unit root testing: Perron, 1989); and to aid the reader, practical examples are included throughout the exposition.

Chapter 7, by Joe Cardinale and Larry Taylor, continues the time series theme of analyzing economic cycles whilst focusing on asymmetries, persistence and synchronization. This is a particularly timely and somewhat prophetic chapter given that we are currently experiencing what is perhaps the deepest recession in recent economic history. How can we analyze the critical question "When will it end?" This chapter provides the analytical and econometric framework to answer such a question. The central point is that cycles are much more interesting than just marking their peaks and troughs would suggest. Whilst "marking time" is important, it is just the first part of the analysis, and should itself be subjected to methods for distinguishing phases (for example, expansions and contractions of the output cycle). Once phases have been distinguished, their duration and characteristics become of interest; for example, do long expansions have a greater chance of ending than short expansions? Critical to the analysis is the hazard function: "the conditional probability that a phase will terminate in period t, given that it has *lasted* t *or more* periods." Cardinale and Taylor consider different models and methods of estimating the hazard function and testing hypotheses related to particular versions of it. They also consider tests of duration dependence, the amplitudes of cycles, and the synchronization of cycles for different but related variables; for example, output and unemployment. Their theoretical analysis is complemented with a detailed consideration of US unemployment.

No handbook of econometrics could be without a contribution indicating the importance of cointegration analysis for non-stationary data. In Chapter 8, Katerina Juselius considers one of the most enduring puzzles in empirical economics, namely, if purchasing power parity (PPP) is the underlying equilibrium state that determines the relationship between real exchange rates, why is there "pronounced persistence" away from this equilibrium state? This has been a common finding of empirical studies using data from a wide range of countries and different sample periods. Juselius shows how a careful analysis can uncover important structures in the data; however, these structures are only revealed by taking into account the different empirical orders of integration of the component variables, the identification of stationary relationships between non-stationary variables, the dynamic adjustment of the system to disequilibrium states, the appropriate deterministic components, and the statistical properties of the model. As Juselius notes, and in contrast to common approaches, the order of integration is regarded here as an empirical approximation rather than a structural parameter. This opens up a

distinction between, for example, a variable being empirically $I(d)$ rather than structurally $I(d)$; a leading example here is the $I(2)$ case which, unlike the $I(1)$ case, has attracted some "suspicion" when applied in an absolute sense to empirical series. The challenging empirical case considered by Juselius is the relationship between German and US prices and nominal exchange rates within a sample that includes the period of German reunification. The methodology lies firmly within the framework of general-to-specific modeling, in which a general unrestricted model is tested down (see also Hendry, Chapter 1) to gain as much information without empirical distortion. A key distinction in the methodological and empirical analysis is between pushing and pulling forces: in the current context, prices push whereas the exchange rate pulls. PPP implies that there should be just a single stochastic trend in the data, but the empirical analysis suggests that there are two, with the additional source of permanent shocks being related to speculative behaviour in the foreign exchange market.

In an analysis of trends and cycles, economists often characterize the state of the economy in terms of indirect or latent variables, such as the output gap, core inflation and the non-accelerating rate of inflation (NAIRU). These are variables that cannot be measured directly, but are nevertheless critical to policy analysis. For example, the need to take action to curb inflationary pressures is informed by the expansionary potential in the economy; whether or not a public sector budget deficit is a matter for concern is judged by reference to the cyclically adjusted deficit. These concepts are at the heart of Chapter 9 by Tommaso Proietti, entitled "Structural Time Series Models for Business Cycle Analysis," which links with the earlier chapters by Pollock and Cardinale and Taylor. Proietti focuses on the measurement of the output gap, which he illustrates throughout using US GDP. In the simplest case, what is needed is a framework for decomposing a time series into a trend and cycle and Proietti critically reviews a number of methods to achieve such a decomposition, including the random walk plus noise (RWpN) model, the local linear trend model (LLTM), methods based on filtering out frequencies associated with the cycle, multivariate models that bring together related macroeconomic variables, and the production function approach. The estimation and analysis of a number of models enables the reader to see how the theoretical analysis is applied and what kind of questions can be answered. Included here are a bivariate model of output and inflation for the US and a model of mixed data frequency, with quarterly observations for GDP and monthly observations for industrial production, the unemployment rate and CPI inflation. The basic underlying concepts, such as the output gap and core inflation, are latent variables and, hence, not directly observable: to complete the chapter, Proietti also considers how to judge the validity of the corresponding empirical measures of these concepts.

To complete the part of the *Handbook* on Times Series Applications, in Chapter 10 Luis Gil-Alana and Javier Hualde provide an overview of fractional integration and cointegration, with an empirical application in the context of the PPP debate. A time series is said to be integrated of order d, where d is an integer, if d is the minimum number of differences necessary to produce a stationary time series. This is a particular form of non-stationarity and one which dominated the econometrics

literature in the 1980s and early 1990s, especially following the unit root literature. However, the integer restriction on d is not necessary to the definition of an integrated series (see, in particular, Granger and Joyeux, 1980), so that d can be a fraction – hence the term "fractionally integrated" for such series. Once the integer restriction is relaxed for a single series, it is then natural to relax it for the multivariate case, which leads to the idea of fractional cointegration. Gil-Alana and Hualde give an overview of the meaning of fractional integration and fractional cointegration, methods of estimation for these generalized cases, which can be approached in either the time or frequency domains, the underlying rationale for the existence of fractionally integrated series (for example, through the aggregation of micro-relationships), and a summary of the empirical evidence for fractionally integrated univariate series and fractionally cointegrated systems of series. The various issues and possible solutions are illustrated in the context of an analysis of PPP for four bivariate series. It is clear that the extension of integration and cointegration to their corresponding fractional cases is not only an important generalization of the theory, but one which finds a great deal of empirical support.

One of the most significant developments in econometrics over the last twenty years or so has been the increase in the number of econometric applications involving cross-section and panel data (see also Ooms, Chapter 29). Hence Part IV is devoted to this development. One of the key areas of application is to choice situations which have a discrete number of options; examples include the "whether to purchase" decision, which has wide application across consumer goods, and the "whether to participate" decision, as in whether to enter the labor force, to retire, or to join a club. Discrete choice models are the subject of Chapter 11 by Bill Greene, who provides a critical, but accessible, review of a vast literature. The binary choice model is a key building block here and so provides a prototypical model with which to examine such topics as specification, estimation and inference; it also allows the ready extension to more complex models such as bivariate and multivariate binary choice models and multinomial choice models. Models involving count data are also considered as they relate to the discrete choice framework. A starting point for the underlying economic theory is the extension of the classical theory of consumer behavior, involving utility maximization subject to a budget constraint, to the random utility model. The basic model is developed from this point and a host of issues are considered that arise in practical studies, including estimation and inference, specification tests, measuring fit, complications from endogenous right-hand-side variables, random parameters, the use of panel data, and the extension of the familiar fixed and random effects. To provide a motivating context, Greene considers an empirical application involving a bivariate binary choice model. This is where two binary choice decisions are linked; in this case, in the first decision the individual decides whether to visit a physician, which is a binary choice, and the second involves whether to visit the hospital, again a binary choice: together they constitute a bivariate (and ordered) choice. An extension of this model is to consider the number of times that an individual visits the doctor or a hospital. This gives rise to a counts model (the number of visits to the doctor and the number of visits to the hospital) with its own particular specification. Whilst a natural place to

start is the Poisson model, this, as Greene shows, is insufficient as a general framework; the extension is provided and illustrated with panel data from the German health care system. A second application illustrates a mixed logit and error components framework for modeling modes of transport choice (air, train, bus, car). Overall, this chapter provides an indication, through the variety of its applications, as to why discrete choice models have become such a significant part of applied econometrics.

The theme of panel data methods and applications is continued in Chapter 12 by Andrew Jones. The application of econometrics to health economics has been an important area of development over the last decade or so. However, this has not just been a case of applying existing techniques: rather, econometrics has been able to advance the subject itself, asking questions that had not previously been asked – and providing answers. This chapter will be of interest not only to health economics specialists, but also to those seeking to understand how treatment effects in particular are estimated and to those investigating the extent of the development and application of panel data methods (it is complemented by Colin Cameron in Chapter 14). At the center of health economics is the question "What are the impacts of specific health policies?" Given that we do not observe experimental data, what can we learn from non-experimental data? Consider the problem of evaluating a particular treatment; for an individual, the treatment effect is the difference in outcome between the treated and the control, but since an individual is either treated or not at a particular time, the treatment effect cannot be observed. "Treatment" is here a general term that covers not only single medical treatments but also broad policies, and herein lies its generality, since a treatment could equally be a policy to reduce unemployment or to increase the proportion of teenagers receiving higher education. In a masterful understanding of a complex and expanding literature, Jones takes the reader through the theoretical and practical solutions to the problems associated with estimating and evaluating treatment effects, covering, *inter alia*, identification strategies, dynamic models, estimation methods, different kinds of data, and multiple equation models; throughout the chapter the methods and discussion are motivated by practical examples illustrating the breadth of applications.

A key development in econometrics over the last thirty years or so has been the attention given to the properties of the data, as these enlighten the question of whether the underlying probability structure is stationary or not. In a terminological shorthand, we refer to data that is either stationary or non-stationary. Initially, this was a question addressed to individual series (see Nelson and Plosser, 1982); subsequently, the focus expanded, through the work of Engle and Granger (1987) and Johansen (1988), to a multivariate approach to non-stationarity. The next step in the development was to consider a panel of multivariate series. In Chapter 13, Anindya Banerjee and Martin Wagner bring us up to date by considering panel methods to test for unit roots and cointegration. The reader will find in this chapter a theoretical overview and critical assessment of a vast and growing body of methods, combined with practical recommendations based on the insights obtained from a wide base of substantive applications. In part, as is evident in other areas

of econometric techniques and applications, theory has responded to the much richer sources of data that have become available, not only at a micro or individual level, as indicated in Chapter 12, combined with increases in computing power. As Banerjee and Wagner note, we now have long time series on macroeconomic and industry-level data. Compared to just twenty years ago, there is thus a wealth of data on micro, industry and macro-panels. A panel dataset embodies two dimensions: the cross-section dimension and the time-series dimension, so that, in a macro-context, for example, we can consider the question of convergence not just of a single variable (say, of a real exchange rate to a comparator, be that a PPP hypothetical or an alternative actual rate), but of a group of variables, which is representative of the multidimensional nature of growth and cycles. A starting point for such an analysis is to assess the unit root properties of panel data but, as in the univariate case, issues such as dependency, the specification of deterministic terms, and the presence of structural breaks are key practical matters that, if incorrectly handled, can lead to misleading conclusions. Usually, the question of unit roots is a precursor to cointegration analysis, and Banerjee and Wagner guide the reader through the central methods, most of which have been developed in the last decade. Empirical illustrations, based on exchange rate pass-through in the euro-area and the environmental Kuznets curve, complement the theoretical analysis.

Whilst the emphasis in Chapter 13 is on panels of macroeconomic or industry-level data, in Chapter 14, Colin Cameron, in the first of two chapters in Part V, provides a survey of microeconometric methods, with an emphasis on recent developments. The data underlying such developments are at the level of the individual, households and firms. A prototypical question in microeconometrics relates to the identification, estimation and evaluation of marginal effects using individual-level data; for example, the effect on earnings of an additional year of education. This example is often used to motivate some basic estimation methods, such as least squares, maximum likelihood and instrumental variables, in undergraduate and graduate texts in econometrics, so it is instructive to see how recent developments have extended these methods. The development of the basic methods include generalized method of moments (GMM), empirical likelihood, simulation-based methods, quantile regression and nonparametric and semiparametric estimation, whilst developments in inference include robustifying standard tests and bootstrap methods. Apart from estimation and inference, Cameron considers a number of other issues that occur frequently in microeconometric studies: in particular, issues related to causation, as in estimating and evaluating treatment effects; heterogeneity, for example due to regressors or unobservables; and the nature of microeconometric data, such as survey data and the sampling scheme, with problems such as missing data and measurement error.

The development of econometrics in the last decade or so in particular has been symbiotic with the development of advances in computing, particularly that of personal computers. In Chapter 15, David Jacho-Chávez and Pravin Trivedi focus on the relationship between empirical microeconometrics and computational considerations, which they call, rather evocatively, a "matrimony" between computing

and applied econometrics. No longer is it the case that the mainstay of empirical analysis is a set of macroeconomic time series, often quite limited in sample period. Earlier chapters in this part of the volume emphasize that the data sources now available are much richer than this, both in variety and length of sample period. As Jacho-Chávez and Trivedi note, the electronic recording and collection of data has led to substantial growth in the availability of census and survey data. However, the nature of the data leads to problems that require theoretical solutions: for example, problems of sample selection, measurement errors and missing or incomplete data. On the computing side, the scale of the datasets and estimation based upon them implies that there must be reliability in the high-dimensional optimization routines required by the estimation methods and an ability to handle large-scale Monte Carlo simulations. The increase in computing power has meant that techniques that were not previously feasible, such as simulation assisted estimation and resampling, are now practical and in widespread use. Moreover, nonparametric and semiparametric methods that involve the estimation of distributions rather than simple parameters, as in regression models, have been developed through drawing on the improved power of computers. Throughout the chapter, Jacho-Chávez and Trivedi motivate their discussion by the use of examples of practical interest, including modeling hedonic prices of housing attributes, female labor force participation, Medicare expenditure, and number of doctor visits. Interestingly, they conclude that there are important problems, particularly those related to assessing public policy, such as identification and implementation in the context of structural, dynamic and high-dimensional models, which remain to be solved.

In Part VI, the theme of the importance of economic policy is continued, but with the emphasis now on monetary policy and macroeconomic policy, which remain of continued importance. Starting in the 1970s and continuing into the 1990s, the development of macroeconometric models for policy purposes was a highly regarded area; during that period computing power was developing primarily through mainframe computers, allowing not so much the estimation as the simulation of macroeconomic models of a dimension that had not been previously contemplated. Government treasuries, central banks and some non-governmental agencies developed their own empirical macro-models comprising hundreds of equations. Yet, these models failed to live up to their promise, either wholly or in part. For some periods there was an empirical failure, the models simply not being good enough; but, more radically, the theoretical basis of the models was often quite weak, at least relative to the theory of the optimizing and rational agent and ideas of intertemporal general equilibrium.

In Chapter 16, Carlo Favero expands upon this theme, especially as it relates to the econometrics of monetary policy and the force of the critiques by Lucas (1976) and Sims (1980). A key distinction in the dissection of the modeling corpse is between structural identification and statistical identification. The former relates to the relationship between the structural parameters and the statistical parameters in the reduced form, while the latter relates to the properties of the statistical or empirical model which represents the data. Typically, structural identification is achieved

by parametric restrictions seeking to classify some variables as "exogenous," a task that some have regarded as misguided (or indeed even "impossible"). Further, a failure to assess the validity of the reduction process in going from the (unknown) data-generating process to a statistical representation, notwithstanding criticisms related to structural identification, stored up nascent empirical failure awaiting the macreconometric model. Developments in cointegration theory and practice have "tightened" up the specification of empirical macromodels, and DSGE models, preferred theoretically by some, have provided an alternative "modellus operandi." Subsequently, the quasi-independence of some central banks has heightened the practical importance of questions such as "How should a central bank respond to shocks in macroeconomic variables?" (Favero, Chapter 16). In practice, although DSGE models are favored for policy analysis, in their empirical form the VAR reappears, but with their own set of issues. Favero considers such practical developments as calibration and model evaluation, the identification of shocks, impulse responses, structural stability of the parameters, VAR misspecification and factor augmented VARs. A summary and analysis of Sims' (2002) small macroeconomic model (Appendix A) helps the reader to understand the relationship between an optimizing specification and the resultant VAR model.

In Chapter 17, Gunnar Bårdsen and Ragnar Nymoen provide a paradigm for the construction of a dynamic macroeconometric model, which is then illustrated with a small econometric model of the Norwegian economy that is used for policy analysis. Bårdsen and Nymoen note the two central critiques of "failed" macroeconometric models: the Lucas (1976) critique and the Clements and Hendry (1999) analysis of forecast failure involving "location" shifts (rather than behavioral parameter shifts). But these critiques have led to different responses; first, the move to explicit optimizing models (see Chapter 16); and, alternatively, to greater attention to the effects of regime shifts, viewing the Lucas critique as a possibility theorem rather than a truism (Ericsson and Irons, 1995). Whilst it is de rigueur to accept that theory is important, Bårdsen and Nymoen consider whether "theory" provides the (completely) correct specification or whether it simply provides a guideline for the specification of an empirical model. In their approach, the underlying economic model is nonlinear and specified in continuous time; hence, the first practical steps are linearization and discretization, which result in an equilibrium correction model (EqCM). Rather than remove the data trends, for example by applying the HP filter, the common trends are accounted for through a cointegration analysis. The approach is illustrated step by step by building a small-scale econometric model of the Norwegian economy, which incorporates the ability to analyze monetary policy; for example, an increase in the market rate, which shows the channels of the operation of monetary policy. Further empirical analysis of the New Keynesian Phillips curve provides an opportunity to illustrate their approach in another context. In summary, Bårdsen and Nymoen note that cointegration analysis takes into account non-stationarities that arise through unit roots, so that forecast failures are unlikely to be attributable to misspecification for that reason. In contrast to the econometric models of the 1970s, the real challenges arise from non-stationarities in functional relationships due to structural breaks; however,

there are ways to "robustify" the empirical model and forecasts from it so as to mitigate such possibilities, although challenges remain in an area that continues to be of central importance in economic policy.

One of the key developments in monetary policy in the UK and elsewhere in the last decade or so has been the move to give central banks a semi-autonomous status. In part, this was thought to avoid the endogenous "stop–go" cycle driven by political considerations. It also carried with it the implication that it was monetary policy, rather than fiscal policy, which would become the major macroeconomic policy tool, notwithstanding the now apparent practical limitations of such a move. In Chapter 18, Brian Henry provides an overview of the institutional and theoretical developments in the UK in particular, but with implications for other countries that have taken a similar route. The key question that is addressed in this chapter is whether regime changes, such as those associated with labor market reforms, inflation targeting and instrument independence for the Bank of England, have been the key factors in dampening the economic cycle and improving inflation, unemployment and output growth, or whether the explanation is more one of beneficial international events (the "good luck" hypothesis) and monetary policy mistakes. Henry concludes, perhaps controversially, that the reforms to the labor market and to the operation of the central bank are unlikely to have been the fundamental reasons for the improvement in economic performance. He provides an econometric basis for these conclusions, which incorporates a role for international factors such as real oil prices and measures of international competitiveness. Once these factors are taken into account, the "regime change" explanation loses force.

The growth of financial econometrics in the last two decades was noted in the first volume of this *Handbook*. Indeed, this development was recognized in the award of the 2003 Nobel Prize in Economics (jointly with Sir Clive Granger) to Robert Engle for "methods of analyzing economic time series with time-varying volatility (ARCH)." Part VII of this volume reflects this development and is thus devoted to applications in the area of financial econometrics.

In Chapter 19, George Dotsis, Raphael Markellos and Terence Mills consider continuous-time stochastic volatility models. What is stochastic volatility? To answer that question, we start from what it is not. Consider a simple model of an asset price, $Y(t)$, such as geometric Brownian motion, which in continuous time takes the form of the stochastic differential equation $dY(t) = \mu Y(t) + \sigma Y(t)dW(t)$, where $W(t)$ is a standard Brownian motion (BM) input; then σ (or σ^2) is the volatility parameter that scales the stochastic BM contribution to the diffusion of $Y(t)$. In this case the volatility parameter is constant, although the differential equation is stochastic. However, as Dotsis *et al.* note, a more appropriate specification for the accepted characteristics of financial markets is a model in which volatility also evolves stochastically over time. For example, if we introduce the variance function $v(t)$, then the simple model becomes $dY(t) = \mu Y(t) + \sqrt{v(t)}Y(t)dW(t)$, and this embodies stochastic volatility. Quite naturally, one can then couple this equation with one that models the diffusion over time of the variance function. ARCH/GARCH models are one way to model time-varying volatility, but there are

a number of other attractive specifications; for example, jump diffusions, affine diffusions, affine jump diffusions and non-affine diffusions. In motivating alternative specifications, Dotsis *et al*. note some key empirical characteristics in financial markets that underlie the rationale for stochastic volatility models, namely fat tails, volatility clustering, leverage effects, information arrivals, volatility dynamics and implied volatility. The chapter then continues by covering such issues as specification, estimation and inference in stochastic volatility models. A comparative evaluation of five models applied to the S&P 500, for daily data over the period 1990–2007, is provided to enable the reader to see some of the models "in action."

One of the most significant ideas in the area of financial econometrics is that the underlying stochastic process for an asset price is a martingale. Consider a stochastic process $X = (X_t, X_{t-1}, \ldots)$, which is a sequence of random variables; then the martingale property is that the expectation (at time $t-1$) of X_t, conditional on the information set $I_{t-1} = (X_{t-1}, X_{t-2}, \ldots)$, is X_{t-1}; that is, $E(X_t|I_{t-1}) = X_{t-1}$ (almost surely), in which case, X is said to be a martingale (the definition is sometimes phrased in terms of the σ-field generated by I_{t-1}, or indeed some other "filtration"). Next, define the related process $Y = (\Delta X_t, \Delta X_{t-1}, \ldots)$; then Y is said to be a martingale difference sequence (MDS). The martingale property for X translates to the property for Y that $E(Y_t|I_{t-1}) = 0$ (see, for example, Mikosch, 1998, sec. 1.5). This martingale property is attractive from an economic perspective because of its link to efficient markets and rational expectations; for example, in terms of X, the martingale property says that the best predictor, in a minimum mean squared error (MSE) sense, of X_t is X_{t-1}.

In Chapter 20, J. Carlos Escanciano and Ignacio Lobato consider tests of the martingale difference hypothesis (MDH). The MDH generalizes the MDS condition to $E(Y_t|I_{t-1}) = \mu$, where μ is not necessarily zero; it implies that past and current information (as defined in I_t) are of no value, in an MSE sense, in forecasting future values of Y_t. Tests of the MDH can be seen as being translated to the equivalent form given by $E[(Y_t - \mu)w(I_{t-1})]$, where $w(I_{t-1})$ is a weighting function. A useful means of organizing the extant tests of the MDH is in terms of the type of functions $w(.)$ that are used. For example, if $w(I_{t-1}) = Y_{t-j}, j \geq 1$, then the resulting MDH test is of $E[(Y_t - \mu)Y_{t-j}] = 0$, which is just the covariance between Y_t and Y_{t-j}. This is just one of a number of tests, but it serves to highlight some generic issues. In principle, the condition should hold for all $j \geq 1$ but, practically, j has to be truncated to some finite value. Moreover, this is just one choice of $w(I_{t-1})$, whereas the MDH condition is not so restricted. Escanciano and Lobato consider issues such as the nature of the conditioning set (finite or infinite), robustifying standard test statistics (for example, the Ljung–Box and Box–Pierce statistics), and developing tests in both the time and frequency domains; whilst standard tests are usually of linear dependence, for example autocorrelation based tests, it is important to consider tests based on nonlinear dependence. To put the various tests into context, the chapter includes an application to four daily and weekly exchange rates against the US dollar. The background to this is that the jury is out in terms of a judgment on the validity of the MDH for such data; some studies have found against the

MDH, whereas others have found little evidence against it. In this context, applying a range of tests, Escanciano and Lobato find general support for the MDH.

Chapter 19 by Dotsis *et al*. was concerned with models of stochastic volatility, primarily using the variance as a measure of volatility. Another measure of volatility is provided by the range of a price; for example, the trading day range of an asset price. In turn, the range can be related to the interval between consecutive trades, known as the duration. Duration is a concept that is familiar from counting processes, such as the Poisson framework for modeling arrivals (for example, at a supermarket checkout or an airport departure gate).

Chapter 21 by Ruey Tsay provides an introduction to modeling duration that is illustrated with a number of financial examples. That duration can carry information about market behavior is evident not only from stock markets, where a cluster of short durations indicates active trading relating to, for example, information arrival, but from many other markets; for example, durations in the housing market and their relation to banking failure. The interest in durations modeling owes much to Engle and Russell (1998), who introduced the autoregressive conditional duration (ACD) model for irregularly spaced transactions data. Just as the ARCH/GARCH family of models was introduced to capture volatility clusters, the ACD model captures short-duration clusters indicating the persistence of periods of active trading, perhaps uncovering and evaluating information arrivals. To see how an ACD model works, let the ith duration be denoted $x_i = t_i - t_{i-1}$, where t_i is the time of the ith event, and model x_i as $x_i = \psi_i \varepsilon_i$, where $\{\varepsilon_i\}$ is an i.i.d sequence and $\beta(L)\psi_i = \alpha_0 + \alpha(L)x_i$, where $\alpha(L)$ and $\beta(L)$ are lag polynomials; this is the familiar GARCH form, but in this context it is known as the exponential ACD or EACD. To accommodate the criticism that the hazard function of duration is not constant over time, unlike the assumption implicit in the EACD model, alternative innovation distributions have been introduced, specifically the Weibull and the Gamma, leading to the Weibull ACD (WACD) and the Gamma ACD (GACD). The chapter includes some motivating examples. Evidence of duration clusters is shown in Figures 21.1, 21.4 and 21.7a for IBM stock, Apple stock and General Motors stock, respectively. The development and application of duration models can then exploit the development of other forms of time series models, such as (nonlinear) threshold autoregressive (TAR) models. ACD models have also been developed to incorporate explanatory variables; an example is provided, which shows that the change to decimal "tick" sizes in the US stock markets reduced the price volatility of Apple stock.

The determination of exchange rates has long been an interest to econometricians and, as a result, there is an extensive literature that includes two constituencies; on the one hand, there have been contributions from economists who have employed econometric techniques and, on the other, to risk a simple bifurcation, the modeling of exchange rates has become an area to test out advances in nonlinear econometrics. Chapter 22, by Efthymios Pavlidis, Ivan Paya and David Peel, provides an evaluative overview of this very substantial area. As they note, the combination of econometric developments, the availability of high-quality and high-frequency data, and the move to floating exchange rates in 1973, has led

to a considerable number of empirical papers in this area. Thus, the question of "Where are we now?" is not one with a short answer. Perhaps prototypically, the econometrics of exchange rates is an area that has moved in tandem with developments in the economic theory of exchange rates (for the latter, the reader is referred to, for example, Sarno and Taylor, 2002). An enduring question over the last thirty years (at least), and one that is touched upon in two earlier chapters (Juselius, Chapter 8, and Gil-Alana and Hualde, Chapter 10), has been the status of PPP, regarded as a bedrock of economic theory and macroeconomic models. One early finding that has puzzled many is the apparent failure to find PPP supported by a range of different exchange rates and sample periods. Consider a stylized version of the PPP puzzle: there are two countries, with a freely floating exchange rate, flexible prices (for tradable goods and services), no trade constraints, and so on. In such a situation, at least in the long run, the nominal exchange rate should equal the ratio of the (aggregate) price levels, otherwise, as the price ratio moves, the nominal exchange rate does not compensate for such movements and the real exchange rate varies over time, contradicting PPP; indeed, on this basis the exchange rate is not tied to what is happening to prices. Early studies used an essentially linear framework – for example, ARMA models combined with unit root tests – to evaluate PPP, and rarely found that it was supported by the data; moreover, estimated speeds of adjustment to shocks were so slow as to be implausible. Another puzzle, in which tests indicated that the theory (of efficient speculative markets) was not supported, was the "forward bias puzzle." In this case, the prediction was that prices should fully reflect publicly available information, so that it should not be possible to make a systematic (abnormal) return; however, this appeared not to be the case. In this chapter, Pavlidis *et al*. carefully dissect this and other puzzles and show how the move away from simple linear models to a range of essentially nonlinear models, the development and application of multivariate models, and the use of panel data methods, has provided some explanation of the exchange rate "puzzles."

Part VIII of this volume of the *Handbook* is comprised of three chapters related to what has become referred to as "growth econometrics"; broadly speaking, this is the area that is concerned with variations in growth rates and productivity levels across countries or regions. Chapters 23 and 24 are a coordinated pair by Steven Durlauf, Paul Johnson and Jonathan Temple; in addition, looking ahead, Chapter 27 by Serge Rey and Julie Le Gallo takes up aspects of growth econometrics, with an emphasis on spatial connections. In Chapter 23, Durlauf *et al*. focus on the econometrics of convergence. Of course, convergence could and does mean a number of things: first, the convergence of what? Usually this is a measure of income or output but, in principle, the question of whether two (or more) economies are/have converged relates to multiple measures, for example, output, inflation, unemployment rates, and so on, and possibly includes measures of social welfare, such as literacy and mortality rates. The first concept to be considered in Chapter 23 is β-convergence (so-called because the key regression coefficient is referred to as β): consider two countries; there is β-convergence if the one with a lower initial income grows faster than the other and so "catches up" with the higher-income country.

Naturally, underlying the concept of convergence is an economic model, typically a neoclassical growth model (with diminishing returns to capital and labor), which indicates the sources of economic growth and a steady-state which the economy will (eventually) attain. At its simplest, growth econometrics leads to cross-country regressions of output growth rates on variables motivated from the underlying growth model and, usually, some "control" variables that, additionally, are thought to influence the growth rate. It is the wide range of choice for these control variables, and the resultant multiplicity of studies, that has led to the, perhaps pejorative, description of this activity as the "growth regression industry." One response has been the technique of model averaging, so that no single model will necessarily provide the empirical wisdom. A second central convergence concept is σ-convergence. As the notation suggests, this form of convergence relates to the cross-section dispersion of a measure, usually log per capita output, across countries. As Durlauf *et al*. note, whilst many studies use the log variance, other measures, such as the Gini coefficient or those suggested in Atkinson (1970), may be preferred. In this measure of convergence, a reduction in the dispersion measure across countries suggests that they are getting closer together. As in Chapter 22 on exchange rates, an important methodological conclusion of Durlauf *et al*. is that nonlinearity (due in this case to endogenous growth models) is likely to be an important modeling characteristic, which is not well captured in many existing studies, whether based on cross-section or panel data.

Having considered the question of convergence in Chapter 23, in Chapter 24 Durlauf *et al*. turn to the details of the methods of growth econometrics. Whilst concentrating on the methods, they first note some salient facts that inform the structure of the chapter. Broadly, these are that: vast income disparities exist despite the general growth in real income; distinct winners and losers have begun to emerge; for many countries, growth rates have tended to slow, but the dispersion of growth rates has increased. At the heart of the growth literature is the one-sector neoclassical growth model, transformed to yield an empirical form in terms of the growth rate of output per labor unit, such that growth is decomposed into growth due to technical progress and the gap between initial output per worker and the steady-state value. Typically, an error is then added to a deterministic equation derived in this way and this forms the basis of a cross-country regression, usually augmented with "control" variables that are also thought to influence growth rates. However, as Durlauf *et al*. note, there are a number of problems with this approach; for example, the errors are implicitly assumed to be exchangeable, but country dependence of the errors violates this assumption; the plethora of selected control variables leads to a multiplicity of empirical models; and parameter heterogeneity. To assess the question of model uncertainty an extreme bounds analysis (Leamer, 1983) can be carried out, and model averaging as in a Bayesian analysis can be fruitful. Parameter heterogeneity is related to the Harberger (1987) criticism that questions the inclusion of countries with different characteristics in a cross-country regression. The key to criticisms of this nature is the meaning of such regressions: is there a DGP that these regressions can be taken as empirically parameterizing? The chapter continues by providing, *inter alia*, an overview of the

different kinds of data that have been used and an assessment of the econometric problems that have arisen and how they have been solved; the conclusion evaluates the current state of growth econometrics, and suggests directions for future research.

A concern that has long antecedents is the relationship between financial development and growth: is there a causal relationship from the former to the latter? In Chapter 25, Thorsten Beck evaluates how this key question has been approached from an econometric perspective. Do financial institutions facilitate economic growth, for example by reducing information asymmetries and transaction costs? Amongst other functions, as Beck notes, financial institutions provide payment services, pool and allocate savings, evaluate information, exercise corporate governance and diversify risk. It would seem, *a priori*, that the provision of such services must surely move out the aggregate output frontier. However, just finding positive correlations between indicators of financial development, such as monetization measures, the development of banking institutions and stock markets, and economic growth is insufficient evidence from an econometric viewpoint. One of the most fundamental problems in econometrics is the problem of identification: by themselves, the correlations do not provide evidence of a causal direction. Beck takes the reader through the detail of this problem and how it has been approached in the finance-growth econometric literature. A classical method for dealing with endogenous regressors is instrumental variables (IV) and, in this context, some ingenuity has been shown in suggesting such variables, including exogenous country characteristics; for example, settler mortality, latitude and ethnic fractionalization. Early regression-based studies used cross-section data on a number of countries; however, more recent datasets now include dynamic panels and methods include GMM and cointegration. More recent developments have been able to access data at the firm and household level, and this has led to much larger samples being used. For example, Beck, Dermirgüç-Kunt and Makisimovic (2005) use a sample of over 4,000 firms in 54 countries to consider the effect of sales growth as a firm-level financing obstacle as well as other variables, including a country-level financial indicator. As Beck notes, the evidence suggests a strong case for a causal link between financial development and economic growth, but there is still much to be done both in terms of techniques, such as GMM, and exploiting advances at the micro-level.

In Volume 1 of the *Handbook*, we highlighted recent developments in theoretical econometrics as applied to problems with a spatial dimension; this is an area that has grown in application and importance, particularly over the last decade, and it is natural that we should continue to emphasize its developmental importance by including two chapters in Part IX. These chapters show how spatial econometrics can bring into focus the importance of the dimension of space in economic decisions and the particular econometric problems and solutions that result. In Chapter 26, Luc Anselin and Nancy Lozano-Gracia consider spatial hedonic models applied to house prices. Hedonic price models are familiar from microeconomics and, in particular, from the seminal contributions of Lancaster (1966) and Rosen (1974). In the context of house prices, there are key characteristics, such as aspects

of neighborhood, proximity to parks, schools, measures of environmental quality, and so on, that are critical in assigning a value to a house. These characteristics lead to the specification of a hedonic price function to provide an estimate of the marginal willingness to pay (MWTP) for a characteristic; a related aim, but one not so consistently pursued, is to retrieve the implied inverse demand function for house characteristics. Two key problems in the estimation of hedonic house price functions, in particular, are spatial dependence and spatial heterogeneity. As Anselin and Lozano-Gracia note, spatial dependence, or spatial autocorrelation, recognizes the importance of geographical or, more generally, network space in leading to a structure in the covariance matrix between observations. Whilst there is an analogy with temporal autocorrelation, spatial autocorrelation is not simply an extension of that concept, but requires its own conceptualization and methods. Spatial heterogeneity can be viewed as a special case of structural instability; two (of several) examples of heterogeneity are spatial regimes (for example, ethnically based sub-neighorhoods) and spatially varying coefficients (for example, different valuations of housing and neighborhood characteristics). In this chapter, Anselin and Lozano-Gracia provide a critical overview of methods, such as spatial two-stage least squares and spatial feasible GLS, a summary of the literature on spatial dependence and spatial heterogeneity, and discussion of the remaining methodological challenges.

In Chapter 27, Serge Rey and Julie Le Gallo consider an explicitly spatial analysis of economic convergence. Recall that Chapter 23, by Durlauf *et al.*, is concerned with the growing interest in the econometrics of convergence; for example, whether there was an emergence of convergence clubs, perhaps suggesting "winners and losers" in the growth race. There is an explicitly spatial dimension to the evaluation of convergence; witness, for example, the literature on the convergence of European countries or regions, the convergence of US states, and so on. Rey and Le Gallo bring this spatial dimension to the fore. The recognition of the importance of this dimension brings with it a number of problems, such as spatial dependence and spatial heterogeneity; these problems are highlighted in Chapter 26, but in Chapter 27 they are put in the context of the convergence of geographical units. Whilst Rey and Le Gallo consider what might be regarded as purely econometric approaches to these problems, they also show how exploratory data analysis (EDA), extended to the spatial context, has been used to inform the theoretical and empirical analysis of convergence. As an example, a typical focus in a non-spatial context is on σ-convergence, which relates to a cross-sectional dispersion measure, such as the variance of log per capita output, across regions or countries. However, in a broader context, there is interest in the complete distribution of regional incomes and the dynamics of distributional change, leading to, for example, the development of spatial Markov models, with associated concepts such as spatial mobility and spatial transition. EDA can then provide the tools to visualize what is happening over time: see, for example, the space-time paths and the transition of regional income densities shown in Figures 27.5 and 27.6. Rey and Le Gallo suggest that explicit recognition of the spatial dimension of convergence, combined with the use of EDA and its extensions to include the spatial element,

offers a fruitful way of combining different methods to inform the overall view on convergence.

Part X comprises two chapters on applied econometrics and its relationship to computing. In Chapter 28, Bruce McCullough considers the problem of testing econometric software. The importance of this issue is hard to understate. Econometric programs that are inaccurate, for any reason, will produce misleading results not only for the individual researcher but, if published, for the profession more generally, and will lead to applications that are impossible to replicate. The development of sophisticated methods of estimation means that we must also be ever-vigilant in ensuring that software meets established standards of accuracy. A seminal contribution to the development of accuracy benchmarks was Longley (1967). As McCullough notes, Longley worked out by hand the solution to a linear regression problem with a constant and six explanatory variables. When run through the computers of the time, he found that the answers were worryingly different. Of course, the Longley benchmark is now passed by the econometric packages that are familiar to applied econometricians. However, the nature of the problems facing the profession is different (sophisticated estimators, large datasets, simulation-based estimators) and McCullough's results imply that there is no reason for complacency. Many econometric estimators involve problems of a nonlinear nature – for example, the GARCH and multivariate GARCH estimators and the probit estimator – and it is in the case where a nonlinear solver is involved that the user will find problems, especially when relying on the default options. Another area that has seen substantial growth in the last two decades has been the use of Monte Carlo experimentation, an area that makes fundamental use of random numbers, and hence any package must have a reliable random number generator (RNG). But are the numbers so generated actually random? The answer is, not necessarily! (The reader may wish to refer to Volume 1 of this *Handbook*, which includes a chapter by Jurgen Doornik on random number generation.) The importance of maintaining standards of numerical accuracy has been recognised in the National Institute of Standards and Technology's Statistical Reference Datasets, which has resulted in a number of articles using these datasets to evaluate software for econometric problems. To illustrate some of the issues in software evaluation, for example in establishing a benchmark, McCullough includes a study of the accuracy of a number of packages to estimate ARMA models. The central methods for the estimation of such models include unconditional least squares (UCLS), conditional least squares (CLS), and exact maximum likelihood. The questions of interest are not only in the accuracy of the point estimates from these methods in different packages, but also what method of standard error calculation is being used. Overall, McCullough concludes that we, as a profession, have some way to go in ensuring that the software that is being used is accurate, that the underlying methods are well-documented, and that published results are replicable.

In Chapter 29, Marius Ooms takes a historical perspective on the nature of applied econometrics as it has been represented by publications and reviews of econometric and statistical software in the *Journal of Applied Econometrics* (*JAE*).

Over the 14-year review period, 1995–2008, there were 513 research articles published in the *JAE*, of which 253 were categorized as applications in time series, 140 as panel data applications and 105 as cross-section applications. Ooms notes that there has been a gradual shift from macroeconometrics to microeconometrics and applications using panel data. The software review section of the *JAE* has been a regular feature, so enabling an analysis of the programmes that have been in use – and continue to be in use, reflecting the development policy of the providers. This section is likely to be a very useful summary for research and teaching purposes. Ooms also notes the growth of high-level programming languages, such as Gauss, MATLAB, Stata and Ox, and illustrates their use with a simple program. In combination, the profession is now very much better served for econometric software than it was twenty years ago. Of course, these developments have not taken place in isolation but rather as a response to developments in theoretical and applied econometrics. A leading example in this context, noted by Ooms, is the Arellano and Bond (1991) approach to the estimation of applications using panel data (dynamic panel data, or DPD, analysis), which led to the widespread implementation of new code in existing software and many new applications; an example in the area of time series applications is the growth of ARCH and GARCH-based methods and the implantation of estimation routines in econometric software. As noted in Chapter 28 by McCullough, reproducibility of results is a key aspect in the progression and reputation of applied econometrics. Results that are irreproducible by reason of either inaccurate software or unavailability of data will do long-term harm to the profession. In this respect, the *JAE*, through Hashem Pesaran's initiative, has been a leader in the context of requiring authors to provide the data and code which they used. The *JAE* archive is indexed and carefully managed, and provides the standard for other journals.

As a final comment, which we hope is evident from the chapters contained in this volume, one cannot help but be struck by the incredible ingenuity of those involved in pushing forward the frontiers of applied econometrics. Had this volume been compiled even, say, just twenty years ago, how different would it have been! Viewed from above, the landscape of applied econometrics has changed markedly. Time series econometrics and macroeconometrics, whilst still important, are not predominant. The combination of the availability of large datasets of a microeconomic nature, combined with enormous increases in computing power, has meant that econometrics is now applied to a vast range of areas. What will the next twenty years bring?

Finally, thanks are due to many in enabling this volume to appear. First, our thanks go collectively to the authors who have cooperated in contributing chapters; they have, without exception, responded positively to our several and sometimes many requests, especially in meeting deadlines and accommodating editorial suggestions. We hope that the quality of these chapters will be an evident record of the way the vision of the *Handbook* has been embraced. We would also like to record our gratitude to the Advisory Editors for this volume: Bill Greene, Philip Hans Franses, Hashem Pesaran and Aman Ullah, whose support was invaluable, especially at an early stage.

Thanks also go the production team at Palgrave Macmillan, only some of whom can be named individually: Taiba Batool, the commissioning editor, Ray Addicott, the production editor, and Tracey Day, the indefatigable copy-editor. A special mention goes to Lorna Eames, secretary to one of the editors, for her willing and invaluable help at several stages in the project.

The Methodology of Empirical Econometric Modeling: Applied Econometrics Through the Looking-Glass

David F. Hendry

Abstract

This chapter considers the methodology of empirical econometric modeling. The historical background is reviewed from before the Cowles Foundation to the rise of economic theory-based econometrics and the decline of data concerns. A theory for "Applied Econometrics" suggests reinterpreting the role of economic theory given that the intrinsic non-stationarity of economic data vitiates analyses of incomplete specifications based on *ceteris paribus*. Instead, the many steps from the data-generation process (DGP) through the local DGP (LDGP) and general unrestricted model to a specific representation allow an evaluation of the main extant approaches. The potential pitfalls confronting empirical research include inadequate theory, data inaccuracy, hidden dependencies, invalid conditioning, inappropriate functional form, non-identification, parameter non-constancy, dependent, heteroskedastic errors, wrong expectations formation, misestimation and incorrect model selection. Recent automatic methods help resolve many of these difficulties. Suggestions on the teaching of "Applied Econometrics" are followed by revisiting and updating the "experiment in applied econometrics" and by automatic modeling of a four-dimensional vector autoregression (VAR) with 25 lags for the numbers of bankruptcies and patents, industrial output per capita and real equity prices over 1757–1989.

1.1 Introduction

> "Now, here, you see, it takes all the running you can do, to keep in the same place. If you want to get somewhere else, you must run at least twice as fast as that!" (Quote from the Red Queen in *Through the Looking-Glass and What Alice Found There*, Lewis Carroll, Macmillan & Co., 1899, [henceforth cited as "Lewis Carroll, 1899"])

Most econometricians feel a bit like Alice did at having to run fast even to stand still. Handbooks are an attempt to alleviate the problem that our discipline moves forward rapidly, and *infoglut* can overwhelm, albeit that one has to run even faster for a short period to also find time to read and digest their contents. That will require some sprinting here, given that the contents of this *Handbook of Econometrics* provide up-to-date coverage of a vast range of material: time series, cross-sections, panels, and spatial; methodology and philosophy; estimation – parametric and nonparametric – testing, modeling, forecasting and policy; macro, micro, finance, growth and development; and computing – although I do not see *teaching*. Such general headings cross-categorize "Applied Econometrics" by types of data and their problems on the one hand – time series, cross-sections, panels, high frequency (see, e.g., Barndorff-Nielsen and Shephard, 2007), limited dependent variables (see, e.g., Heckman, 1976), or count data (excellently surveyed by Cameron and Trivedi, 1998), etc. – and by activities on the other (modeling, theory calibration, theory testing, policy analysis, forecasting, etc.). The editors considered that I had written on sufficiently many of these topics during my career to "overview" the volume, without also noting how markedly all of them had changed over that time. The

main aim of an introductory chapter is often to overview the contents of the volume, but that is manifestly impossible for the *Handbook of Econometrics* given its wide and deep coverage. In any case, since the *Handbook* is itself an attempt to overview Applied Econometrics, such an introduction would be redundant.

Thus, my focus on empirical econometric modeling concerns only one of the activities, but I will also try to present an interpretation of what "Applied Econometrics" is; what those who apply econometrics may be trying to achieve, and how they are doing so; what the key problems confronting such applications are; and how we might hope to resolve at least some of them. Obviously, each aspect is conditional on the previous one: those aiming to calibrate a theory model on a claimed set of "stylized facts" are aiming for very different objectives from those doing data modeling, so how they do so, and what their problems are, naturally differ greatly. This chapter will neither offer a comprehensive coverage, nor will it be an uncontroversial survey. En route, I will consider why "Applied Econometrics" does not have the highest credibility within economics, and why its results are often attacked, as in Summers (1991) among many others (see Juselius, 1993, for a reply). Evidence from the contents of textbooks revealing the marginal role of "Applied Econometrics" and "economic statistics" within the discipline has been provided recently by Qin (2008) and Atkinson (2008) respectively. Since two aspects of our profession with even lower status than "Applied Econometrics" are data (measurement, collection and preparation), and teaching, I will try and address these as well, as they are clearly crucial to sustaining and advancing a viable "Applied Econometrics" community. Economic forecasting and policy are not addressed explicitly, being uses of empirical models, and because the criteria for building and selecting such models differ considerably from those applicable to "modeling for understanding" (see, e.g., Hendry and Mizon, 2000; and for complete volumes on forecasting, see Clements and Hendry, 2002a, 2005; Elliott, Granger and Timmermann, 2006).

Economists have long been concerned with the status of estimated empirical models. How a model is formulated, estimated, selected and evaluated all affect that status, as do data quality and the relation of the empirical model to the initial subject-matter theory. All aspects have been challenged, with many views still extant. And even how to judge that status is itself debated. But current challenges are different from past ones – partly because some of the latter have been successfully rebutted. All empirical approaches face serious problems, yet the story is one of enormous progress across uncharted terrain with many mountains climbed – but many more to surmount. I will recount some of that story, describe roughly where we are presently located, and peer dimly into the future. Why "*Applied Econometrics Through the Looking-Glass*"? Lewis Carroll was the pseudonym for Charles Dodgson, a mathematician who embodied many insights in the book which is cited throughout the present chapter: a Looking-Glass is a mirror, and applied findings in economics can only reflect the underlying reality, so obtaining a robust and reliable reflection should guide its endeavors.

Following the brief section 1.2 on the meaning of the topic, section 1.3 summarizes some of the history of our fallible discipline. Then section 1.4 proposes a

"theory of Applied Econometrics" which highlights some of the problems empirical modeling confronts in a non-stationary environment, where non-stationary is used throughout in the "wide sense" to denote any changes in the distributions of the random variables modeled by economists. Section 1.5 discusses a recent tool for automatic modeling, Autometrics, based on the last decade of research into model selection (see Doornik, 2007a; Hendry and Krolzig, 2005; Hendry, with Doornik and Nielsen, 2007). Section 1.6 comments on teaching Applied Econometrics, and section 1.7 revisits the experiment in applied econometrics conducted by Magnus and Morgan (1999). Section 1.8 then looks at automatic modeling of a four-variable dynamic system related to industrial output since 1700, with 25 lags in its initial formulation and many outliers over more than 250 years. Section 1.9 concludes. Throughout, I draw heavily on a number of my previous papers. Despite there being almost 200 citations to other scholars, I am conscious that documentation is bound to be incomplete, and apologize for omitting many contributions.

1.2 What is "Applied Econometrics"?

> "When I use a word," Humpty Dumpty said in rather a scornful tone, "it means just what I choose it to mean – neither more nor less." (Lewis Carroll, 1899)

At the superficial level, "Applied Econometrics" is "any application of econometrics," as distinct from theoretical econometrics. If it were not for the imperialist tendencies of econometricians, that would suffice, but econometrics has been applied in space science, climatology, political science, sociology, epidemiology, marketing, *inter alia*, not to mention the claim in *How the Laws of Physics Lie* (see Cartwright, 1983) that econometrics is the key methodology for all of science ... Sorry to disappoint the eager reader, but I will not be covering even a wide range of the economic applications, never mind that plethora of outside studies.

Some applied econometricians would include any applications involving analyses of "real economic data" by econometric methods, making "Applied Econometrics" synonymous with empirical econometrics. However, such a view leads to demarcation difficulties from applied economics on the one hand and applied statistics on the other. Defining "econometrics," as in Frisch (1933), to comprise only studies involving the unification of economic theory, economic statistics (data), and mathematics (statistical methods) helps in demarcation, but limits its scope and inadvertently excludes (say) developing econometric theory itself, or just improving data measurement and collection.

Outsiders might have thought that "Applied Econometrics" was just the application of econometrics to data, but that is definitely not so; virtually no journal editor would publish such a piece. Rather, the notion of mutual penetration dominates – but as a one-way street. Economic theory comes first, almost mandatorially. Perhaps this just arises from a false view of science, namely that theory precedes evidence, even though, apart from a few famous occasions, science rarely proceeds by imposing a preconceived theory on evidence, and evidence regularly shapes and

stimulates theory. Yet the latter is rarely the case in applied econometrics – and to see how we arrived at such a state, we need to consider the contingent history of our discipline.

1.3 Historical background

> "The time has come," the Walrus said, "To talk of many things: Of shoes – and ships – and sealing-wax – Of cabbages – and kings – And why the sea is boiling hot – And whether pigs have wings." (Lewis Carroll, 1899)

The histories of statistics and econometrics are now reasonably well documented: on the former, see, e.g., the books by Stigler (1986, 1999) and Hald (1990, 1998); and for the latter, see Epstein (1987), Morgan (1990), Qin (1993), Klein (1997), and Le Gall (2007); also see Christ (1994), Spanos (2006), Farebrother (2006) and Gilbert and Qin (2006); and for reprints of key papers, see Darnell (1994) and Hendry and Morgan (1995), with related material in Caldwell (1993), Hamouda and Rowley (1997), Mills (1999) and Campos, Ericsson and Hendry (2005). These books provide overall bibliographic perspective.

1.3.1 Pre-Cowles

> The shop seemed to be full of all manner of curious things – but the oddest part of it all was, that whenever she looked hard at any shelf, to make out exactly what it had on it, that particular shelf was always quite empty: though the others round it were crowded as full as they could hold. (Lewis Carroll, 1899)

An aspect of that history which is still somewhat under-emphasized, despite being stressed by Hendry and Morgan (1995), is the role that empirical studies have played as a driver of new econometric concepts, theories and methods, standing in some contrast to its direct impact on economics. Certainly, early attempts were replete with what we would now view as blunders – William Stanley Jevons' sunspot, and Henry Moore's Venus, theories of business cycles are regularly trotted out as examples of how silly econometricians can be, yet Jevons (1875) and Moore (1923) respectively need to be contrasted with other careful and insightful empirical analyses in Jevons' research, edited by Foxwell (1884), and in Moore (1911). On the former, see the appraisal in Peart (2001); and on the latter, e.g., Stigler (1962) comments: "Moore's standard of craftsmanship is high: the basic data are fully reported and the work was carefully done." Also, note the cited comment from Alfred Marshall to Moore in 1912 that "the 'ceteris paribus' clause – though formally adequate seems to me impracticable,"a point that will recur below. The "upward sloping demand curve" for pig-iron in Moore (1914) is perhaps the most notorious misinterpretation, but in fact led to many later insights – in particular, reactions to it helped unravel the whole complicated and intertwined issues

of simultaneity, identification, exogeneity, and partial effects (see Wright, 1915, 1929; Working, 1927; Tinbergen, 1930, *inter alia*).

Equally importantly, many "strange" empirical correlations had been found that stimulated the unraveling of both spurious, and later nonsense, regressions in works such as Yule (1897), Hooker (1901), and especially the famous explanation in Yule (1926), leading first to a distinction between short-run and long-term relationships, then unit roots, and eventually cointegration, as in Granger (1981), and dozens of later contributions surveyed in Hendry and Juselius (2000, 2001). Despite obvious progress – Stigler (1962) begins his article about Moore by "If one seeks distinctive traits of modern economics, traits which are not shared to any important degree with the Marshallian or earlier periods, he will find only one: the development of statistical estimation of economic relationships" – trouble lay ahead.

The attack by Robbins (1932) on the empirical studies of Schultz (1928) – portrayed as the feckless Dr. Blank studying the demand for herring (rather than sugar) – was the first of several critiques which sought to deny any substantive role for econometrics in economics.[1] Tinbergen's attempts to build empirical models of investment activity brought down the wrath of John Maynard Keynes (see Tinbergen, 1939, 1940; Keynes, 1939, 1940), who insisted that the economist had to be "in the saddle" with the econometrician as the "patient ass," and sarcastically demanded that Tinbergen satisfy:

> an experiment on his part. It will be remembered that the seventy translators of the Septuagint were shut up in seventy separate rooms with the Hebrew text and brought out with them, when they emerged, seventy identical translations. Would the same miracle be vouchsafed if seventy multiple correlators were shut up with the same statistical material? And anyhow, I suppose, if each had a different economist perched on his *a priori*, that would make a difference to the outcome.

We will return in section 1.4 both to that issue, which may well now be possible, and to Keynes' general claims – one might like to ponder whether 70 economic theorists asked to tackle the same puzzle would derive precisely the same model? As ever, other more constructive outcomes followed from that debate, especially the memorandum by Frisch (1938), and it certainly did not discourage Haavelmo (1944).

1.3.2 War and post-war

> "I'll tell you all my ideas about Looking-glass House. First, there's the room you can see through the glass – that's just the same as our drawing-room, only the things go the other way." (Quote from Alice in Lewis Carroll, 1899)

Despite Koopmans (1937) being a key precursor to the establishment of modern econometrics in Haavelmo (1944), the attack by Koopmans (1947) on Burns and

Mitchell (1946) allowed the assertion of "measurement without theory" to become capable of dismissing empirical work without further serious consideration. The vigorous reply by Vining (1949a, 1949b) still merits reading. With a few honorable exceptions (such as Atkinson, 2005), even the use of the word "measurement" as a title for economics' papers seems to have decreased since (other than in "measurement errors"). Tress (1959) offers a near contemporary analysis of the acrimony between economics and econometrics at that time, and a possible reconciliation.

Keynes (1939) had asserted that a long list of "preconditions" had to be satisfied to validate empirical inferences, implicitly arguing that empirical econometrics must fail unless everything was known in advance (see, e.g., Hendry, 1980). But if it was impossible to empirically uncover things not already known theoretically, then no science could have progressed; rather, scholasticism would still rule. There are several flaws in Keynes' claims, of which three are the most important.

First, "partial knowledge" can be valuable, and can be learnt from evidence, with or without prior theories, albeit being subject to revision later. Our understanding of gravity remains incomplete, but has advanced greatly since Aristotle's early view of objects' natural places (smoke rises, stones fall, as natural to go to heaven or the centre of the earth, respectively), through Ptolemy's epicycle theory of planetary motions, Descartes' vortex theory, and Newtonian inverse-square laws, which Adam Smith (1795) presciently noted was just a model and not the "truth" (as most of his contemporaries assumed). Einstein's relativity theory is still not the "final answer." Retrospectively, Aristotle's theory did not go beyond "explaining" the phenomena themselves, whereas Newtonian theory, while closely based on Kepler's laws of motion of planetary bodies, explained many additional aspects, so was a clear advance in knowledge, even if later it too was found to be incomplete, and at relativistic speeds, incorrect. Moreover, despite neither Aristotle's nor Newton's theories being "true," both were at least consistent with the observed facts of their time. The relevant empirical regularities persisted through many theories, which provided better explanations, often with unanticipated predictions of new phenomena – genuine "mutual penetration." Thus, progress is the key to science, not one-off forging of true laws that hold forever.

Second, if there are invariant features of reality – as in physics and chemistry – then empirical research can discover them without prior knowledge, as happened historically in many branches of science. Conversely, if nothing is invariant (an extreme of Heraclitus of Ephesus supposed view that "reality is change"), neither economic theories nor econometric models would be of any practical value (see Hendry, 1995b). Following Bachelier (1900), equity prices have long been viewed as close to random walks, which may be thought to entail the absence of any invariants, but if correct – as suggested by some modern theories and empirical tests of efficient markets – is actually a powerful invariant, as contrasted with a data generating process whose structure alters every period.

Third, empirical econometrics could still "advance" by rejecting economic theories. This would at least allow economists to focus on theories that were not yet rejected, if any, and improve those that faced discordant evidence. However,

progress might be somewhat inefficient when new theories are easily generated as variants of previous incarnations.

Similar comments apply to Koopmans' claim that "without resort to theory, in the sense indicated, conclusions relevant to the guidance of economic policies cannot be drawn." Such an argument is not sustainable in general. Originally, aspirin was a folk remedy for hangovers, derived from brewing willow-tree bark – of which acetylsalicylic acid, aspirin's active ingredient, is a natural constituent – without any theory as to how or why that policy intervention worked (see Weissmann, 1991). A less well known example is the use in folk medicine of fungal-based products, some of which contain natural antibiotics such as penicillin: over 3,000 years ago, the Chinese had used moldy soybean curd for treating skin infections, again with no theory on which to base that policy. Theories can be invaluable, and can enhance the credibility of proposed policies, but they are not essential, especially when they are incorrect.

1.3.3 The rise of economic theory-based econometrics

> "If you'll tell me what language 'fiddle-de-dee' is, I'll tell you the French for it!" she exclaimed triumphantly. (Quote from Alice to the Red Queen in Lewis Carroll, 1899)

Another critique of empirical modeling follows from the joint dependence of economic events, namely the resulting issues of endogeneity and identification. It seems widely believed that identification restrictions must be given *a priori* by economic theory, especially in simultaneous systems, yet that belief also does not have a substantive basis, as shown in section 1.4.7 on identification.

Together, the cumulative critiques just noted led to an almost monolithic approach to empirical econometric research: first postulate an individualistic, intertemporal optimization theory; next derive a model therefrom; third, find data with the same names as the theory variables; then select a recipe from the econometrics cookbook that appropriately blends the model and the data, or if necessary, develop another estimator; finally report the newly forged empirical law. Thus, we have a partial answer to the issue posed in section 1.2: the contingent history of econometrics suggested that the only viable route for applied research in economics, where all current-dated variables are potentially endogenous, was to provide the quantitative cloth for a completely pre-specified theoretical formulation derived from general economic principles. But that approach too is problematic and not without its critics. Economic theory has progressed dramatically over the past century – imagine being forced to impose 1900's economic theory today as the basis for empirical research. If you recoil in horror at that idea, then you have understood why much past Applied Econometrics research is forgotten: discard the economic theory that it quantified and you discard the empirical evidence. Instead of progress, we find fashions, cycles and "schools" in research. The problem is not that early pioneers ignored economic theory, but that the available theory was seriously incomplete – as it still is today. Indeed, the Cowles Commission research was essentially predicated on the belief that the relevant economic

theory already existed, so complicated issues of model choice could be avoided by imposing valid restrictions derived from correct economic theories: on discovering that such theory was not available, many turned to help develop it (see, e.g., Qin, 2008; Bjerkholt, 2007 (Bjerkholt, 2005, is a useful precursor). Koopmans, Hurwicz and Arrow all made major contributions to economic theory, and to quote Bjerkholt (2007): "Haavelmo stated later on various occasions that economic theory needed further development for the econometric methods to become fully applicable" (also see Moene and Rødseth, 1991). Indeed, to quote Haavelmo (1989) himself:

> The basis of econometrics, the economic theories that we had been led to believe in by our forefathers, were perhaps not good enough. It is quite obvious that if the theories we build to simulate actual economic life are not sufficiently realistic, that is, if the data we get to work on in practice are not produced the way that economic theories suggest, then it is rather meaningless to confront actual observations with relations that describe something else.

He reiterated that view in his presidential address to the Econometric Society (published as Haavelmo, 1958):

> What I believe to be true, however, is this: The training in the technical skills of econometrics can represent a powerful tool for imaginative speculation upon the basic phenomena of economic life; and, furthermore, it would be fruitful to bring the requirements of an econometric "shape" of the models to bear upon the formulation of fundamental economic hypotheses from the very beginning.

Once model choice cannot be avoided, methodology becomes a salient issue, and it would seem every conceivable methodology has at least one advocate. Pagan (1987) considered what he viewed as the three main econometric methodologies, relating mine to Leamer (1978) and Sims (1980), yet the ubiquitous "theory-based" approach was not mentioned, albeit that there are really many variants thereof.

1.3.4 The decline of data concerns

> "You're travelling the wrong way." (Train guard to Alice in Lewis Carroll, 1899)

At about the same time that *a priori* theory-based econometrics became dominant, data measurement and quality issues were also relegated as a central component of empirical publications. Early on, data series were often published in their entirety, with careful caveats about accuracy, but later, at best, were recorded in appendices, or not at all. For example, Clark (1932) allowed the first famous estimate of the size of the Keynesian "multiplier." Although computerized databases have recently started to compensate for the absence of the printed record, electronic data are sometimes revised in situ, making it difficult for later investigators to duplicate previously-published findings. In a detailed study of a number of cases, Atkinson

(2008) emphasizes that the outcomes reported would change substantively if data had been more carefully evaluated prior to the econometric analysis. To quote:

> my concern (is) with the status, within economics, of economic statistics. By "economic statistics," I mean the study of how we create, use and assess economic data – what one might call "data appreciation." ... It is true that economists are using empirical data to an unprecedented extent, and applying tools of great sophistication. Economics is a much more data-driven subject than it was in the past. But, I shall argue, economists have too often come to take data for granted, without critical examination of their strengths and weaknesses.

With that caveat about data firmly in mind, let us turn to methodology: measurement is reconsidered in section 1.4.3, and an illustration of some effects of substantial revisions in section 1.7.1.

The route ahead views all models as arising from reductions of whatever process generated the data, which is a combination of the economic outcome and the measurement system. We discuss these reductions in relation to their impact on the parameters that actually governed the economic decisions of the relevant agents. Most reductions occur implicitly, as investigators usually approach modeling from the opposite perspective, namely what to include in their analysis, although its success or failure will depend on whether the sub-set of variables considered allows a model to capture the salient and constant characteristics of the data-generating process (DGP). What to include and how to include it certainly depends on the economics behind the analysis; but what is found depends on the unknown data-generating process and the losses of information from the reductions that were necessary to derive the postulated model.

1.4 A theory of Applied Econometrics

> "Why, sometimes I've believed as many as six impossible things before breakfast." (Quote from the White Queen in Lewis Carroll, 1899)

If only it were just six! To believe that he or she has ascertained the "truth," an applied econometrician would have to believe at least the following dozen impossible (composite) assumptions:

1. a correct, complete, and immutable underlying economic theory derivation
2. a correct, comprehensive choice of all relevant variables, including all dynamic specifications
3. exact data measurements on every variable
4. the absence of any hidden dependencies, including collinearity and simultaneity
5. the validity and relevance of all conditioning variables (including instruments)
6. the precise functional forms for every variable
7. that all parameters of interest are identified in the resulting model specification

8. that all entities treated as parameters are constant over time, and invariant to all potentially omitted variables and regime changes
9. the errors have "independent," homoskedastic, distributions
10. all expectations formulations are correct, or agents' expectations are accurately measured
11. the choice of estimator is appropriate at relevant sample sizes
12. a valid and non-distortionary method of model selection is used.

If all of these assumptions had to be perfectly correct to produce useful empirical evidence, there would be no hope of ever doing so. In Hendry (1987), I suggested the four "golden prescriptions" of econometrics, abbreviated here as:

(i) think brilliantly: if you think of the right answer before modeling, then the empirical results will be optimal and, of course, confirm your brilliance;
(ii) be infinitely creative: if you do not think of the correct model before commencing, the next best is to think of it as you proceed;
(iii) be outstandingly lucky: if you do not think of the "true model" before starting nor discover it en route, then luckily stumbling over it before completing the study is the final sufficient condition. This may be the most practical of these suggestions. Failing this last prescription:
(iv) stick to doing theory.

Lest the reader thinks the list of a dozen requirements above is overly dramatic, or even new, Hendry and Morgan (1995) record:

> In the thesis as a whole, Koopmans (1937) assembles together and confronts most of the major issues in econometrics, which we have translated into current terminology as:
> 1. the joint occurrence of errors-in-variables and errors-in-equations
> 2. the need for a complete set of determining variables to leave an innovation error
> 3. a reductionist approach of proceeding from general to simple
> 4. the distinctions between the activities of specification, estimation and distribution, as spelt out by R.A. Fisher
> 5. the non-experimental nature of economic data
> 6. the need to condition on systematic components with independently varying error terms
> 7. the choice of functional form, using linearity for convenience
> 8. the formulation of the parameters of interest
> 9. the need to test underlying assumptions
> 10. the importance of incorporating all relevant information
> 11. the avoidance of unnecessary assumptions
> 12. the need for the general model to be estimable
> 13. the need for the model specification to be robust.

We now consider each of the twelve assumptions in turn, devoting the separate section 1.5 to the last, namely model selection.

1.4.1 Economic theory

> "It seems very pretty," she said when she had finished it, "but it's rather hard to understand." (Alice after reading the Jabberwocky poem in Lewis Carroll, 1899)

Economic theory has created many major ideas that have in turn changed the world, from the "invisible hand" in (Smith, 1759, p. 350), understanding the gains from trade and the problems with mercantilism, through the effects of tariffs and taxes, to modern insights into issues such as welfare economics, option pricing, auctions, contracts, principal–agent and game theories, trust and moral hazard, asymmetric information, institutions, and all their attendant impacts on market functioning and industrial, and even political, organization. In doing so, economics has evolved dramatically over time, and will undoubtedly continue doing so, hence at no instant can it be claimed to be correct, complete and immutable. For example, most theories take preferences as a given – sometimes even as "deep parameters" – but there are many endogenous determinants, from learning, adaptation, and advertising among others (see, e.g., von Weizsacker, 2005), with psychological, behavioral, and neuro-economics bidding fair to play key roles in the future (see, *inter alia*, Fehr and Falk, 2002; Fehr, Fischbacher, Kosfeld, 2005; Camerer, 2007).

Theories need to be distinguished in terms of their "levels', where low-level theories are well established and widely accepted (e.g., the optical theory behind the design of telescopes and the interpretation of their evidence), whereas high-level theories usually assume the validity of many lower levels, but are subject to doubt (as in theories of the accelerating expansion of the universe as due to "dark energy"). Facts are items of empirical information which depend only on low-level theories and measurements, and can be reliably replicated. Since all empirical evidence is theory laden to some degree, albeit often just from very low-level theories, "measurement without theory" is trivially impossible, and must relate to the lack of use of high level theories – the appropriate blend of theory and empirical evidence affects research efficiency, not necessarily the validity of any resulting findings (see, e.g., Gilbert and Qin, 2007). Many low-level statements are correct, complete and immutable, such as $1 + 1 = 2$, and although essential to arithmetic, cannot "explain" economic behavior. Conversely, testing theories just by their predictions is problematic, as false assumptions can entail correct conclusions: assume $1 = 2$, then $2 = 1$, so adding both sides, $3 = 3$, which is valid and presumably thereby establishes that $1 = 2$ (also see Ericsson and Hendry, 1999).

General theories that do "explain" the *Gestalt* of empirical evidence are a boon, but are not essential. Similarly, although experimentation can be helpful, it is far from the only source of evidence: observational science is not an oxymoron. The progressivity of science – its cumulation of findings that cohere, are consolidated in theoretical explanations, and suggest where next to investigate – is its most salient

attribute. There is simply no case that we understand no more than (say) Aristotle, or Kepler, etc.: lights work, computers run, planes fly. Moreover, it is possible to "predict" with considerable accuracy what changes to chips will speed up calculations, and what putative aircraft will not fly, which are inferences beyond any local set of experiments and evidence, are not purely inductive, and can be generalized, though doubtless with limits. Science seeks progress, whether by new experiments, new instruments or observations, new theories or refutations of extant ones. We now know that ulcers are caused by helicobacter pylori bacteria – not by stress – so cheap, painless antibiotics can cure ulcers, replacing life-threatening operations or expensive drugs. The path that led to that idea is irrelevant to its validity, and could be serendipity, careful testing, or a theory prediction, whereas stringent evaluation and replicability are crucial. In turn, such advances can lead to radical new thinking, albeit that initially they often face considerable opposition – sometimes even derision: scientists are humans, and rarely change their views until evidence overwhelms. Even then, theories are usually not rejected by evidence, but rather are replaced when "better" theories develop that explain more, especially if they account for previous anomalies.

Statistical analyses become essential in observational sciences, such as astronomy and economics, where "field" experiments are almost impossible to control. Then theory and modeling difficulties both explode and certainty declines, especially when behavioral change is possible: despite rendering previous analyses less than fully relevant to new settings, progress remains the key. It is widely recognized that special factors may intrude on a theory-based model (e.g., changes in credit rationing, nationalization, deregulation, price controls, wars, etc.), but less recognized that such special factors can dominate when accounting for data variability. Morgan (1990), Spanos (1995), Hendry (1995b) and Hendry and Mizon (2000) discuss some of the problems involved in testing theories using observational data.

Economists have not formally justified the principle of deriving empirical models from theory – most seem to assume it is obvious – so a substantial proportion of empirical econometric evidence is "high level" in that its credibility depends on the prior credibility of the theoretical model from which it was derived. Given any conjecture, we can usually test its empirical validity, thereby sustaining a destructive approach (see, e.g., Popper, 1963, on conjectures and refutations), although issues of inference from small and heterogeneous data samples complicate the analysis. If a theory implementation is simply discarded when it is rejected, the process fails to incorporate learning from the evidence. Conversely, if it is not discarded, some or all of the empirical model, the measurements and the theory must be revised, although there is no unique or even structured way of doing so. It is a *non sequitur* to assume that the particular alternative considered is true when the null is rejected. A progressive research approach of successively encompassing congruent (see section 1.4.2.4) models consolidated by empirically-relevant theories offers one possibility.

Alternative approaches to "macroeconomic theory" abound in the literature: Samuelson (1947) initiated a tradition of models based on constrained optimization, implemented by Hall (1978) as Euler equations; Kydland and Prescott (1990,

1991) formulate real-business cycle theories with rational expectations, leading to dynamic stochastic general equilibrium (DSGE) models as in Smets and Wouters (2003), whereas Hildenbrand (1994, 1999) emphasizes heterogeneity of endowments; Stiglitz (2003) stresses that asymmetric information can induce Keynesian effects, and Aghion *et al.* (2002) argue that agents only have imperfect-knowledge expectations. Moreover, many aspects of economic theory models can be chosen freely, such as the units of time and forms of utility functions: indeed, Stigum (1990) views theories as characterizing "toy agents in toy economies." However, when data are non-stationary, few transformations will be able to characterize the evidence in a constant relationship. For example, linear relationships between variables, which often arise in Euler equations, seem unlikely to be good descriptions in growing economies (see Ermini and Hendry, 2008, and Spanos, Hendry and Reade, 2008, for tests of log versus linear dependent variables in I(1) processes).

The absence from many economic theories of some of the main sources of data variability occurs across most research areas in economics, and although it differs in form, is probably part of the reason for the rash of "puzzles" (i.e., anomalous or even contradictory evidence) so beloved of the present generation of journal editors. In microeconomics, low R^2 values reveal that much of the variability is not accounted for by the postulated models. That outcome is usually ascribed to individual heterogeneity and idiosyncrasies, which can indeed generate high levels of unexplained variability, but there has to be some doubt that all the major factors have been included. In panel data studies, much observed data variation is attributed to "individual effects," which are removed by (e.g.) differencing or deviations from individual means. However, if the evidence that most micro-variability is due to individual heterogeneity is correct, then "representative" agent theories cannot be the best basis for macro-behavior, although aggregation could sustain some approaches (see, e.g., Granger, 1987; Blundell and Stoker, 2005), but not others (Granger, 1980). Finally, cross-country studies rarely account for key institutional differences between the constituent economies, and often use averages of data over historical epochs where considerable changes occurred between periods (see, e.g., Sala-i-Martin, 1997, and the criticisms in Hoover and Perez, 2004; Hendry and Krolzig, 2004).

1.4.1.1 Non-stationarity and ceteris paribus

> "You don't know how to manage Looking-glass cakes," the Unicorn remarked. "Hand it round first, and cut it afterwards." (Lewis Carroll, 1899)

A time series process is non-stationary if its moments or distributional form change over time. Two important forms of non-stationarity are unit roots and structural breaks, both of which lead to permanent changes. The former induce stochastic trends, which can be eliminated by differencing, or cointegration can also remove unit roots and retain linear combinations of levels of the variables (however, unit roots and cointegration are only invariant under linear transformations of variables). There is a vast literature, and recent surveys include Hendry and Juselius

(2000, 2001) and Johansen (2006). Structural breaks matter most when they induce location shifts in the processes under analysis, but those can also be removed in part by differencing or co-breaking (see Hendry and Massmann, 2007). Forecast failure – defined as a significant deterioration in forecast performance relative to its anticipated outcome, usually based on historical performance – is all too common, and is almost certainly due to structural breaks (see, e.g., Clements and Hendry, 1998, 1999, 2002b).

Because much observed data variability is due to factors absent from economic theories, a serious gap exists between macroeconomic theory models and applied econometric findings (see Spanos, 1989; Juselius, 1993; Hendry, 1995b; Nymoen, 2002). All economic theories rely on implicit *ceteris paribus* clauses, as "controls in thought experiments," although in a general equilibrium system in which everything depends on everything else, *ceteris paribus* is suspect. In empirical modeling, *ceteris paribus* cannot apply under non-stationarity even if the relevant variables are strongly exogenous, since "other things" will not be "equal." Cartwright (2002) describes *ceteris paribus* as roughly equivalent to "if nothing interferes then . . . some regularity is observed." In non-stationary processes, nothing will interfere only if all other factors are irrelevant, not because they will not change. Many sources of wide-sense non-stationarity impinge on economic data, including technical progress, R&D, new legislation, institutional changes, regime shifts, financial innovation, shifting demography, evolving social and political mores, as well as conflicts and other major catastrophes, inducing both evolution and structural breaks, all of which change the distributional properties of data.

Two resolutions are possible to wide-sense non-stationarity. First, a "minor influence" theorem could show on theoretical or evidential grounds that all omitted factors can be neglected, either because changes in them are of a smaller order of importance than included effects, or because they are orthogonal to all the effects that matter (see Hendry, 2005, and compare Boumans, 2005, who refers to *ceteris neglectis* and *ceteris absentibus*). Neither condition is plausible unless at least all the major influences have been included. Doing so brings us anyway to the second solution, namely including all potentially relevant variables at the outset, embedding theory models in more general systems that also allow for all the empirically-known influences, as well as the many historical contingencies that have occurred. Thus, institutional knowledge and economic history become essential ingredients in Applied Econometrics. Far from diminishing the importance of economic reasoning as a basis for empirical econometrics, including all non-stationarities seems the only way to reveal the underlying economic behavior uncontaminated by excluded changes. Of course, theory models of the likely behavioral reactions of economic agents to major changes would also help. As macro-data are the aggregates of the economic microcosm, these problems must afflict all empirical econometric studies, and are not merely a problem for time series analysts. Since the need to model all non-stationarities if empirical results are to be useful is important for both economics and econometrics, the next section considers its prevalence.

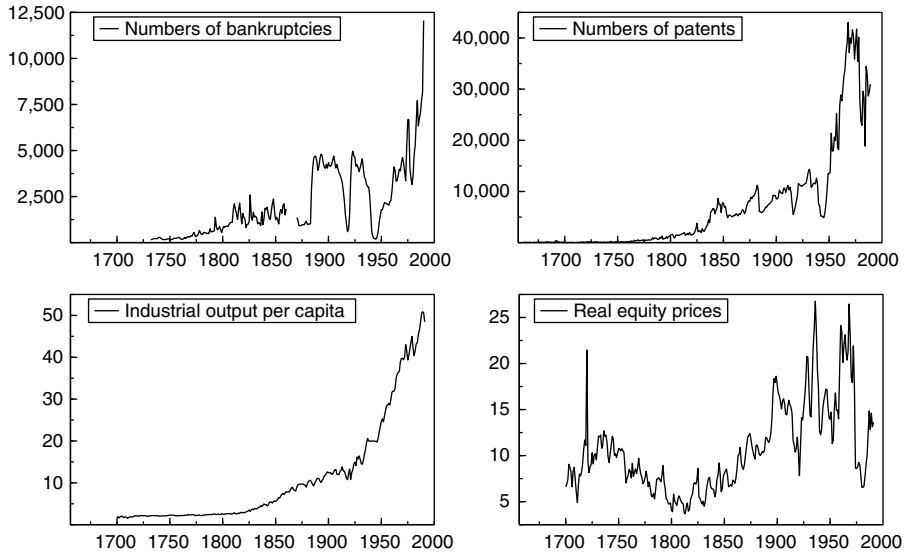

Figure 1.1 Historical time series for the UK

1.4.1.2 Long-run change

> "I see you're admiring my little box," the Knight said in a friendly tone. "It's my own invention – to keep clothes and sandwiches in. You see I carry it upside-down, so that the rain can't get in."
>
> "But the things can get out," Alice gently remarked. "Do you know the lid's open?" (Lewis Carroll, 1899)

Figure 1.1 records some historical time series for the UK over the period from about 1700 to 1991 (the dates differ for the various variables). Many other variables manifesting dramatic non-stationarities are shown in Hendry (2001a, 2001b, 2005) and Clements and Hendry (2001), where the first and last examine UK industrial output in more detail. Here we focus on numbers of bankruptcies and patents, industrial output per capita, and real equity prices (deflated by a cost of living price index) (see Feinstein, 1972; Mitchell, 1988; Crafts and Mills, 1994, *inter alia*).

These four variables were selected from a range of alternatives as being related to advances in technology and medicine, their implementation, incentives for progress through intellectual property, and one source of financing (see Siegel and Wright, 2007, for a recent review and bibliographic perspective). Technological change is sometimes modeled as an "exogenous" random walk. While that is an improvement over a deterministic trend, it is hardly a convincing representation of a process which requires substantial inputs of human and physical capital, as highlighted by endogenous growth models (see, e.g., Crafts, 1997). At the very

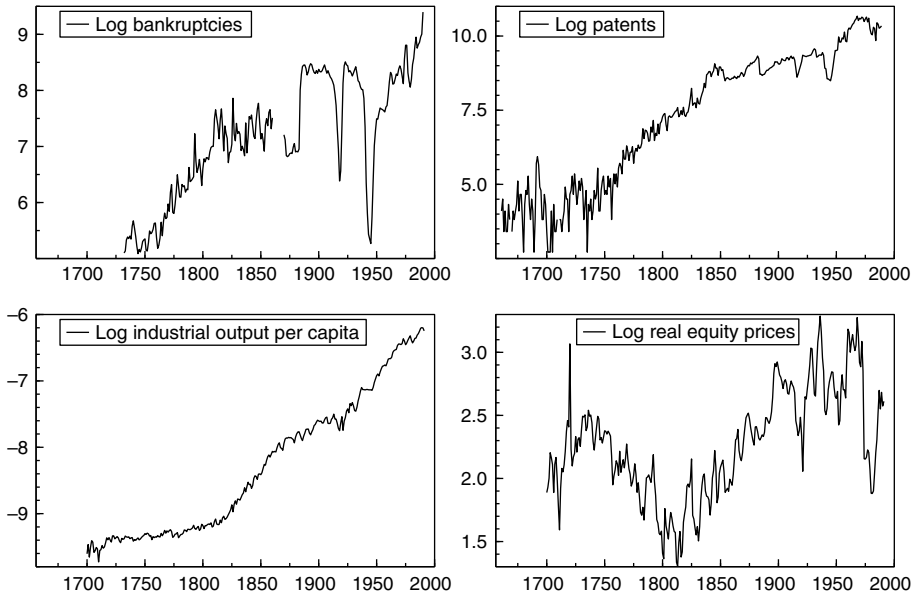

Figure 1.2 Logs of historical UK time series

start of the industrial revolution, Smith (1776, Ch. 1) notes the key development of specialists in R&D: "In the progress of society, philosophy or speculation becomes, like every other employment, the principal or sole trade and occupation of a particular class of citizens."

The non-stationarities in Figure 1.1 are blatant, and reflect more than just unit roots. Major historical events are clear: e.g., real equity prices exploded in the South Sea Bubble, not regaining such levels again for 200 years, collapsed in the Napoleonic and both world wars, as well as the first oil crisis, and today are little above pre-industrial revolution levels. Frankly, it is almost infeasible to build sensible empirical models of these levels series.

Figure 1.2 records the same four series in logs. Non-stationarity remains clear, but one can at least imagine ways of sucessfully modeling such data. Figure 1.3 reports their data densities separately in each of (approximately) the three centuries involved. The shifts in means and variances are marked, even if the presence of heterogeneity and dependence within each century can distort such histograms. Nor is the non-stationarity restricted to the levels of the variables, as Figure 1.4 illustrates for the annual changes in the four variables. Variance changes are clear, which also serves to make the densities of the changes look much more alike, as seen in Figure 1.5. Differencing alone can be insufficient to induce stationarity.

We will analyze the log transformations of these data in section 1.8.

In the absence of complete theoretical guidance on all relevant and irrelevant variables, functional forms, exogeneity, dynamics, and non-stationarities, empirical determination is essential. Consequently, the initially postulated models of

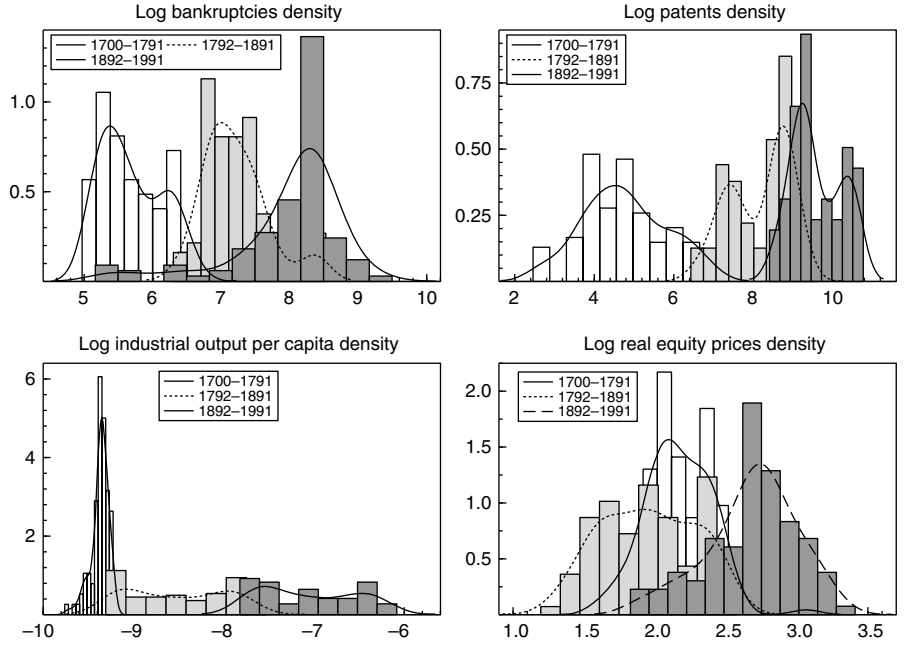

Figure 1.3 Three centuries of data distributions of levels

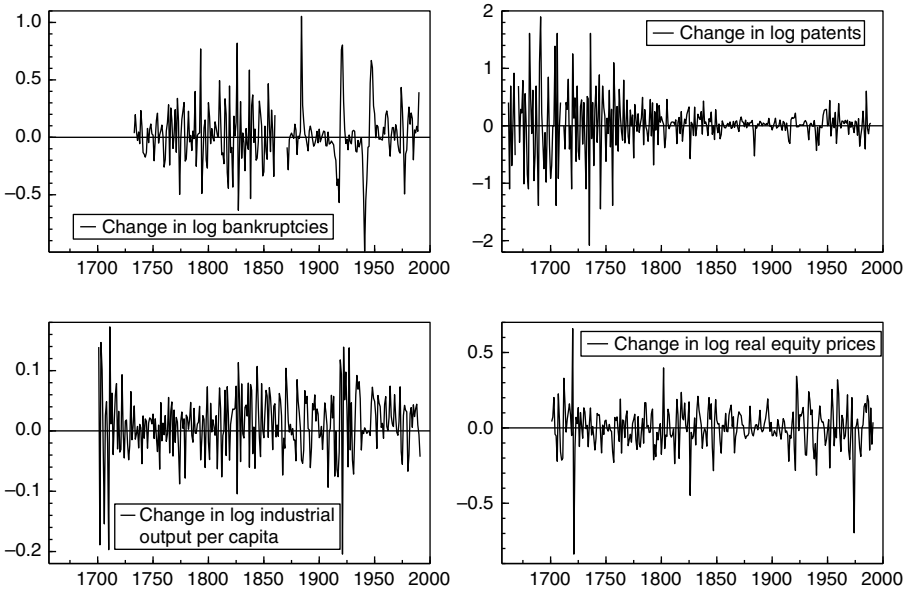

Figure 1.4 Changes in historical time series for the UK

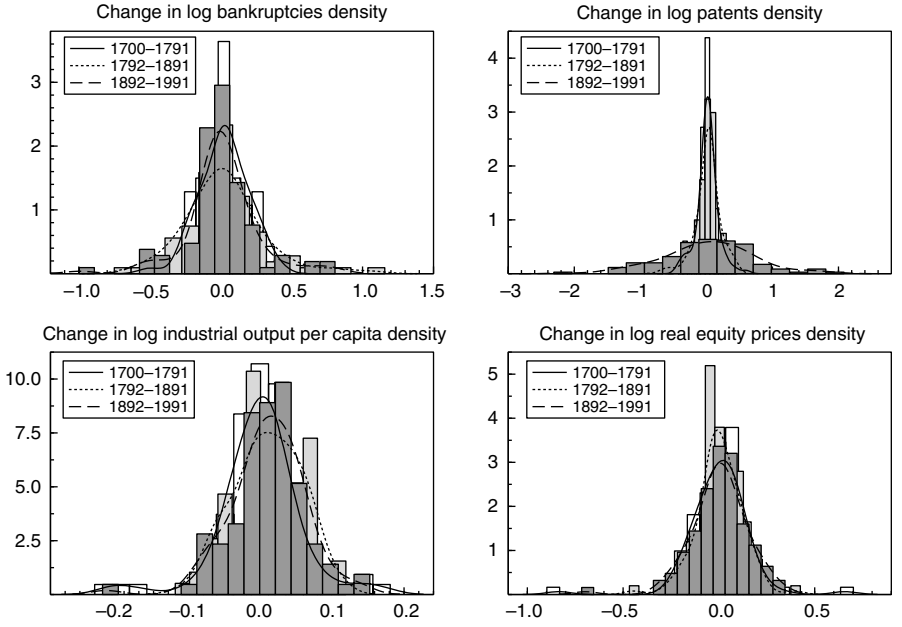

Figure 1.5 Three centuries of data distributions of changes

empirical research should usually involve many variables, although final selections may prove to be parsimonious (an implication is considered in section 1.5): we now consider that route.

1.4.2 Incomplete specifications

> "What am I to do?" exclaimed Alice, looking about in great perplexity as first one round head, and then the other, rolled down from her shoulder, and lay like a heavy lump in her lap. (Lewis Carroll, 1899)

Economies are so high dimensional, interdependent, heterogeneous, and evolving that a comprehensive specification of all events is impossible: the number of economy-wide relevant variables is uncountable in a human lifetime. Reducing that high dimensionality by aggregation over any or all of time, space, commodities, agents, initial endowments, etc., is essential, but precludes any claim to "truth." So if one cannot get at the "truth," what is on offer in economics? Three alternatives are: imposing theory-based models; constructing partial models, which aim to estimate some parameters associated with a theory, usually by generalized method of moments (GMM); or seeking the local DGP guided by economic theory. All three could operate, but depend on different assumptions. We first outline how empirical models must arise, then evaluate the three approaches in general against that basis.

1.4.2.1 From DGP to LDGP

> "The prettiest are always further!" she said at last. (Quote from Alice in Lewis Carroll, 1899)

Granted a stochastic basis for individual agent decision taking, such that any economic transaction can be described as an event in an event space, which could have been different for a myriad of reasons, then outcomes are measurable random variables with (possibly different) distributions at each point in time. Let $\mathbf{U}_T^1 = (\mathbf{u}_1, \ldots, \mathbf{u}_T)$ be the complete set of random variables relevant to the economy under investigation over a time span $t = 1, \ldots T$, defined on the probability space $(\Omega, \mathcal{F}, \mathsf{P})$, where Ω is the sample space, $\mathcal{F}$ the event space and P the probability measure. Denote the vast, complex, and ever-changing joint distribution of $\{\mathbf{u}_t\}$ conditional on the pre-sample outcomes $\mathbf{U}_0$ and all necessary deterministic terms $\mathbf{Q}_T^1 = (\mathbf{q}_1, \ldots, \mathbf{q}_T)$ (like constants, seasonal effects, trends, and shifts) by:

$$\mathsf{D}_{\mathsf{U}}\left(\mathbf{U}_T^1 \mid \mathbf{U}_0, \mathbf{Q}_T^1, \xi_T^1\right), \tag{1.1}$$

where $\xi_T^1 \in \Xi \subseteq \mathcal{R}^k$ are the parameters of the agents' decision rules that led to the outcomes in (1.1). Then $\mathsf{D}_{\mathsf{U}}(\cdot)$ is the unknown, and almost certainly unknowable, data-generation process of the relevant economy. The theory of reduction discussed in, *inter alia*, Hendry (1987), Florens, Mouchart and Rolin (1990) and Hendry (1995a, Ch. 9) shows that a well-defined sequence of operations leads to the "local" DGP (LDGP), which is the actual generating process in the space of the variables under analysis. The resulting LDGP may be complex, non-linear and non-constant from aggregating, marginalizing (following the relevant data partition), and sequential factorization (the order of these reductions below is not a central aspect), so the choice of the set of variables to analyze is crucial if the LDGP is to be viably "captured" by an empirical modeling exercise. In turn, that LDGP can be approximated by a "general unrestricted model" (GUM) based on truncating lag lengths, approximating the functional form (perhaps after data transformations) and specifying which parameters are to be treated as constant in the exercise. Finally, a further series of reductions, involving mapping to non-integrated data, conditioning, and simultaneity, lead to a parsimonious representation of the salient characteristics of the dataset. Tests of losses from all these reductions are feasible, as discussed in section 1.4.2.4.

Aggregation. Almost all econometric data are aggregated in some way, implicitly discarding the disaggregates: although some finance data relate to point individual transactions, their determinants usually depend on aggregates (such as inflation). We represent this mapping as $\mathbf{U}_T^1 \rightarrow \mathbf{V}_T^1$, where the latter matrix is a mix of the data to be analyzed and all other variables. The key issue is the impact of that mapping on $\xi_T^1 \rightarrow \phi_T^1$, where the latter set may include more or fewer constant parameters depending on the benefits or costs of aggregation. Aggregates are linear sums, so their means have variances proportional to population size: if $x_{i,t} \sim \mathsf{IN}\left[\mu_t, \sigma_t^2\right]$

then $\overline{x}_t = N_t^{-1} \sum_{i=1}^{N_t} x_{i,t} \sim \mathsf{IN}\left[\mu_t, N_t^{-1}\sigma_t^2\right]$. Log transforms of totals and means, $\overline{x} > 0$, only differ by that population size as $\ln \sum_{i=1}^{N_t} x_{i,t} = \ln \overline{x}_t + \ln N_t$, so standard deviations of log aggregates are proportional to scaled standard deviations of means: $\mathsf{SD}[\ln \sum_{i=1}^{N_t} x_{i,t}] \simeq N_t^{-1}\sigma_t/\mu_t$ (see, e.g., Hendry, 1995a, Ch. 2). Thus logs of aggregates can be well behaved, independently of the underlying individual economic behavior.

Data transformations. Most econometric models also analyze data after transformations (such as logs, growth rates, etc.), written here as $\mathbf{W}_T^1 = \mathbf{g}(\mathbf{V}_T^1)$. Again, the key impact is on $\phi_T^1 \rightarrow \varphi_T^1$ and the consequences on the constancy of, and cross-links between, the resulting parameters. At this stage we have created:

$$\mathsf{D}_{\mathsf{W}}\left(\mathbf{W}_T^1 \mid \mathbf{U}_0, \mathbf{Q}_T^1, \varphi_T^1\right). \tag{1.2}$$

The functional form of the resulting representation is determined here by the choice of $\mathbf{g}(\cdot)$. Many economic variables are intrinsically positive in levels, a property imposed in models by taking logs, which also ensures that the error standard deviation is proportional to the level.

Data partition. No reduction is involved in specifying that $\mathbf{W}_T^1 = (\overline{\mathbf{W}}_T^1 : \mathbf{R}_T^1)$, where $\mathbf{R}_T^1$ denotes the $n \times T$ data to be analyzed and $\overline{\mathbf{W}}_T^1$ the rest. However, this decision is a fundamental one for the success of the modeling exercise, in that the parameters of whatever process determines $\mathbf{R}_T^1$ must deliver the objectives of the analysis.

Marginalizing. To implement the choice of $\mathbf{R}_T^1$ as the data under analysis necessitates discarding all the other potential variables, which corresponds to the statistical operation of marginalizing (1.2) with respect to $\overline{\mathbf{W}}_T^1$:

$$\mathsf{D}_{\mathsf{W}}\left(\overline{\mathbf{W}}_T^1, \mathbf{R}_T^1 \mid \mathbf{U}_0, \mathbf{Q}_T^1, \varphi_T^1\right) = \mathsf{D}_{\overline{\mathsf{W}}}\left(\overline{\mathbf{W}}_T^1 \mid \mathbf{R}_T^1, \mathbf{U}_0, \mathbf{Q}_T^1, \overline{\varphi}_T^1\right) \mathsf{D}_{\mathsf{R}}\left(\mathbf{R}_T^1 \mid \mathbf{U}_0, \mathbf{Q}_T^1, \omega_T^1\right). \tag{1.3}$$

While such a conditional-marginal factorization is always possible, a viable analysis requires no loss of information from just retaining ω_T^1. That will occur only if $\left(\overline{\varphi}_T^1, \omega_T^1\right)$ satisfy a cut, so their joint parameter space is the cross-product of their individual spaces, precluding links across those parameters. At first sight, such a condition may seem innocuous, but it is very far from being so: implicitly, it entails Granger non-causality of (all lagged values of) $\overline{\mathbf{W}}_T^1$ in $\mathsf{D}_{\mathsf{R}}(\cdot)$, which is obviously a demanding requirement (see Granger, 1969; Hendry and Mizon, 1999). Spanos (1989) calls the marginal distribution $\mathsf{D}_{\mathsf{R}}(\cdot)$ in (1.3) the Haavelmo distribution.

Sequentially factorizing. Next, letting $\mathbf{R}_{t-1}^1 = (\mathbf{r}_1, \ldots, \mathbf{r}_{t-1})$, the retained marginal density from (1.3) can be sequentially factorized as (see, e.g., Doob, 1953):

$$\mathsf{D}_{\mathsf{R}}\left(\mathbf{R}_T^1 \mid \mathbf{U}_0, \mathbf{Q}_T^1, \omega_T^1\right) = \prod_{t=1}^{T} \mathsf{D}_{\mathsf{r}_t}\left(\mathbf{r}_t \mid \mathbf{R}_{t-1}^1, \mathbf{U}_0, \mathbf{q}_t, \lambda_t\right). \tag{1.4}$$

The right-hand side of (1.4) completes the intrinsic reductions from the DGP to the LDGP for the set of variables under analysis (generally, the effects of the initial conditions $\mathbf{U}_0$ are ignored and assumed to be captured by $\mathbf{R}_0$). The sequential densities in (1.4) create a martingale difference (or innovation) process:

$$\epsilon_t = \mathbf{r}_t - \mathsf{E}\left[\mathbf{r}_t \mid \mathbf{R}_{t-1}^1, \mathbf{U}_0, \mathbf{q}_t\right], \tag{1.5}$$

where $\mathsf{E}[\epsilon_t | \mathbf{R}_{t-1}^1, \mathbf{U}_0, \mathbf{q}_t] = \mathbf{0}$ by construction.

Parameters of interest. These are the targets of the modeling exercise, and are hypothesized – on the basis of prior reasoning, past studies, and institutional knowledge – to be the features of interest. We denote them by $\theta \in \Theta$, and any later reduction choices must be consistent with obtaining θ from the final specification. To the extent that the economic theory supporting the empirical analysis is sufficiently comprehensive, the $\{\lambda_t\}$ in (1.4) should still contain the required information about the agents' decision parameters, so $\theta = \mathbf{h}(\omega_T^1)$. The next stage is to formulate a general model of (1.4) that also retains the necessary information.

1.4.2.2 From LDGP to general unrestricted model

The LDGP in (1.4) can be approximated by a model based on a further series of reductions, which we now discuss. Indeed, (1.4) is often the postulated basis of an empirical analysis, as in a vector autoregression, albeit with many additional assumptions to make the study operational. There are no losses when the LDGP also satisfies these reductions, and if not, evidence of departures can be ascertained from appropriate tests discussed in section 1.4.2.4, so that such reductions are then not undertaken.

Lag truncation. The potentially infinite set of lags in (1.4) can usually be reduced to a small number, so $\mathbf{R}_{t-1}^1 \simeq \mathbf{R}_{t-1}^{t-s} = (\mathbf{r}_{t-s} \ldots \mathbf{r}_{t-1})$, where the maximum lag length becomes s periods, with initial conditions $\mathbf{R}_0^{1-s}$. Long-memory and fractional integration processes are considered in, e.g., Granger and Joyeux (1980), Geweke and Porter-Hudak (1983), Robinson (1995) and Baillie (1996). Letting $\mathsf{f}_{\mathsf{r}_t}(\cdot)$ denote the resulting statistical model of the $\{\mathbf{r}_t\}$, which could coincide with the LDGP when the reduction is without loss, then the mapping is:

$$\prod_{t=1}^{T} \mathsf{D}_{\mathsf{r}_t}\left(\mathbf{r}_t \mid \mathbf{R}_{t-1}^1, \mathbf{U}_0, \mathbf{q}_t, \lambda_t\right) \Rightarrow \prod_{t=1}^{T} \mathsf{f}_{\mathsf{r}_t}\left(\mathbf{r}_t \mid \mathbf{R}_{t-1}^{t-s}, \mathbf{R}_0^{1-s}, \mathbf{q}_t, \psi_t\right). \tag{1.6}$$

The obvious check on the validity of such a reduction is whether longer lags matter; and as before, the key criterion is the impact on $\{\psi_t\}$.

Parameter constancy. The parameters in question are those that characterize the distribution $\mathsf{f}_{\mathsf{r}}(\cdot)$ in (1.6). Then their constancy entails that the $\{\psi_t\}$ depend on a smaller set of parameters that are constant, at least within regimes. Complete constancy requires $\psi_t = \psi_0 \ \forall t$, and while unlikely in economics, is often the assumption made, at least until there is contrary evidence. When there is no loss, $\theta = \mathbf{f}(\psi_0)$, so all parameters of interest can be recovered from the model.

Linearity. The distribution in (1.6) may correspond to the linear Normal when the functional form is chosen appropriately to ensure that a homoskedastic process also results:

$$\mathsf{f}_{\mathsf{r}_t}\left(\mathbf{r}_t \mid \mathbf{R}_{t-1}^{t-s}, \mathbf{R}_0^{1-s}, \mathbf{q}_t, \psi_0\right) \underset{app}{\sim} \mathsf{IN}_k\left[\sum_{i=1}^{s} \Pi_i \mathbf{r}_{t-i} + \Pi_{s+1}\mathbf{q}_t, \Omega\right]. \tag{1.7}$$

The LDGP distribution need not be Normal, but that is partly dependent on the specification of $\mathbf{q}_t$, especially whether breaks in deterministic terms are modeled therein. The constancy of the coefficients of any model also depends on the functional forms chosen for all the data transformations, and an operational GUM presumes that $\{\mathbf{r}_t\}$ has been transformed appropriately, based on theoretical and empirical evidence. Checks for various nonlinear alternatives and homoskedasticity are merited.

1.4.2.3 From the general to the specific

Providing that a viable set of basic parameters is postulated (and below we will allow for the possibility of many shifts), then a variant of (1.7) can act as the GUM for a statistical analysis. When the LDGP is nested in the GUM, so none of the reductions above led to important losses, a well-specified model which embeds the economic theory and can deliver the parameters of interest should result. When the LDGP is not nested in the GUM, so the reductions in the previous sub-section entail losses, it is difficult to establish what properties the final specific model will have, although a well-specified approximation at least will have been found. Because wide-sense non-stationarity of economic variables is such an important problem, and within that class, location shifts are the most pernicious feature, section 1.5 considers the recent approach of impulse saturation (see Hendry, Johansen and Santos, 2008; Johansen and Nielsen, 2008).

Mapping to a non-integrated representation. Many economic variables appear to be integrated of at least first order (denoted I(1)), so there is a mapping $\mathbf{r}_t \rightarrow (\Delta \mathbf{r}_{p,t} : \beta' \mathbf{r}_t) = \mathbf{x}_t$, where there are $n - p$ cointegrating relations and p unit roots, so $\mathbf{x}_t$ is now I(0). Processes that are I(2) can be handled by mapping to second differences as well (see, e.g., Johansen, 1995). This reduction to I(0) transforms ψ_0 to ρ_0 (say)

and leads from (1.6) to:

$$\prod_{t=1}^{T} \mathsf{f}_{\mathbf{x}_t}\left(\mathbf{x}_t \mid \mathbf{X}_{t-1}^{t-s}, \mathbf{X}_0^{1-s}, \mathbf{q}_t, \rho_0\right). \tag{1.8}$$

VARs like (1.7) are often formulated for $\mathbf{r}_t$, rather than $\mathbf{x}_t$, as occurs in the first stage of some cointegration analyses.

Contemporaneous conditioning. Conditioning concerns both contemporaneous variables in models and current-dated instrumental variables (IVs), so let $\mathbf{x}_t' = (\mathbf{y}_t' : \mathbf{z}_t')$, where the former are the k variables to be modeled and the latter $n-k$ are taken as given. Then for $\rho_0 = (\kappa_1 : \kappa_2)$:

$$\begin{aligned}\mathsf{f}_{\mathbf{x}_t}\left(\mathbf{x}_t \mid \mathbf{X}_{t-1}^{t-s}, \mathbf{X}_0^{1-s}, \mathbf{q}_t, \rho_0\right) = \mathsf{f}_{\mathbf{y}_t|\mathbf{z}_t}\left(\mathbf{y}_t \mid \mathbf{z}_t, \mathbf{X}_{t-1}^{t-s}, \mathbf{X}_0^{1-s}, \mathbf{q}_t, \kappa_1\right) \\ \mathsf{f}_{\mathbf{z}_t}\left(\mathbf{z}_t \mid \mathbf{X}_{t-1}^{t-s}, \mathbf{X}_0^{1-s}, \mathbf{q}_t, \kappa_2\right).\end{aligned} \tag{1.9}$$

A viable analysis from the conditional distribution alone in (1.9) requires that $\theta = \mathbf{h}_1(\kappa_1)$; and there will be no loss of information only if (κ_1, κ_2) satisfy a cut so $(\kappa_1, \kappa_2) \in \mathcal{K}_1 \times \mathcal{K}_2$, in which case $\mathbf{z}_t$ is weakly exogenous for θ. When (1.7) holds, both conditional and marginal distributions in (1.9) will be Normal, and the relationships linear. The former leads to VAR-type modeling as noted, whereas the conditional representation in (1.9) underpins more "structural" approaches when the $\mathbf{z}_t$ are instruments: we return to conditioning in section 1.4.5 below.

Simultaneity. Finally, at least for the order of reductions considered here, simultaneity can allow a more parsimonious representation of the conditional distribution by modeling in terms of $\Gamma\mathbf{y}_t$, where Γ is a non-singular matrix that captures the current-dated interdependencies. If $\mathbf{z}_t$ does not enter the conditional distribution, $\Gamma\mathbf{x}_t$ could be modeled directly relative to lagged information (see, e.g., Demiralp and Hoover, 2003).

1.4.2.4 Implications

Five important issues are clarified by these reductions from the DGP down to a specific model of a sub-set of the variables.

Econometric concepts. First, there exists an LDGP as in (1.4) for whatever choices are made of $\mathbf{x}_t$. When all reductions are without loss, the statistical model $\mathsf{f}_{\mathbf{y}_t|\mathbf{z}_t}(\cdot)$ in (1.9) could also be the LDGP. Although most empirical analyses seem to commence by specifying what is included, rather than what is eliminated, almost all the central concepts in econometrics (in italics below) correspond to when reductions (in bold face) can be achieved without loss of relevant information:

- **Aggregation** entails no loss of information on marginalizing with respect to disaggregates when the formulation retains *sufficient statistics* for θ.
- **Data transformations** have no associated reduction, but relate to *parameters of interest*, θ, and hence the need for these to be *invariant and identifiable*.

- **Data partition** determines which variables to include and which to omit in the model *specification*, a decision that is dependent on the purpose of the modeling exercise, but is fundamental to the success of the empirical model.
- **Marginalizing** with respect to $\mathbf{v}_t$ is without loss if $\mathbf{X}_T^1$ is *sufficient* for θ; and marginalizing with respect to $\mathbf{V}_{t-1}^1$ is without loss if it is *Granger non-causal* for $\mathbf{x}_t$ and the conditional-marginal parameters satisfy a *cut*.
- **Sequential factorization** induces no loss as ϵ_t from (1.5) is an *innovation* relative to $\mathbf{R}_{t-1}^1$.
- **Parameter constancy** over time is fundamental to most uses of a model, and *invariance* (constancy across interventions to the marginal process) is essential for policy.
- **Lag truncation** leads to no loss if ϵ_t remains an *innovation* against $\mathbf{X}_{t-1}^1$.
- **Integrated data** can be reduced to I(0) by *cointegration* and *differencing*, sustaining a more *parsimonious* representation, and supporting *conventional inference*.
- **Functional form** specification may or may not entail a reduction, and does not when the two densities are equivalent (e.g., logs of log-normal variables are normal).
- **Conditional factorizations** entail no loss of information when $\mathbf{z}_t$ is *weakly exogenous* for θ, addressed in section 1.4.5.
- **Simultaneity** can allow one to *parsimoniously* capture *joint dependence*.

Testing reductions. Second, reductions are testable against any preceding, less reduced, distributions. Indeed, there is an accompanying taxonomy of evaluation information that seeks to ascertain the statistical significance of the losses imposed by the various reductions. This leads to six major null hypotheses about the final model's specification: homoskedastic innovations $\{\epsilon_t\}$; $\mathbf{z}_t$ weakly exogenous for θ; constant, invariant θ; data-admissible formulations on accurate observations; theory consistent, identifiable structures; encompassing rival models. While this exhausts the nulls to test, there are many alternatives to each. Models which satisfy the first and third are well specified on the available information, and if satisfying the first three are said to be (empirically) congruent. One model (parsimoniously) variance dominates another if it has a smaller unexplained variance (and no more parameters): the notion of one model explaining the results of other models extends variance dominance to account for all other parameters. The principle of encompassing was formalized in Hendry and Richard (1982), and the theory of testing developed by Mizon (1984) and Mizon and Richard (1986) (see Hendry and Richard, 1989, and Hendry, Marcellino, and Mizon, 2008, for surveys). An admissible, theory-consistent, encompassing, congruent model satisfies all six criteria.

Choosing the Haavelmo distribution. Third, knowledge of the LDGP is the "optimum" one can achieve for the given set of variables. Different choices of $\{\mathbf{r}_t\}$, and hence the Haavelmo distribution, will lead to different LDGPs with more or less constancy and congruence with the available evidence. If (1.7) were indeed the LDGP, then model selection could target its variables. The congruence of

an empirical model corresponds to its encompassing the LDGP (so not deviating significantly from it in any of the first five directions) (see Bontemps and Mizon, 2003). Testing the selected model against all extant models of the same variables allows a rigorous evaluation of its "closeness" to the LDGP (see, *inter alia*, White, 1990; Mayo and Spanos, 2006).

Parameter dependence. Fourth, the resulting coefficients in (1.7) or (1.9) remain dependent on the initial DGP parameters. If those DGP parameters change, induced shifts can occur in the parameters of the LDGP. The extent to which these shifts occur, and when they do so, whether they can be anticipated, modeled or even understood, will depend on how usefully the reduced representation captures the structure of the relevant sub-set of the economy under analysis. Here, "structure" denotes invariance under extensions of the information set over (i) time (i.e., constancy), (ii) regimes (i.e., changes to marginal distributions or policy variables) and (iii) variables (so the reductions did not eliminate any important explanatory factors). When the initial economic analysis that led to the specification of $\{\mathbf{x}_t\}$ (i.e., the transformed sub-set of data under analysis) actually captured the main features of the behavior of the agents involved, then ρ_0, or κ_1, should be an invariant that also throws light on the agents' decision parameters underlying φ_T^1 in (1.2). Thus, properly embedded in a general congruent model, the economics should carry through.

Minimizing reductions. Finally, given the inertial dynamics of a high dimensional, interdependent and non-stationary system like an economy, reductions seem likely to be costly in practice and involve real information losses. These will manifest themselves through non-constant models, empirical "puzzles" and poor forecasts, so general systems seem generically preferable. "Errors" on empirical models are created by reductions, so will be highly composite, reflecting many components. It is unclear whether that also favors disaggregation, given problems posed by measurement errors and heterogeneity difficulties as disaggregation increases, or whether a "law of large numbers" may induce substantial offsets (as discussed above).

1.4.2.5 Evaluating the three main approaches

We now consider how the three basic approaches fare against the above analysis. Given their assumptions, each would of course work well; and with sufficiently rigorous testing, the choice of approach becomes a matter of research efficiency (see White, 1990). But efficiency is important, as the assumptions may not adequately characterize reality, and rigorous attempts to reject are not always undertaken.

Imposing economic theory. First, if one simply imposes an *a priori* theory on the data, then the outcome will be excellent when the theory is complete (relative to the issue under analysis) and "correct" (in that all omissions are relatively negligible). Otherwise, it is difficult to ascertain in general how poor the outcome will be (see, e.g., Juselius and Franchi, 2007). If no testing occurs, that strategy is both highly

risky and theory dependent. The risk is that a major discrepancy is not detected, leading to a poor description of the underlying agents' behavior: we addressed the issue of "*ceteris paribus*" in section 1.4.1.1, but if economies are inherently wide-sense non-stationary, then other things will not stay constant. When theories lack precise formulations of lag lengths, functional dependencies, other potential determinants, breaks, and non-economic factors of importance, such difficulties seem all too likely. The problem with theory dependence is that since no economic analysis has yet proved immutable, the empirical results will be discarded when the theory is altered, so there is no progressive knowledge accumulation. This is the real reason that Summers (1991) finds little contribution from empirical econometrics – it was not really allowed to make one, being restricted to providing empirical cloth for a pre-designed framework.

Partial use of economic theory. Second, a partial use of economic theory often leads to pre-specified moment conditions linking variables, $\mathbf{x}_t$, and parameters, φ, usually being zero for the "true" value of the parameter, φ_0, in the form (sometimes without conditioning):

$$\mathsf{E}\left[\mathbf{h}\left(\mathbf{x}_t, \varphi_0 \mid \mathbf{X}_{t-1}^1\right)\right] = \mathbf{0} \; \forall t, \tag{1.10}$$

enabling GMM estimation of φ (see, e.g., Smith, 2007) (also, Smith, 1992, develops non-nested tests applicable after GMM). Equally often, inference has to be based on heteroskedastic and autocorrelation-consistent covariance (HAC) matrices (see White, 1980a; Andrews, 1991), which assume that the residuals reflect precisely those problems in the errors. Unfortunately, residuals can be heteroskedastic and autocorrelated for many other reasons, including unmodeled breaks, measurement errors, incorrect dynamics, omitted variables, or an inappropriate functional form *inter alia*, most of which would invalidate the estimates derived from (1.10), and possibly refute the underlying theory. Thus, rigorous testing against that range of hypotheses would seem necessary, leading to three important difficulties. First, unless a joint test is used, non-rejection of each may occur when there are several failures. Second, if any test rejects at the chosen significance level (controlling for the number of tests undertaken), the validity of all the other tests is cast into doubt. Third, if rejection does occur, it remains a *non sequitur* to assume that the hypothesis which was rejected was the source of the failure, so model revision may require a theory revamp. Again, there seem to be distinct advantages to beginning with general formulations that can be simplified when evidence permits, subject to maintaining identifiability – which can also be a problem with GMM (section 1.4.7 discusses identification).

Economic theory guidelines. Finally, seeking a congruent model of the LDGP based on economic theory guidelines by embedding the theory-based model in a more general GUM for the set of candidate variables, with a range of possible specifications of lags, functional forms, breaks, etc., offers many advantages, not least avoiding restrictive assumptions dependent on hope rather than evidence. Such a general-to-specific (Gets) approach can be demanding, and while it can

help mitigate problems of under-specification, it is no free lunch, as it leads to a different set of possible problems relating to data-based model selection, discussed in section 1.5. However, the criticism that the LDGP is too complicated for Gets to work well must also apply to all other approaches, as they will not fare any better in such a state of nature unless some remarkable requirements chance to hold (e.g., the complexity of the LDGP happens to lie in directions completely unrelated to the aspects under study). In general, even if one simply wants to test an economic hypothesis as to whether some effect is present, partial inference cannot be conducted alone, unless one is sure about the complete absence of all contaminating influences.

1.4.3 Data exactitude

> "She can't do Addition," the Red Queen interrupted. "Can you do Subtraction? Take nine from eight." "Nine from eight I can't, you know," Alice replied very readily. (Lewis Carroll, 1899)

No agency produces perfect data measures on every variable, and although some observations may be both accurate and precise (e.g., specific stock market, or foreign exchange, transactions), most are subject to measurement errors. These can be difficult to handle, especially when there are both revisions and changes in exactitude over time, which thereby introduce an additional source of non-stationarity. Moreover, in any given sample of time series, more recent data will be subject to potentially larger later revisions: section 1.7.1 considers the impact of one example of considerable data revisions.

Mapping theoretical constructs to data counterparts and measuring (or modeling) latent variables both raise further issues. Many commonly used macro variables do not have established measurements, e.g., output gaps, business cycles, capacity utilization, trade union power, etc. Even those that do, such as constructs for consumption, user costs, etc., are open to doubt. These types of measurement errors are not directly caused by inaccurate data collection, but both impinge on empirical studies, and can change over time.

Incentives to improve data quality, coverage and accuracy were noted in section 1.3.4 (see Boumans, 2007, for recent discussions of various measurement issues). In the absence of exact data, there must remain trade-offs between using theory to impose restrictions on badly-measured data, using such data to reject theory specifications, or building data-based models. Again, a balance utilizing both theory and evidence in a progressive process seems advisable.

1.4.4 Hidden dependencies

> "Why, it's a Looking-glass book of course! And if I hold it up to a glass, the words will all go the right way again." (Quote from Alice in Lewis Carroll, 1899)

Hidden dependencies abound in all data forms, including cross-sections, time series and panels. An important aspect of sequential conditioning in time series

is to explicitly remove temporal dependence, as (1.4) showed, where a martingale difference process is created by the sequential conditioning. In principle, the same concepts apply to cross sections. It must be stressed that "random sampling" by itself does not justify factorizing a joint density or likelihood function. As an extreme form of cross-section dependence, put 1,000 copies of the number "1" in a hat, then draw a random sample of 100 therefrom: one learns nothing after the first draw, although all are "randomly drawn." Sequential factorization correctly reveals that difficulty. Denote the randomly-drawn data sample by $(r_1 \dots r_N)$; then for any ordering when τ is the mean value of all the numbers in the hat:

$$\mathsf{D}_{\mathsf{r}}\left(r_1 \dots r_N \mid \tau\right) = \prod_{i=1}^{N} \mathsf{D}_{\mathsf{r}_i}\left(r_i \mid r_{i-1} \dots r_1; \tau\right) = \mathsf{D}_{\mathsf{r}_1}\left(r_1; \tau\right), \tag{1.11}$$

since all the other probabilities are precisely unity. As $r_1 = 1$, we correctly deduce $\tau = 1$. Certainly, the other $N - 1$ draws add the information that all the numbers are unity, but would do so even if not randomly drawn.

More generally, the order of an independent sample does not matter, so unlike (1.11), for any ordering the joint density should factorize as:

$$\mathsf{D}_{\mathsf{r}}\left(r_1 \dots r_N \mid \tau\right) = \prod_{i=1}^{N} \mathsf{D}_{\mathsf{r}_i}\left(r_i \mid r_{i-1} \dots r_1; \tau\right) = \prod_{i=1}^{N} \mathsf{D}_{\mathsf{r}_i}\left(r_i \mid \tau\right). \tag{1.12}$$

Consequently, potential dependence is testable by conditioning on s "neighbors" after a suitable exogenous ordering to check if their influence is non-zero; i.e., to see whether:

$$\prod_{i=1}^{N} \mathsf{D}_{\mathsf{r}_i}\left(r_i \mid r_{i-1} \dots r_{i-s}; \tau\right) \neq \prod_{i=1}^{N} \mathsf{D}_{\mathsf{r}_i}\left(r_i \mid \tau\right). \tag{1.13}$$

Suitable tests for the absence of dependence would seem essential before too great a weight is placed on results that base (1.12) on the claim of random sampling, especially when the units are large entities like countries. More generally, when all units are affected in part by macro-forces and their attendant non-stationarities, dependence like (1.13) is likely. If an ordering based on an outside variable is available, then models of $\mathsf{D}_{\mathsf{r}_i}\left(r_i \mid r_{i-1} \dots r_{i-s}; \tau\right)$ could be investigated directly, similar to some cases of spatial dependence (see Anselin, 2006).

There is a large literature on panel data analysis recently discussed in Choi (2006) and Baltagi (2006).

1.4.5 Conditioning variables

> "I'm afraid he'll catch cold with lying on the damp grass," said Alice, who was a very thoughtful little girl. (Lewis Carroll, 1899)

Instrumental variables are a key part of any conditioning set, so require weak exogeneity as well as correlation with the relevant endogenous variables (or the auxiliary assumptions of orthogonality to any unknown vector of excluded influences and independence from the "true" model's errors).

1.4.5.1 Weak exogeneity

The notion of exogeneity, or synonyms thereof, in relation to econometric modeling dates back to the origins of the discipline (see, e.g., Morgan, 1990; Hendry and Morgan, 1995), with key contributions by Koopmans (1950) and Phillips (1957). Weak exogeneity was formalized by Engle, Hendry and Richard (1983), building on Richard (1980) (see Ericsson, 1992, for an exposition), and is a fundamental requirement for efficient conditional inference, which transpires to be at least as important in integrated systems as in stationary processes (see Phillips and Loretan, 1991). Weak exogeneity is equally relevant to instrumental variables estimation, since the marginal density of $\mathbf{z}_t$ then relates to the distribution of the claimed instruments: asserting orthogonality to the error term is often inadequate, as shown by the counter-examples in Hendry (1995a).

Further, $\mathbf{z}_t$ is strongly exogenous for θ if $\mathbf{z}_t$ is weakly exogenous for θ, and:

$$\mathsf{D}_{z_t}\left(\mathbf{z}_t \mid \mathbf{X}_{t-1}^{t-s}, \mathbf{X}_0^{1-s}, \mathbf{q}_t, \kappa_2\right) = \mathsf{D}_{z_t}\left(\mathbf{z}_t \mid \mathbf{Z}_{t-1}^{t-s}, \mathbf{X}_0^{1-s}, \mathbf{q}_t, \kappa_2\right). \tag{1.14}$$

When (1.14) is satisfied, $\mathbf{z}_t$ does not depend upon $\mathbf{Y}_{t-1}$ so $\mathbf{y}$ does not Granger-cause $\mathbf{z}$, following Granger (1969). This requirement sustains marginalizing $\mathsf{D}_{z_t}(\mathbf{z}_t|\mathbf{X}_{t-1}^{t-s}, \mathbf{X}_0^{1-s}, \mathbf{q}_t, \kappa_2)$ with respect to $\mathbf{Y}_{t-1}^1$, but does not concern conditioning. Consequently, Granger causality alone is neither necessary nor sufficient for weak exogeneity, and cannot validate inference procedures (see Hendry and Mizon, 1999).

The consequences of failures of weak exogeneity can vary from just a loss of estimation efficiency through to a loss of parameter constancy, depending on the source of the problem (see Hendry, 1995a, Ch. 5). We now illustrate both extreme cases and one intermediate example.

Outperforming Gauss–Markov. First, consider a standard regression setting where Gauss–Markov conditions seem satisfied:

$$\mathbf{y} = \mathbf{Z}\beta + \epsilon \;\text{ with }\; \epsilon \sim \mathsf{N}_T\left[\mathbf{0}, \sigma_\epsilon^2 \mathbf{I}\right], \tag{1.15}$$

when $\mathbf{Z} = (\mathbf{z}_1 \dots \mathbf{z}_T)'$ is a $T \times k$ matrix, $\text{rank}(\mathbf{Z}) = k$, and $\epsilon' = (\epsilon_1 \dots \epsilon_T)$, with:

$$\mathsf{E}[\mathbf{y} \mid \mathbf{Z}] = \mathbf{Z}\beta,$$

and hence $\mathsf{E}[\mathbf{Z}'\epsilon] = \mathbf{0}$. OLS estimates of β, the parameter of interest here, are:

$$\widehat{\beta} = \beta + \left(\mathbf{Z}'\mathbf{Z}\right)^{-1}\mathbf{Z}'\epsilon \sim \mathsf{N}_k\left[\beta, \sigma_\epsilon^2\left(\mathbf{Z}'\mathbf{Z}\right)^{-1}\right].$$

However, ordinary least squares (OLS) need not be the most efficient unbiased estimator of β, and an explicit weak exogeneity condition is required to preclude that possibility when $\mathbf{Z}$ is stochastic. For example, let:

$$\mathbf{z}_t = \beta + \nu_t \;\text{ where }\; \nu_t \sim \mathsf{IN}_k\left[\mathbf{0}, \Sigma\right],$$

estimated by the mean vector:

$$\overline{\beta} = \beta + \overline{\nu} \sim \mathsf{N}_k\left[\beta, T^{-1}\Sigma\right],$$

then it is easy to construct scenarios where $\overline{\beta}$ is much more efficient than $\widehat{\beta}$. Consequently, even in simple regression, for the Gauss–Markov theorem to be of operational use one needs the condition that β cannot be learned from the marginal distribution.

Weak exogeneity in cointegrated systems. Second, cointegrated systems provide a major forum for testing one aspect of exogeneity. Formulations of weak exogeneity conditions and tests for various parameters of interest in cointegrated systems are discussed in, *inter alia*, Johansen and Juselius (1990), Phillips and Loretan (1991), Hunter (1992), Urbain (1992), Johansen (1992), Dolado (1992), Boswijk (1992) and Paruolo and Rahbek (1999). Equilibrium-correction mechanisms which cross-link equations violate long-run weak exogeneity, confirming that weak exogeneity cannot necessarily be obtained merely by choosing the "parameters of interest." Conversely, the presence of a given disequilibrium term in more than one equation is testable. Consider an apparently well-defined setting with the following bivariate DGP for the I(1) vector $\mathbf{x}_t = (y_t : z_t)'$ from Hendry (1995c):

$$y_t = \beta z_t + u_{1,t} \tag{1.16}$$

$$z_t = \lambda y_{t-1} + u_{2,t}, \tag{1.17}$$

where:

$$\begin{pmatrix} u_{1,t} \\ u_{2,t} \end{pmatrix} = \begin{pmatrix} 0 & 0 \\ \rho & 1 \end{pmatrix} \begin{pmatrix} u_{1,t-1} \\ u_{2,t-1} \end{pmatrix} + \begin{pmatrix} \epsilon_{1,t} \\ \epsilon_{2,t} \end{pmatrix}, \tag{1.18}$$

and:

$$\begin{pmatrix} \epsilon_{1,t} \\ \epsilon_{2,t} \end{pmatrix} \sim \mathsf{IN}_2 \left[\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma_1^2 & \gamma\sigma_1\sigma_2 \\ \gamma\sigma_1\sigma_2 & \sigma_2^2 \end{pmatrix} \right] = \mathsf{IN}_2 \left[\mathbf{0}, \Sigma \right]. \tag{1.19}$$

The DGP in (1.16)–(1.19) defines a cointegrated vector process in triangular form (see Phillips and Loretan, 1991) which can be written in many ways, of which the following equilibrium-correction form is perhaps the most useful:

$$\begin{aligned} y_t &= \beta z_t + \epsilon_{1,t} \\ \Delta z_t &= \lambda \Delta y_{t-1} + \rho \left(y_{t-1} - \beta z_{t-1} \right) + \epsilon_{2,t}, \end{aligned} \tag{1.20}$$

where $\epsilon_t = \left(\epsilon_{1,t} : \epsilon_{2,t} \right)'$ is distributed as in (1.19).

The parameters of the DGP are $(\beta, \lambda, \rho, \gamma, \sigma_1, \sigma_2)$. When cointegration holds, β and σ_1 can be normalized at unity without loss of generality, and we also set $\sigma_2 = 1$. The parameter of interest is β, which characterizes the long-run relationship between y_t and z_t. Let $\mathcal{I}_{t-1}$ denote available lagged information (the σ-field generated by $\mathbf{X}_{t-1}$). Then, from (1.19) and (1.20), the conditional expectation of y_t given $(z_t, \mathcal{I}_{t-1})$ is:

$$\mathsf{E}\left[y_t \mid z_t, \mathcal{I}_{t-1} \right] = \beta z_t + \gamma \Delta z_t - \gamma\rho \left(y_{t-1} - \beta z_{t-1} \right) - \gamma\lambda \Delta y_{t-1}. \tag{1.21}$$

For some parameter values in the DGP, the conditional expectation will coincide with (1.16), whereas for other parameter configurations, (1.16) and (1.21) will differ, in which case it is unsurprising that (1.16) is not fully informative. However, an exact match between the equation to be estimated and the conditional expectation of the dependent variable given $\mathcal{I}_{t-1}$ is not sufficient to justify least squares estimation, even when the error is an innovation against $\mathcal{I}_{t-1}$. Indeed, when $\lambda = \gamma = 0$, but $\rho \neq 0$, there is a failure of weak exogeneity of z_t for β, even though the conditional expectation is:

$$\mathsf{E}\left[y_t \mid z_t, \mathcal{I}_{t-1}\right] = \beta z_t. \tag{1.22}$$

Nevertheless, z_t is not weakly exogenous for β when $\rho \neq 0$ since:

$$\Delta z_t = \rho \left(y_{t-1} - \beta z_{t-1}\right) + \epsilon_{2t}, \tag{1.23}$$

so a more efficient analysis is feasible by jointly estimating (1.16) (or (1.22)) and (1.23). Here the model coincides with both the conditional expectation and the DGP equation, but as shown in Phillips and Loretan (1991) and Hendry (1995c), the violation of weak exogeneity can lead to important distortions to inference when estimating the parameters of (1.16), highlighting the important role of weak exogeneity in conditional inference.

1.4.5.2 Super exogeneity and structural breaks

Next, processes subject to structural breaks sustain tests for super exogeneity and the Lucas (1976) critique (following Frisch, 1938): (see, e.g., Hendry, 1988; Fischer, 1989; Favero and Hendry, 1992; Engle and Hendry, 1993; Hendry and Santos, (2009). Formally, super exogeneity augments weak exogeneity with the requirement that the parameters of the marginal process can change (usually over some set) without altering the parameters of the conditional. Reconsider (1.9), written with potentially non-constant parameters as:

$$\begin{aligned}\mathsf{D}_{\mathbf{x}_t}\left(\mathbf{x}_t \mid \mathbf{X}_{t-1}^{t-s}; \mathbf{X}_0^{1-s}, \mathbf{q}_t, \rho_t\right) = \mathsf{D}_{\mathbf{y}_t|\mathbf{z}_t}\left(\mathbf{y}_t \mid \mathbf{z}_t, \mathbf{X}_{t-1}^{t-s}, \mathbf{X}_0^{1-s}, \mathbf{q}_t, \kappa_{1,t}\right) \\ \mathsf{D}_{\mathbf{z}_t}\left(\mathbf{z}_t \mid \mathbf{X}_{t-1}^{t-s}; \mathbf{X}_0^{1-s}, \mathbf{q}_t, \kappa_{2,t}\right).\end{aligned} \tag{1.24}$$

When θ enters both $\kappa_{1,t}$ and $\kappa_{2,t}$ in (1.24), inference can again be distorted if weak exogeneity is falsely asserted. When conditional models are constant despite data moments changing considerably, there is *prima facie* evidence of super exogeneity for that model's parameters; whereas, if the model as formulated does not have constant parameters, resolving that failure ought to take precedence over issues of exogeneity. However, while super exogeneity tests are powerful in detecting location shifts, changes to "reaction parameters" of mean-zero stochastic variables are difficult to detect (see, e.g., Hendry, 2000b). Hendry and Santos (2009) propose a test for super exogeneity based on impulse saturation (see Hendry, Johansen and Santos, 2008) to automatically select breaks in the marginal processes, then test their relevance in the conditional. When none of the breaks enters the conditional model, that provides evidence in favor of $\mathbf{z}_t$ causing y_t, since the same response

occurs to changes across different "regimes" (see, e.g., Heckman, 2000; Hendry, 2004; and the references therein).

1.4.5.3 Weak exogeneity and economic theory

Much economic theory concerns relationships between means such as:

$$\mu_y = \beta' \mu_z. \tag{1.25}$$

A famous example is the permanent income hypothesis (PIH), where μ_y is permanent consumption and μ_z is permanent income, so the income elasticity of consumption is unity $\forall \beta$. Most demand and supply functions relate to expected plans of agents; expectations and Euler equation models involve conditional first moments, as do GMM approaches; policy relates planned instruments to expected targets, etc. Since constructs like μ_y and μ_z are inherently unobservable, additional assumptions are needed to complete the model. For example, Friedman (1957) uses:

$$y_t = \mu_y + \epsilon_{y,t} \text{ and } z_t = \mu_z + \epsilon_{z,t} \text{ where } \mathsf{E}\left[\epsilon_{y,t}\epsilon_{z,t}\right] = 0, \tag{1.26}$$

which precludes weak exogeneity of z_t for β given the dependence between the means in (1.25). Allowing μ_y to also depend on second moments would not alter the thrust of the following analysis.

Econometrics, however, depends on second moments of observables. Consider the regression:

$$y_t = \gamma' \mathbf{z}_t + v_t \text{ where } v_t \sim \mathsf{IN}\left[0, \sigma_v^2\right]. \tag{1.27}$$

For $\mathbf{z}_t \sim \mathsf{IN}_n\left[\mu_z, \Sigma_{zz}\right]$ with $\mathsf{E}\left[\mathbf{z}_t v_t\right] = \mathbf{0}\ \forall t$:

$$\mathsf{E}\left[y_t \mid \mathbf{z}_t\right] = \gamma' \mathbf{z}_t, \tag{1.28}$$

then, for $\mathbf{y}' = (y_1 \dots y_T)$ and $\mathbf{Z}' = (\mathbf{z}_1 \dots \mathbf{z}_T)$:

$$\widehat{\gamma} = \left(\mathbf{Z}'\mathbf{Z}\right)^{-1} \mathbf{Z}'\mathbf{y}, \tag{1.29}$$

so that second moments are used to estimate γ. Here, (1.27) entails $\mathsf{E}[y_t] = \gamma' \mathsf{E}[\mathbf{z}_t]$, and from (1.28):

$$\mathsf{E}\left[\mathbf{z}_t y_t\right] = \mathsf{E}\left[\mathbf{z}_t \mathbf{z}_t'\right] \gamma \text{ or } \sigma_{yz} = \Sigma_{zz}\gamma, \tag{1.30}$$

both of which involve γ. Thus, there seems to be no difference between how means and variances are related, which is why second moments can be used to infer about links between first moments. However, when any relation like (1.25) holds, then σ_{yz} and Σ_{zz} in (1.30) must be connected by β, not γ, if valid inferences are to result about the parameters of interest β. Weak exogeneity is needed, either directly in (1.27), or indirectly for "instrumental variables." This is more easily seen from the joint distribution:

$$\begin{pmatrix} y_t \\ \mathbf{z}_t \end{pmatrix} \sim \mathsf{IN}_{n+1}\left[\begin{pmatrix} \mu_y \\ \mu_z \end{pmatrix}, \begin{pmatrix} \sigma_{yy} & \sigma_{yz}' \\ \sigma_{zy} & \Sigma_{zz} \end{pmatrix}\right], \tag{1.31}$$

so given (1.25):

$$\mathsf{E}\left[y_t \mid \mathbf{z}_t\right] = \mu_y - \gamma' \mu_z + \gamma' \mathbf{z}_t = (\beta - \gamma)' \mu_z + \gamma' \mathbf{z}_t, \tag{1.32}$$

which coincides with (1.28) only if $\gamma = \beta$, so means and variances are then related by identical parameters.

Note from (1.31):

$$\mathbf{z}_t = \mu_z + \mathbf{u}_t, \tag{1.33}$$

so impulse responses cannot be identified uniquely as originating from perturbing $\mathbf{u}_t$ or μ_z. But from (1.32), the response of y_t to these perturbations in (1.33) will differ unless $\gamma = \beta$, so weak exogeneity is essential for unique impulse responses, which cannot be based on an arbitrary choice of Cholesky decompositions (only one variant could coincide with valid conditioning).

1.4.6 Functional form

> Alice began to remember that she was a Pawn, and that it would soon be time to move. (Lewis Carroll, 1899)

In practice, one cannot expect every functional form specification to coincide with that which generated the data, however well-based its logic or theory credentials. There are theories of what various linear and other approximations deliver (see, e.g., White, 1980b, 2008), but such approximations cannot ensure non-systematic residuals. Automatic model selection has been extensively applied to select functional forms from quite large classes using data evidence (see, *inter alia*, Perez-Amaral, Gallo and White, 2003, 2005; Castle, 2005; Castle and Hendry, 2005, and section 1.5). In low-dimensional models, semiparametric and nonparametric methods are often used to avoid specifying the functional form, but can be susceptible to unmodeled outliers and breaks.

1.4.7 Identification

> . . . watching one of them that was bustling about among the flowers, poking its proboscis into them, "just as if it was a regular bee," thought Alice. However, this was anything but a regular bee: in fact, it was an elephant. (Lewis Carroll, 1899)

Identification has three attributes of uniqueness, interpretation, and correspondence to reality (see, e.g., Hendry, 1995a), which we discuss in turn. Since unidentified parameters entail a non-unique model specification – so what is estimated need not match the parameters of the generating process – identification is a fundamental attribute of a parametric specification.

First, a general understanding of identification as uniqueness has been developed (see, e.g., Fisher, 1966; Rothenberg, 1971; Sargan, 1983: Hsiao, 1983, provides an overview), building on the rank and order conditions so well known to be necessary

and sufficient in simultaneous systems when the restrictions are given by subject-matter theory: we could call this a technical issue. Cowles Commission researchers showed that the "reduced form" (or statistical system) was always identified in their formulation, and that all just-identified models were isomorphic to that statistical system, hence tests of overidentified "structural forms" could be derived by comparing their two likelihoods. Their analysis, therefore, entailed that the "structural form" is actually a *reduction* of the statistical system, so logically can be obtained from it without any prior knowledge of the relevant restrictions. Thus, when a model is identified relative to an identified system, the identification restrictions in question do not have to be known *a priori*, but can be found by a suitable algorithm (see, e.g., Hendry and Krolzig, 2005) – indeed, several overidentified, but distinct, representations can coexist (see, e.g., Hendry, Lu and Mizon, 2008). Such a conclusion is predicated on the statistical system itself being identified, which requires sufficient explanatory variables – the vexed topic of "exogeneity" discussed in section 1.4.5 above. Moreover, for an overidentification test to be valid, the statistical system must be well specified, so needs to be modeled and evaluated first (see, e.g., Spanos, 1990), after which it can be reduced to a "structural form." Nevertheless, that prior identification restrictions must be known in advance remains the dominant belief, which if true, would preclude empirical modeling not preceded by a rigorous theory derivation that entailed sufficient restrictions.

Second, interpretation is a regular seminar question along the lines: "How do you know you have identified the demand curve" (as opposed to some other entity)? This is essentially an economic theory issue, and only substantive theory can resolve such a debate. It is separate from uniqueness: a regression of price on quantity is always unique, but hardly qualifies as a demand curve just because the regression coefficient is negative.

Third, even if both uniqueness and interpretation are confirmed, the result still need not correspond to reality, which is an empirical issue (and related to the usage of the word "identification" in, say, Box and Jenkins', 1976, analysis, as well as the quote above). An estimated equation may be unique and interpretable but not the relevant relation. Thus, all aspects of model building are involved in establishing satisfactory identification.

Recently, problems of weak instruments, and the resulting issue of identification, have become salient (see, among others, Staiger and Stock, 1997; Stock and Wright, 2000; Stock, Wright and Yogo, 2002; Kleibergen, 2002; Mavroeidis, 2004).

1.4.8 Parameter constancy

> "Yes, all his horses and all his men," Humpty Dumpty went on. "They'd pick me up again in a minute, they would!" (Lewis Carroll, 1899)

Parameters are the entities which must be constant if the specified model is to be a useful characterization of reality. However, that does not preclude the coefficients in any model formulation from changing, as in "random coefficients" models or "structural time series" (see, e.g., Hildreth and Houck, 1968; Harvey,

1993). The main problem for economic forecasting using econometric models is that coefficients of deterministic terms do not seem to stay constant, but suffer location shifts, which in turn induce forecast failure (see, e.g., Clements and Hendry, 2005, 2006). While changes in zero-mean variables seem less damaging to forecasts (see, e.g., Hendry and Doornik, 1997), such breaks nevertheless remain pernicious for policy analyses.

1.4.9 "Independent" homoskedastic errors

> "Contrariwise," continued Tweedledee, "if it was so, it might be; and if it were so, it would be: but as it isn't, it ain't. That's logic." (Lewis Carroll, 1899)

Joint densities can always be factorized into sequential forms, as with martingale difference sequences. Moreover, equations can often be standardized to be homoskedastic by dividing by contemporaneous error variances (when these exist), so this category may be one of the least stringent requirements.

1.4.10 Expectations formation

> "What sort of things do you remember best?" Alice ventured to ask. "Oh, things that happened the week after next" the Queen replied in a careless tone. (Lewis Carroll, 1899)

Surprisingly little is known about how economic agents actually form their expectations for variables relevant to their decisions. Almost no accurate expectations data exist outside financial market traders, so resort is usually needed to proxies for the unobserved expectations, or to untested assumptions, such as "rational" expectations (RE), namely the correct conditional expectation $\mathsf{E}[\cdot]$ of the variable in question (y_{t+1}) given the available information ($\mathcal{I}_t$). There is a large gap between economic theory models of expectations – which often postulate that agents hold RE – and the realities of economic forecasting, where forecast failure is not a rare occurrence. The "rational" expectation is often written as (see Muth, 1961):

$$y^{re}_{t+1} = \mathsf{E}\left[y_{t+1} \mid \mathcal{I}_t\right], \tag{1.34}$$

which implicitly assumes free information and free computing power as available information is vast. The usual argument, perhaps loosely worded to avoid contradictions, is that otherwise there would be arbitrage opportunities, or agents would suffer unnecessary losses. But expectations are instrumental to agents' decisions, and the accuracy thereof is not an end in itself, so agents should just equate the marginal benefits of improved forecast accuracy against the extra costs of achieving that, leading to "economically rational expectations" (ERE) (see Aghion *et al.*, (2002)). "Model consistent expectations" instead impose the expectations formation process as the solved estimated model specification, so – unless the model is perfect – suffer the additional drawback of imposing invalid restrictions.

While ERE may be more realistic than RE, it still assumes knowledge of the form of dependence of y_{t+1} on the information used: as expressed in $\mathsf{E}\left[y_{t+1}|\mathcal{I}_t\right]$ in (1.34),

that assumption corresponds to agents knowing precisely what the conditioning operator is. In a stationary world, one could imagine learning mechanisms that eventually led to its discovery (see, e.g., Evans and Honkapohja, 2001). However, in a wide-sense non-stationary environment, an explicit statement of the form of (1.34) is:

$$y^{re}_{t+1} = \mathsf{E}_{t+1}\left[y_{t+1} \mid \mathcal{I}_t\right] = \int y_{t+1} f_{t+1}\left(y_{t+1} \mid \mathcal{I}_t\right) \mathrm{d}y_{t+1}. \tag{1.35}$$

Thus, when $f_t(\cdot) \neq f_{t+1}(\cdot)$, agents need to *know the future* conditional density function $f_{t+1}(y_{t+1}|\mathcal{I}_t)$, given present information, to obtain the appropriate conditioning relation, since only then will y^{re}_{t+1} be an unbiased predictor of y_{t+1}. That $f_t(\cdot) \neq f_{t+1}(\cdot)$ is precisely why forecasting is so prone to problems. Unfortunately, knowing $f_{t+1}(\cdot)$ virtually requires agents to have crystal balls that genuinely "see into the future." When distributions are changing over time, agents can at best form "sensible expectations," y^{se}_{t+1}, based on forecasting $f_{t+1}(\cdot)$ by $\widehat{f}_{t+1}(\cdot)$ from some rule, such that:

$$y^{se}_{t+1} = \int y_{t+1} \widehat{f}_{t+1}\left(y_{t+1} \mid \mathcal{I}_t\right) \mathrm{d}y_{t+1}. \tag{1.36}$$

There are no guaranteed good rules for estimating $f_{t+1}(y_{t+1}|\mathcal{I}_t)$ when $\{y_t\}$ is wide-sense non-stationary. In particular, when the conditional moments of $f_{t+1}(y_{t+1}|\mathcal{I}_t)$ are changing in unanticipated ways, setting $\widehat{f}_{t+1}(\cdot) = f_t(\cdot)$ could be a poor choice, yet that underlies most of the formal derivations of RE, which rarely distinguish between $f_t(\cdot)$ and $f_{t+1}(\cdot)$. Outside a stationary environment, agents cannot solve (1.34), or often even (1.35). The drawbacks of (1.34) and (1.35), and the relative success of robust forecasting rules (see, e.g., Clements and Hendry, 1999; Hendry, 2006), suggest agents should use them, an example of imperfect-knowledge expectations (IKE) (see Aghion *et al.*, 2002; Frydman and Goldberg, 2007). IKE acknowledges that agents cannot know how $\mathcal{I}_t$ enters $f_t(\cdot)$ when processes are evolving in a non-stationary manner, let alone $f_{t+1}(\cdot)$, which still lies in the future. Collecting systematic evidence on agents' expectations to replace the unobservables by estimates, rather than postulates, deserves greater investment (see, e.g., Nerlove, 1983).

Finally, take expectations conditional on the available information set $\mathcal{I}_{t-1}$ in a regression model with valid weak exogeneity:

$$y_t = \beta' \mathbf{z}_t + \epsilon_t, \tag{1.37}$$

so that:

$$\mathsf{E}\left[y_t \mid \mathcal{I}_{t-1}\right] = \beta' \mathsf{E}\left[\mathbf{z}_t \mid \mathcal{I}_{t-1}\right], \tag{1.38}$$

as $\mathsf{E}\left[\epsilon_t|\mathcal{I}_{t-1}\right] = 0$. Writing (1.38) as $y^e_t = \beta' \mathbf{z}^e_t$, the conditional model (1.37) always has an expectations representation, although the converse is false. Importantly, therefore, contemporaneous conditioning variables can also be expectations variables, and some robust forecasting rules like $\Delta\widehat{p}_{t+1} = \Delta p_t$ have that property.

The New Keynesian Phillips curve is perhaps the best-known model which includes expected inflation to explain current inflation. Models of this type are usually estimated by replacing the expected value by the actual future outcome, then using IV or GMM to estimate the resulting parameters, as in, say, Galí, Gertler and Lopez-Salido (2001). As shown in Castle *et al.* (2008), since breaks and regime shifts are relatively common, full-sample estimates of equations with future values can deliver spuriously significant outcomes when breaks are not modeled, a situation detectable by impulse saturation (see section 1.5).

1.4.11 Estimation

> "I was wondering what the mouse-trap was for," said Alice. "It isn't very likely there would be any mice on the horse's back."
>
> "Not very likely, perhaps," said the Knight; "but if they do come, I don't choose to have them running all about." (Lewis Carroll, 1899)

Developing appropriate estimators comprises a major component of extant econometric theory, and given any model specification, may seem an uncontentious task. However, only in recent decades has it been clear how to avoid (say) nonsense correlations in non-stationarity data, or tackle panel dependencies, so unknown pitfalls may still lurk.

1.5 Model selection

> In another moment Alice was through the glass, and had jumped lightly down into the Looking-glass room. (Lewis Carroll, 1899)

Model selection is the empirical route whereby many of the simplifications in sections 1.4.2.2 and 1.4.2.3 are implemented in practice. In that sense, it is not a distinct step *per se*, but a way of carrying out some of the earlier steps, hence our treating the topic in a separate section.

Selection remains a highly controversial topic. It must be granted that the best approaches cannot be expected to select the LDGP on every occasion, even when the GUM nests the LDGP, and clearly cannot do so ever when the LDGP is not a nested special case. However, that statement remains true when the GUM is exactly the LDGP, but conventional inference is nevertheless undertaken to check that claim. If the LDGP were known at the outset of a study, apart from the unknown values of its parameters, then if any specification or misspecification testing was undertaken, one could only end by doubting the claim that the initial formulation was indeed the LDGP. The least worst outcome would be weak confirmation of the prior specification, and otherwise either some included variables will be found insignificant, or some assumptions will get rejected, casting doubt on the claim. That is the risk of undertaking statistical inference. The alternative of not testing claimed models is even less appealing, namely never learning which ones are useless. To quote Sir Francis Bacon: "If a man will begin with certainties, he

shall end in doubts; but if he will be content to begin with doubts he shall end in certainties."

Conversely, the list at the beginning of section 1.4 makes it clear that "model uncertainty" comprises much more than whether one selected the "correct model" from some set of candidate variables that nested the LDGP. If, say, 1,000 possibly lagged, nonlinear functions of a set of candidate exogenous variables in a model with many breaks are checked for relevance at a significance level of 0.1%, and all are indeed irrelevant, then on average *one* will be retained adventitiously, so uncertainty is greatly reduced by eliminating about 999 potential influences. The entire point of model selection is to reduce some of the uncertainties about the many aspects involved in model specification, and the cost for doing so is a "local increase" in uncertainty as to precisely which influences should be included and which excluded around the margin of significance. Thus, embedding the claimed theory in a more general specification that is congruent with all the available evidence offers a chance to both utilize the best available theory insights and learn from the empirical evidence. Since such embedding can increase the initial model size to a scale where a human has intellectual difficulty handling the required reductions, we next consider computerized, or automatic, methods for model selection.

1.5.1 Automatic model selection

> "Does – the one – that wins – get the crown?" she asked, as well as she could, for the long run was putting her quite out of breath.
>
> "Dear me, no!" said the King. "What an idea!" (Alice to the White King in Lewis Carroll, 1899)

The many alternatives now available include, but are not restricted to, Phillips (1994, 1995, 1996), Tibshirani (1996), Hoover and Perez (1999, 2004), Hendry and Krolzig (1999, 2001), White (2000), Krolzig (2003), Kurcewicz and Mycielski (2003), Demiralp and Hoover (2003), and Perez-Amaral *et al*. (2003); also see the special issue on model selection edited by Haldrup, van Dijk and Hendry (2003) (the references cited therein provide bibliographic perspective on this huge literature). Complaints about model selection have a long pedigree, from Keynes (1939) about "data-based modeling" and Koopmans (1947) on "measurement without theory," through "pre-test biases" from test-based selection in Judge and Bock (1978); "repeated testing" inducing adventitious significance in Leamer (1978, 1983) and Lovell (1983) criticizing selection rules seeking "significance," to Pagan (1987) on the potential "path dependence of any selection"; Hendry, Leamer and Poirier (1990) debating "arbitrary significance levels"; Chatfield (1995) criticizing "ignoring selection effects" as misrepresenting uncertainty, and Faust and Whiteman (1997) on "lack of identification," but most have now been rebutted (see, e.g., Hendry, 2000a). Concerning Keynes' comment quoted above, not only should everyone get the same answer from an automatic algorithm applied to the same GUM using the same selection criteria, investigators with different GUMs, which differed only by irrelevant variables, could also end with the same model.

Here we consider Autometrics, an Ox package (see Doornik, 2006, 2007a) implementing automatic Gets modeling based on the theory of reduction discussed above. The present implementation of Autometrics is primarily for linear regression models, but extensions have been derived theoretically to automatically model dynamic, cointegrated, simultaneous systems; nonlinear equations; structural breaks; more variables (N) than observations (T); and testing exogeneity (see, e.g., Hendry and Krolzig, 2005; Castle and Hendry, 2005; Hendry, *et al.*, 2008; Johansen and Nielsen, 2008; Doornik, 2007b; and Hendry and Santos, 2009, respectively). Given any available theoretical, historical, institutional, and measurement information, as well as previous empirical evidence, a GUM must be carefully formulated, preferably with a relatively orthogonal parameterization, a subject-matter basis, and must encompass existing models. When $T \gg N$, the GUM can be estimated from all the available evidence, and rigorously tested for congruence. If congruence fails, a new formulation is required: but at least one has learned the general inadequacy of a class of models. If congruence is accepted, it is then maintained throughout the selection process by not following simplification paths which are rejected on diagnostic checking (using the same statistics), ensuring a congruent final model. When $N > T$, as must happen when impulse saturation is used and can occur more generally (discussed below), misspecification testing can only be undertaken once a feasible model size $n < T$ has been reached.

Statistically insignificant variables are eliminated by selection tests, using a tree-path search in Autometrics, which improves on the multi-path procedures in Hoover and Perez (1999) and Hendry and Krolzig (2001). Checking many paths prevents the algorithm from becoming stuck in a sequence that inadvertently eliminates a variable which actually matters, and thereby retains other variables as proxies (as in stepwise regression). Path searches terminate when no variable meets the elimination criteria. Non-rejected (terminal) models are collected, then tested against each other by encompassing: if several remain acceptable, so are congruent, undominated, mutually encompassing representations, the search is terminated using, e.g., the Schwarz (1978) information criterion, although all are reported and can be used in, say, forecast combinations.

To understand why an automatic search procedure might work, consider a case where the complete set of N candidate regressors is mutually orthogonal, but which ones are relevant is unknown *a priori*, and $T \gg N$. The postulated GUM nests the LDGP. Estimate the GUM, then, squaring to eliminate signs, rank the resulting t_i^2 statistics from the largest to the smallest. When c_α is the criterion for retention, let n be such that $t_n^2 \geq c_\alpha$ when $t_{n+1}^2 < c_\alpha$. Then select the model with those n regressors. That required precisely *one* decision – what to include, and hence what to exclude. No issues of search, repeated testing, path dependence, etc., arise. Goodness-of-fit is not directly used to select models; and no attempt is made to "prove" that a given number of variables matters. In practice, the role of the tree search is to ascertain "true" relevance when orthogonality does not hold; and the choice of c_α affects R^2 and n through retention of t_n^2. Generalizations to other maximum likelihood estimators, or approximations thereto such as IV, are feasible (see Hendry and Krolzig, 2005; Doornik, 2007a).

However, it does matter that selection occurs: the selected model's estimates do not have the same properties as if the LDGP equation had been estimated without any testing. Sampling vagaries entail that some variables which enter the LDGP will by chance have a sample $t^2 < c_\alpha$ (low power). Since they are only retained when $t^2 \geq c_\alpha$, their estimated magnitudes will be biased away from the origin, and hence selected coefficients need to be bias corrected, which is relatively straightforward (see Hendry and Krolzig, 2005). Some variables which are irrelevant will have $t^2 \geq c_\alpha$ (adventitiously significant), where the probability of that event is $\alpha\left(N - n^*\right)$ when n^* variables actually matter. Fortunately, bias correction will also drive such estimates sharply towards the origin. Thus, despite selecting from a large set of potential variables, nearly unbiased estimates of coefficients and equation standard errors can be obtained with little loss of efficiency from testing many irrelevant variables, and some loss for relevant, from the increased value of c_α. The normal distribution has "thin tails," so the power loss from tighter significance levels is usually not substantial, whereas financial variables may have fat tails, so power loss could be more costly at tighter α.

Impulse saturation is described in Hendry *et al.* (2008) and Johansen and Nielsen (2008) as including an indicator for every observation, entered (in the simplest case) in blocks of $T/2$, with the significant outcomes retained. This approach both helps remove outliers, and is a good example of why testing large numbers of candidate regressors does not cost much efficiency loss under the null that they are irrelevant. Setting $c_\alpha \leq 1/T$ maintains the average false null retention at one "outlier," and that is equivalent to omitting one observation, so is a tiny efficiency loss despite testing for the relevance of T variables. Since all regressors are exact linear functions of T impulses, that effect carries over directly in the independent and identically distributed (i.i.d.) setting, and in similar ways more generally. Thus, $N > T$ is not problematic for automatic model selection, opening the door to large numbers of new applications.

Since an automatic selection procedure is algorithmic, simulation studies of its operational properties are straightforward. In the Monte Carlo experiments reported in Hendry and Krolzig (2005), commencing from highly over-parameterized GUMs (between 8 and 40 irrelevant variables; zero and 8 relevant), PcGets recovered the LDGP with an accuracy close to what one would expect if the LDGP specification were known initially, but nevertheless coefficient tests were conducted. To summarize its simulation-based properties, false rejection frequencies of null hypotheses (measured as retention rates for irrelevant variables) can be controlled at approximately the desired level; correct rejections of alternatives are close to the theoretical upper bound of power (measured as retention rates for relevant variables); model selection is consistent for a finite model size as the sample size grows without bound; nearly unbiased parameter estimates can be obtained for all variables by bias-correction formulae, which also reduce the mean square errors of adventitiously retained irrelevant variables; and reported equation standard errors are nearly unbiased estimates of those of the correct specification (see, e.g., Hendry and Krolzig, 2005). Empirically, automatic Gets selects

(in seconds) models at least as good as those developed over several years by their authors (see Ericsson, 2007, for several examples). Although automatic model selection is in its infancy, exceptional progress has already been achieved (see Hoover and Perez, 1999; Hoover and Perez, 2004, provide additional evidence).

1.5.2 Costs of inference and costs of search

> "Don't keep him waiting, child! Why, his time is worth a thousand pounds a minute!" (Train passengers to Alice in Lewis Carroll, 1899)

Costs of inference are inevitable when tests have non-zero size and non-unit power, even if investigators commence from the LDGP – but do not know that is the correct specification, so have to test for congruence and significance. Costs of search are due to commencing from any GUM that is over-parameterized relative to the LDGP. Under-specification ensures that an invalid model of the LDGP will result. Given the many criticisms of model selection, it may surprise readers that costs of search are small in comparison to costs of inference: the main difficulty is not selection *per se*, but the vagaries of sampling. In selecting a model from a GUM, there are two possible mistakes. The first is including irrelevant variables (ones not in the LDGP), the second is omitting relevant variables. Since the first group are absent when the DGP is the GUM, that is purely a cost of search. The second is primarily a cost of inference, with possible additional search costs if there are lower probabilities of retaining relevant variables when commencing from the GUM.

When the nominal rejection frequency of individual selection tests is set at $\alpha \leq 1/N \rightarrow 0$ as $T \rightarrow \infty$, on average at most one irrelevant variable will be retained as adventitiously significant out of N candidates. Thus, there is little difficulty in eliminating almost all of the irrelevant variables when starting from the GUM (a small cost of search). The so-called overall "size" of the selection procedure, namely $1-(1-\alpha)^N$, can be large, but is uninformative about the success of a simplification process that on average correctly eliminates $(1-\alpha)N$ irrelevant variables.

Conversely, even for a loose significance level like $\alpha = 0.05$, and commencing from the LDGP, there is only a 50% chance of keeping a relevant variable where the t-test on its coefficient has a non-centrality of 2 (a high cost of inference). A more stringent critical value (say $\alpha = 0.01$, so $c_\alpha \simeq 2.63$) worsens the costs of inference as the retention probability falls to 27% despite the correct specification being postulated. Costs of inference usually exceed costs of search, the exception being when all relevant variables have large non-central t-statistics (in excess of about ± 5), so there are no costs of inference. The probabilities of locating the LDGP commencing from the GUM are reasonably close to the corresponding outcomes when the search commences from the LDGP. Since the LDGP is sometimes never retained even when it is the initial specification, the apparent problem of a search algorithm may be a cost of inference.

The limits of automatic model selection must also be clarified. If the LDGP equation would not be reliably selected by the given inference rules applied to itself as the initial specification, then selection methods cannot rectify that. Many

apparent criticisms of selection have failed to note that key limitation. In the simulations described above, the same algorithm and selection criteria were always applied to commencing from both the GUM and the LDGP, and only the additional costs attributable to starting from the former comprise search costs. Also, when there are relevant variables with small t-statistics because the parameters are $\mathsf{O}(1/\sqrt{T})$, especially if they are highly correlated with other regressors (see Pötscher, 1991; Leeb and Pötscher, 2003, 2005), then selection is not going to work well: one cannot expect success in selection if a parameter cannot be consistently estimated. Thus, although uniform convergence seems infeasible, selection works for parameters larger than $\mathsf{O}(1/\sqrt{T})$ (as they are consistently estimable) or smaller than $\mathsf{O}(1/T)$ (as they vanish), yet $1/\sqrt{T}$ and $1/T$ both converge to zero as $T \to \infty$, so "most" parameter values are unproblematic. If the LDGP would always be retained by the algorithm when commencing from it, then a close approximation will generally be selected when starting from a GUM which nests that LDGP.

Additional problems for any empirical modeling exercise arise when the LDGP is not nested in the GUM, due to the regressor set being incomplete, the functional form misspecified or structural breaks and other non-stationarities not being fully accommodated, as well as serious measurement errors contaminating the data or endogenous variables being incorrectly treated as regressors. For very high levels of collinearity between relevant and irrelevant variables, the selected approximation may use the incorrect choice if that is undominated, but in a progressive research strategy when there are intermittent structural breaks in both relevant and irrelevant variables, such a selection will soon be dominated. Phillips (2003) provides an insightful analysis of the limits of econometrics.

1.6 Teaching "Applied Econometrics"

> "Manners are not taught in lessons," said Alice. "Lessons teach you to do sums, and things of that sort."
>
> "And you do Addition?" the White Queen asked. "What's one and one and one and one and one and one and one and one and one and one?"
>
> "I don't know," said Alice. "I lost count." (Lewis Carroll, 1899)

Both economic theory and theoretical econometrics are relatively structured subjects to teach, whereas applied econometrics is not, so many approaches are extant. The obvious way might be to include substantive empirical findings in the relevant subject-matter part of other economics courses, and so effectively abolish the need to teach what applied econometrics has established. This certainly happens in part, usually with a lag after the relevant study was published, but seems less common than courses specifically oriented to applied econometrics. I was taught in such a course, the bulk of which concerned studying how the "masters" had conducted their investigations, and what they found – essentially an apprenticeship. Other courses focus more on the economic and econometric theory behind key studies, with less attention to their empirical outcomes: systems of demand equations seem to be addressed that way. Presumably the aim is to explicate the relation between

economics and its applications in particular cases. Finally, some courses require students to undertake empirical work themselves, often replicating or evaluating existing studies rather than novel research. Combinations of some or all of these also happen.

If the objective is one where completing students are to be able to reliably tackle a new application, then teaching applied econometrics becomes very demanding. A wide range of skills and insights need to be conveyed, many of which concern "auxiliary" issues such as data availability, its quality and its correspondence to the target of the analysis, including frequency, seasonality, transformations, etc.; institutions and policy agencies that impinge on the economic process; important historical and non-economic contingencies that occurred; the specification of the candidate list, their dynamics, exogeneity, functional forms and constancy of possible models; and the use of software. When the first attempt fails on the desired criteria, a revision process is needed, so difficulties of expanding searches and sequentially correcting problems with a model must be confronted, all too often leaving the student floundering.

A key job of an applied econometrician is to formulate the general model that underpins the analysis, which includes the specification of all candidate variables that might influence the "target" variables of interest in the modeling problem, their general functional forms (e.g., logs), and putative exogeneity assumptions. General economic reasoning plays a substantive part at this stage. Further, one must collect and carefully check all the data series to be modeled, and investigate their historical context. Finally, the easier part is using appropriate software to congruently model the relevant series. Yet, many studies by "experts" remain clever "detective exercises" in which a feel for the evidence helped point towards a viable conclusion. The approach in Hendry and Nielsen (2007a), summarized in Hendry and Nielsen (2007b), is to first prepare students to understand the elements of likelihood theory, using likelihood ratio tests for inference and evaluation – testing the assumptions for the validity of those inferences – leading to model selection in the econometric theory part of the course. A sequence of increasingly realistic theoretical models is developed from i.i.d. binary data through to cointegrated equations with structural breaks. On the applied part of the course, we thoroughly examine an agreed data set, and after teaching the relevant software, students can rapidly move from simple models to general ones using automatic methods. Our focus is on developing well-specified empirical models of interesting economic issues. Given a new problem, students then have a structured approach to follow in their investigations. We consider there has been a marked improvement in their resulting empirical studies.

An example of my own approach is recorded in Hendry (1999): there may be some "tacit knowledge" therein (and I hope there is value added), but most of the above steps can be formalized without the need for an extensive apprenticeship. The next section focuses on comparing how well automatic model selection does without any "prior" historical knowledge or empirical modeling experience. The results reported in section 1.7 took about 20 minutes of real time, including the write-up: even granted that the data were pre-prepared and the log

transformations were entailed by the pre-analysis, the efficiency gains over my previous "handcrafted" study are huge. In addition, hypotheses that were previously imposed or sequentially investigated can be evaluated jointly.

1.7 Revisiting the "experiment in applied econometrics"

> "If I wasn't real," Alice said – half-laughing though her tears, it all seemed so ridiculous – "I shouldn't be able to cry."
>
> "I hope you don't suppose those are real tears?" Tweedledum interrupted in a tone of great contempt. (Lewis Carroll, 1899)

The recent huge increases in the prices of many foods makes the exercise of re-examining US food expenditure over 1931–89 (based on the update of Tobin, 1950, by Magnus and Morgan, 1999) of more than just historical interest. If the various price and income elasticities estimated below are approximately correct, then substantial responses can be anticipated (indeed, could this be the long-sought solution to society's burgeoning obesity problem?). Hendry (1999) sought to explain why other contributors to Magnus and Morgan (1999) had found their models were non-constant over the combined inter-war and post-war samples, so had eschewed modeling the 1930s data. Impulse dummies for a food program and post-war de-rationing allowed a constant equation to be developed over the sample 1931–89. While an indicator variable is a crude level of measurement, the converse strategy of not modeling major institutional interventions seems even less attractive. Theory and common sense suggest that food programs and switches in rationing matter; but few theory models allow for such factors in a way suitable for empirical implementation (although the original analyst of this data also published on rationing in Tobin, 1952).

The per capita variables are as follows (lower case denotes logs):

e_f: constant-price expenditure on food
$p_f - p$: real price of food
e: total constant-price expenditure
$s = \log Y - \log E$: (an approximation to the savings ratio)
a: average family size.

Figure 1.6 shows the time series, and reveals considerable changes over the period. After falling sharply at the commencement of the Great Depression, both e_f and e rise substantially till World War II, fall after, then resume a gentle rise (panels (a) and (c)), so $\Delta e_{f,t}$ is vastly more volatile pre-war (panel (e)) (Δe_t has a similar but less pronounced pattern). Next, $p_f - p$ is quite volatile till after the war, then is relatively stable (panel (b)), whereas the dramatic rise in s from "forced saving" during the war is manifest (panel (d)).

The earlier study of a cointegrated VAR for the system established that e, s, and $p_f - p$ were weakly exogenous in the food demand equation. Here, the general conditional model allowed for two lags on each of e_f, e, $p_f - p$, s and one lag

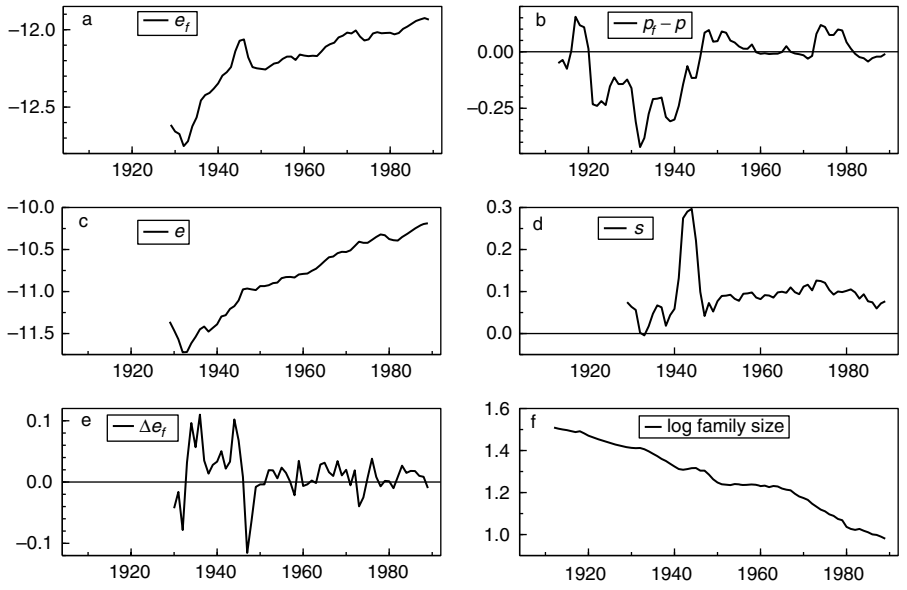

Figure 1.6 Food expenditure and related time series

on a, and was selected by Autometrics at 1% for all candidate variables, including impulse saturation. All diagnostic tests were insignificant, and the PcGive unit root test strongly rejected the null of no cointegration ($t_{ur} = -11.37^{**}$: (see Banerjee and Hendry, 1992; Ericsson and MacKinnon, 2002) with the long-run solution:

$$c_0 = e_f + 7.99 - 0.4e + 0.36(p_f - p). \tag{1.39}$$

Transforming to differences and the equilibrium-correction term from (1.39), Autometrics selected over 1931–89 (at 2.5%, again including impulse saturation):

$$\begin{aligned}
\Delta e_{f,t} = {} & \underset{(0.02)}{0.34}\, s_{t-1} - \underset{(0.02)}{0.32}\, c_{0,t-1} + \underset{(0.04)}{0.67}\, \Delta e_t + \underset{(0.03)}{0.13}\, \Delta e_{t-1} \\
& - \underset{(0.03)}{0.64}\, \Delta(p_f - p)_t - \underset{(0.01)}{0.09}\, \mathrm{I}_{31} - \underset{(0.01)}{0.10}\, \mathrm{I}_{32} + \underset{(0.01)}{0.04}\, \mathrm{I}_{34} \\
& + \underset{(0.01)}{0.03}\, \mathrm{I}_{41} + \underset{(0.01)}{0.05}\, \mathrm{I}_{42} + \underset{(0.01)}{0.03}\, \mathrm{I}_{51} + \underset{(0.01)}{0.02}\, \mathrm{I}_{52} + \underset{(0.01)}{0.03}\, \mathrm{I}_{70} \\
& \left(\mathsf{R}^*\right)^2 = 0.96 \;\; \mathsf{F}_{\mathsf{M}}(13, 45) = 94.9^{**} \;\; \widehat{\sigma} = 0.0078 \;\; \mathsf{F}_{\mathsf{ar}}(2, 44) = 1.34 \\
& \chi^2(2) = 1.04 \;\; \mathsf{F}_{\mathsf{arch}}(1, 44) = 2.25 \;\; \mathsf{F}_{\mathsf{reset}}(1, 45) = 0.35 \\
& \mathsf{F}_{\mathsf{het}}(18, 27) = 0.48 \;\; \mathsf{F}_{\mathsf{Chow}}(9, 37) = 0.99.
\end{aligned} \tag{1.40}$$

In (1.40), $\left(\mathsf{R}^*\right)^2$ is the squared multiple correlation when a constant is added, $\mathsf{F}_{\mathsf{M}}(13, 45)$ is the associated test of the null, and $\widehat{\sigma}$ is the residual standard deviation, with coefficient standard errors shown in parentheses. The diagnostic tests are of the form $\mathsf{F}_{\mathsf{j}}(k, T - l)$, which denotes an approximate F-test against the alternative hypothesis j for: kth-order serial correlation (F_{ar}: see Godfrey, 1978), kth-order autoregressive conditional heteroskedasticity ($\mathsf{F}_{\mathsf{arch}}$: see Engle, 1982), heteroskedasticity ($\mathsf{F}_{\mathsf{het}}$: see White, 1980a); the RESET test ($\mathsf{F}_{\mathsf{reset}}$: see Ramsey, 1969); parameter constancy ($\mathsf{F}_{\mathsf{Chow}}$ (see Chow, 1960) over k periods; and a chi-square test for normality ($\chi^2_{\mathsf{nd}}(2)$ (see Doornik and Hansen, 2008). No misspecification test rejects.

The result in (1.40) is to be contrasted with the equation reported earlier, which had a similar equilibrium correction term based on Johansen (1988):

$$c_2 = e_f + 7.88 - 0.4e + 0.4\left(p_f - p\right), \tag{1.41}$$

leading to (D3133 and D4446 are dummies with the value unity over the periods 1931–33 and 1944–46 respectively):

$$\begin{aligned}\Delta e_{f,t} = {} & \underset{(0.04)}{0.27}\, s_{t-1} - \underset{(0.02)}{0.34}\, c_{2,t-1} - \underset{(0.004)}{0.019} + \underset{(0.05)}{0.24}\, \Delta s_t \\ & + \underset{(0.05)}{0.53}\, \Delta e_t - \underset{(0.04)}{0.46}\, \Delta(p_f - p)_t - \underset{(0.01)}{0.12}\, \mathrm{D3133} + \underset{(0.010)}{0.038}\, \mathrm{D4446} \\ & \mathsf{R}^2 = 0.936 \;\; \mathsf{F}_{\mathsf{M}}(7, 51) = 107.2^{**} \;\; \widehat{\sigma} = 0.0098 \;\; \mathsf{F}_{\mathsf{ar}}(2, 49) = 0.18 \\ & \chi^2(2) = 0.21 \;\; \mathsf{F}_{\mathsf{arch}}(1, 49) = 0.59 \;\; \mathsf{F}_{\mathsf{reset}}(1, 50) = 0.26 \;\; \mathsf{F}_{\mathsf{het}}(13, 37) = 0.47. \end{aligned} \tag{1.42}$$

Thus, six additional outliers have been detected in (1.40), whereas none of the components of D4446 was found, nor was I_{33}: neither dummy is remotely significant if added to (1.40). Consistent with that result, when (1.42) and (1.40) are denoted models 1 and 2 on encompassing tests, $\mathsf{F}_{\mathsf{Enc}_{1,2}}(10, 41) = 4.83^{**}$ and $\mathsf{F}_{\mathsf{Enc}_{2,1}}(5, 41) = 2.18$, so (1.42) is encompassed by (1.40) but not vice versa. Nevertheless, both models are rejected against the other on Cox (1961) and Ericsson (1983) non-nested tests with $\widehat{\sigma}_J = 0.0074$.

Another recent development that can be implemented based on impulse saturation is to test for the super exogeneity of the parameters of the conditional model in response to changes in the LDGPs of the two main conditioning variables, Δe_t and $\Delta(p_f - p)_t$ (see section 1.4.5 and Hendry and Santos, 2009). The latter's equation revealed no significant breaks, but commencing from one lag of Δe, $\Delta(p_f - p)$, Δs and Δa, the former produced:

$$\begin{aligned}\Delta e_t = {} & \underset{(0.003)}{0.016} + \underset{(0.081)}{0.256}\, \Delta e_{t-1} - \underset{(0.083)}{0.302}\, \Delta(p_f - p)_{t-1} - \underset{(0.02)}{0.11}\, \mathrm{I}_{31} \\ & - \underset{(0.02)}{0.19}\, \mathrm{I}_{32} + \underset{(0.02)}{0.10}\, \mathrm{I}_{34}\end{aligned}$$

$$+ \underset{(0.02)}{0.06}\,\mathrm{I}_{35} + \underset{(0.02)}{0.07}\,\mathrm{I}_{36} - \underset{(0.02)}{0.08}\,\mathrm{I}_{38} + \underset{(0.02)}{0.07}\,\mathrm{I}_{41} + \underset{(0.02)}{0.08}\,\mathrm{I}_{43}$$

$$+ \underset{(0.02)}{0.10}\,\mathrm{I}_{46} - \underset{(0.02)}{0.06}\,\mathrm{I}_{80}$$

$$\mathsf{R}^2 = 0.86 \;\; \mathsf{F}_{\mathsf{M}}(12, 46) = 23.9^{**} \;\; \widehat{\sigma} = 0.019 \;\; \mathsf{F}_{\mathsf{ar}}(2, 44) = 0.14$$

$$\chi^2(2) = 1.27 \;\; \mathsf{F}_{\mathsf{arch}}(1, 44) = 4.42^{*} \;\; \mathsf{F}_{\mathsf{reset}}(1, 45) = 0.01 \;\; \mathsf{F}_{\mathsf{het}}(14, 31) = 0.69. \quad (1.43)$$

Almost all the inter-war and war years are revealed as discrepant, with four impulses in common with (1.40). Adding the 6 additional impulses found in (1.43) to (1.40) and testing their significance yields $\mathsf{F}_{\mathsf{SExog}}(6, 40) = 1.14$, not rejecting. Nevertheless, that there are four impulses in common is strongly against the exogeneity of Δe_t in (1.40), especially as their signs all match, and even the magnitudes are not too far from 0.67 times those in (1.43). It is not surprising that major shifts in total expenditure are associated with shifts in expenditure on a subcomponent, but since Δe_t is included in (1.40), the conclusion must be that agents altered their decision rules more than that effect. Since a food program was in place for several of the common impulses and rationing for the other, additional shifts do not necessarily invalidate the economics behind the equation, so the overall outcome is inconclusive.

An alternative check on the commonality of the inter-war and post-war periods is to use the former to predict the latter, given the actual outcomes for the regressors. We have implicitly done so via impulse saturation, which revealed only one post-war outlier in 1970. The F-test of constancy, $\mathsf{F}_{\mathsf{Chow}}(37, 10) = 2.02$, does not reject. Figure 1.7 shows the outcomes: panel (a) reports the fitted and actual values till 1952 and the predicted thereafter, with the full-sample fit shown immediately below in panel (c), the residuals and forecast errors in panel (b), and one-step 95% forecast intervals in panel (d). The outlier in 1970 is obvious, and otherwise there is little difference between the sub-sample and full-sample fit. Such constancy in the face of changing data behavior supports both the specification in (1.40) and the use of the whole sample to estimate and evaluate these models.

1.7.1 An update

> Everything was happening so oddly that she didn't feel a bit surprised. (Lewis Carroll, 1899)

The obvious extension is to update the data, and test the model on the extended information. Unfortunately, Applied Econometrics is never that easy: the data have been extensively revised. It came as a surprise even to an experienced empirical modeler that data back to 1929 could differ so much between a 1989-based set (denoted by a subscript $_0$ in the graphs) and a 2008 update when extending the data to 2000 (denoted $_1$), but Figures 1.8 (data) and 1.9 (deviations) show the extent of the revisions. Both food and total real expenditure have changed, the latter by up to 15%, and savings have shifted by up to 5%, whereas the relative price of

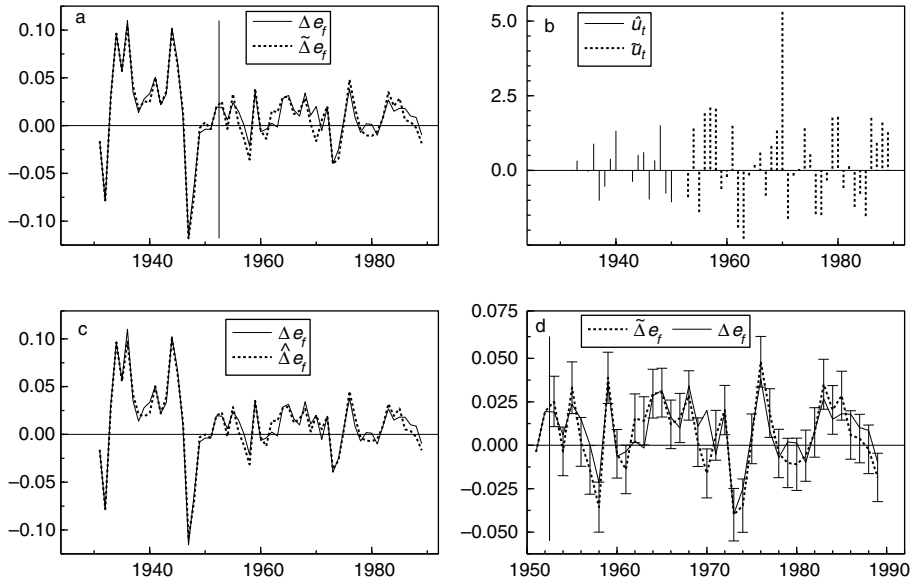

Figure 1.7 Fitted and actual values, residuals and forecasts for $\Delta e_{f,t}$

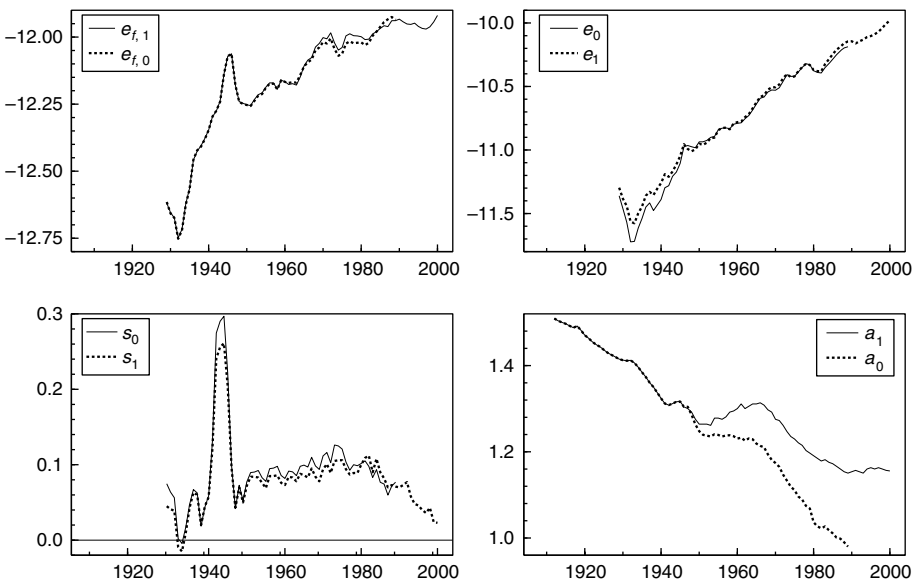

Figure 1.8 Revised data on food expenditure time series

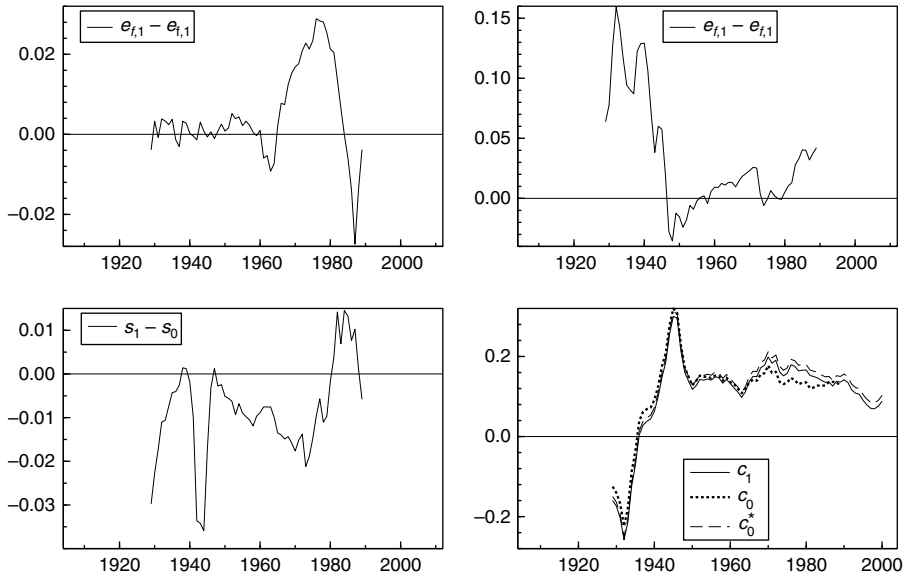

Figure 1.9 Deviations between old and revised data on food expenditure time series

food is unaltered – yet family size is unrecognizably different. The impacts on the equilibrium-correction terms, c_0 in (1.39), that calculated for the revised data c_0^*, and c_1 in (1.45) below, are also shown (see Hendry, 1994; Cook, 2008, on possible approaches for cross-data-vintage encompassing).

First, enforcing the identical specification to (1.40) but on the revised data over 1930–89, testing on the 11 new years led to:

$$\begin{aligned}\Delta e_{f,t} = {} & \underset{(0.04)}{0.34}\, s_{t-1} - \underset{(0.02)}{0.27}\, c_{0,t-1} + \underset{(0.06)}{0.57}\, \Delta e_t + \underset{(0.05)}{0.09}\, \Delta e_{t-1} \\ & - \underset{(0.04)}{0.40}\, \Delta(p_f - p)_t - \underset{(0.01)}{0.10}\, \mathrm{I}_{31} - \underset{(0.01)}{0.12}\, \mathrm{I}_{32} + \underset{(0.01)}{0.04}\, \mathrm{I}_{34} \\ & + \underset{(0.01)}{0.02}\, \mathrm{I}_{41} + \underset{(0.01)}{0.05}\, \mathrm{I}_{42} + \underset{(0.01)}{0.03}\, \mathrm{I}_{51} + \underset{(0.01)}{0.02}\, \mathrm{I}_{52} + \underset{(0.01)}{0.04}\, \mathrm{I}_{70} \\ & \left(\mathsf{R}^*\right)^2 = 0.93 \;\; \mathsf{F}_{\mathsf{M}}(13,45) = 94.9^{**} \;\; \widehat{\sigma} = 0.011 \;\; \mathsf{F}_{\mathsf{ar}}(2,44) = 5.74^{**} \\ & \chi^2(2) = 2.40 \;\; \mathsf{F}_{\mathsf{arch}}(1,44) = 2.79 \;\; \mathsf{F}_{\mathsf{reset}}(1,45) = 0.01 \\ & \mathsf{F}_{\mathsf{het}}(18,27) = 0.82 \;\; \mathsf{F}_{\mathsf{Chow}}(11,46) = 1.42. \end{aligned} \tag{1.44}$$

The revisions have altered the coefficients to some extent, the fit is poorer and there is significant residual autocorrelation, but (without "correcting" the standard errors for that problem), the Chow test does not reject, although as Figure 1.10 reveals, the forecast errors are clearly autocorrelated.

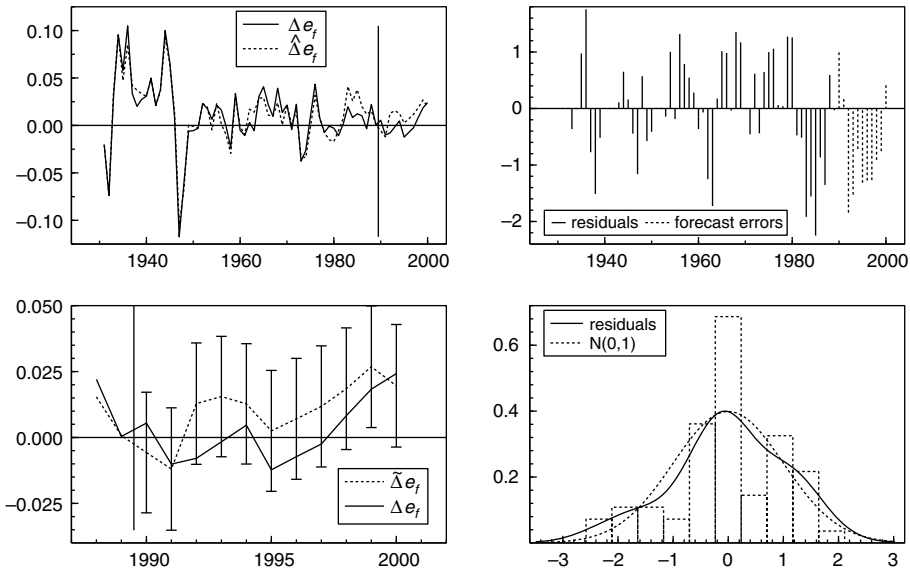

Figure 1.10 Old model revised data fitted and actual values, residuals and forecasts for $\Delta e_{f,t}$

Next, automatic remodeling at 1% on the revised data up to 1989 (with impulse saturation to remove the outliers) led to:

$$c_1 = e_f + 8.49 - 0.35e + 0.21(p_f - p), \tag{1.45}$$

with a much simpler final equation being selected:

$$\begin{aligned}\Delta e_{f,t} = {} & \underset{(0.032)}{0.35}\, s_t - \underset{(0.02)}{0.25}\, c_{1,t-1} + \underset{(0.05)}{0.65}\, \Delta e_t - \underset{(0.04)}{0.29}\, \Delta(p_f - p)_t \\ & - \underset{(0.01)}{0.05}\, \mathrm{I}_{30} - \underset{(0.01)}{0.08}\, \mathrm{I}_{31} - \underset{(0.01)}{0.08}\, \mathrm{I}_{32} + \underset{(0.01)}{0.03}\, \mathrm{I}_{70}\end{aligned}$$

$$\begin{aligned}\left(\mathsf{R}^*\right)^2 = 0.90 \;\; \mathsf{F}_{\mathsf{M}}(8,51) = 60.4^{**} \;\; \widehat{\sigma} = 0.012 \;\; \mathsf{F}_{\mathsf{ar}}(2,50) = 0.65 \\ \chi^2(2) = 2.09 \;\; \mathsf{F}_{\mathsf{arch}}(1,50) = 0.13 \;\; \mathsf{F}_{\mathsf{reset}}(1,51) = 0.11 \\ \mathsf{F}_{\mathsf{het}}(18,33) = 0.89 \;\; \mathsf{F}_{\mathsf{Chow}}(11,52) = 0.68 \; (1990 - 2000).\end{aligned} \tag{1.46}$$

Nevertheless, despite the revisions, the model in (1.46) has many features in common with both its predecessors, and is constant over the next 11 years as Figure 1.11 reports, and $\mathsf{F}_{\mathsf{Chow}}(11,52)$ confirms. The short-run elasticities still exceed their long-run counterparts, but by less than previously.

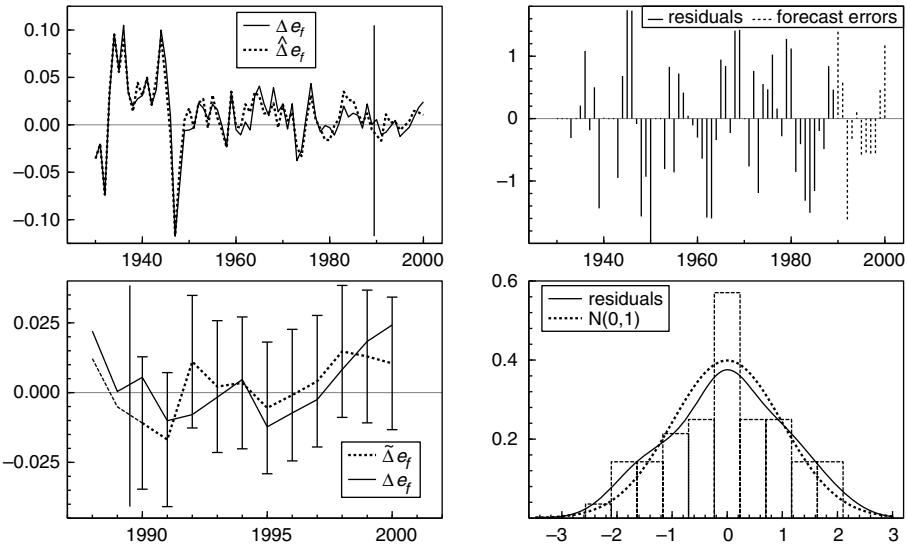

Figure 1.11 New model on revised data fitted and actual values, residuals and forecasts for $\Delta e_{f,t}$

1.8 Automatic modeling of a VAR_4 (25)

> "The Eighth Square at last!" she cried as she bounded across ... "Oh, how glad I am to get here! And what is this on my head?" she exclaimed ... It was a golden crown. (Quote from Alice in Lewis Carroll, 1899)

To illustrate that automatic modeling is not restricted to single equations (see, e.g., Krolzig, 2003), we now model the four variables in section 1.4.1.1, namely industrial output per capita, $y_{c,t}$, numbers of bankruptcies, b_t, and patents, p_t, and real equity prices (deflated by a cost of living index), e_t, using a VAR with 25 lags, augmented by impulse saturation over the common sample T =1757–1989 at $\alpha = 0.0025$ (so on average about one variable will be retained by chance as there are 337 candidates in the initial general model). The marginal critical t-ratio is about 3.1, and only about 3 regressors (other than impulses) were near or below that in the four finally-selected models. Most diagnostic tests were insignificant in those final models (but not computable at the start). The entire exercise took under two hours, including this write-up: technical progress in undertaking empirical econometrics is huge, as such an analysis would have been simply impossible (conceptually and practically) when I first started empirical modeling in 1967.

$$\Delta y_{c,t} = \underset{}{-} \underset{(0.031)}{0.128}\, y_{c,t-1} + \underset{(0.037)}{0.143}\, y_{c,t-5} - \underset{(0.037)}{0.152}\, y_{c,t-19} + \underset{(0.034)}{0.135}\, y_{c,t-23}$$

$$+ \underset{(0.004)}{0.016}\, p_t - \underset{(0.005)}{0.016}\, b_{t-3} + \underset{(0.013)}{0.081}\, e_t - \underset{(0.013)}{0.084}\, e_{t-2}$$

$$+ \underset{(0.038)}{0.129}\ \mathrm{I}_{1827} - \underset{(0.039)}{0.206}\ \mathrm{I}_{1921} + \underset{(0.037)}{0.119}\ \mathrm{I}_{1927}$$

$$\widehat{\sigma} = 0.0368 \quad \mathsf{F}_{\mathsf{AR1-2}}(2, 220) = 1.08 \quad \mathsf{F}_{\mathsf{ARCH1}}(1, 220) = 0.14$$

$$\chi^2_{\mathsf{nd}}(2) = 1.09 \quad \mathsf{F}_{\mathsf{Het}}(19, 202) = 2.24^{**} \quad \mathsf{F}_{\mathsf{RESET}}(1, 221) = 5.97^{*}$$

$$\widehat{\sigma} = 0.18 \quad \mathsf{F}_{\mathsf{AR1-2}}(2, 216) = 1.60 \quad \mathsf{F}_{\mathsf{ARCH1}}(1, 216) = 2.48$$

$$\chi^2_{\mathsf{nd}}(2) = 5.25 \quad \mathsf{F}_{\mathsf{Het}}(25, 192) = 1.64^{*} \quad \mathsf{F}_{\mathsf{RESET}}(1, 217) = 1.59$$

$$\begin{aligned} e_t = {} & \underset{(0.06)}{1.12}\ e_{t-1} - \underset{(0.06)}{0.17}\ e_{t-2} + \underset{(0.16)}{0.69}\ y_{c,t} - \underset{(0.16)}{0.69}\ y_{c,t-1} \\ & - \underset{(0.03)}{0.10}\ b_t + \underset{(0.03)}{0.12}\ b_{t-1} + \underset{(0.10)}{0.35}\ \mathrm{I}_{1802} + \underset{(0.11)}{0.31}\ \mathrm{I}_{1922} \\ & + \underset{(0.10)}{0.31}\ \mathrm{I}_{1959} - \underset{(0.10)}{0.31}\ \mathrm{I}_{1973} - \underset{(0.11)}{0.58}\ \mathrm{I}_{1974} \end{aligned}$$

$$\widehat{\sigma} = 0.10 \;\; \mathsf{F}_{\mathsf{AR1-2}}(2,220) = 2.59 \;\; \mathsf{F}_{\mathsf{ARCH1}}(1,220) = 0.01$$
$$\chi^2_{\mathsf{nd}}(2) = 3.72 \;\; \mathsf{F}_{\mathsf{Het}}(17,204) = 1.21 \;\; \mathsf{F}_{\mathsf{RESET}}(1,221) = 3.72.$$

Most of the effects found make economic sense in the context of the limited information set used here as an illustration. In reverse order, real equity prices are near a random walk, but respond positively to changes in output, and negatively to changes in bankruptcies. In turn, bankruptcies fall with increased output or equity prices, but rise with patent grants. Neither equation has many outliers, whereas the patents equation does, especially in the eighteenth century. Patents fall initially as output, equity prices, bankruptcies rise, but adjust back later. Finally, changes in output respond positively to patents and changes in equity prices, but negatively to bankruptcies.

A substantive exercise would involve additional variables like interest rates and human and physical capital; would check whether bankruptcies and patents should also be per capita; and investigate cointegration reductions. Are the long lags 'spurious'? The general historical record suggests that major innovations are both creative and destructive of output, the former by the enlargement of the production frontier, and the latter through the negative impact on those already engaged in the occupations concerned (spinners, weavers, etc., initially; clerks and secretaries in more modern times), so a "generation" is required for the new state to dominate – that motivated the original choice of 25 lags. Innovations take time to develop and be adopted; and the seeds for bankruptcy are often sown well before the reaping, even if the span is not quite "clogs to clogs in three generations." Notably, the equation for equity prices still has short lags despite the "opportunity" to find other correlations.

1.9 Conclusion

> Ever drifting down the stream –
> Lingering in the golden gleam –
> Life, what is it but a dream? (Lewis Carroll, 1899)

"Applied Econometrics" has a vast range of empirical issues to investigate: the very non-stationarity of economies keeps creating new topics for analysis. However, so long as "Applied Econometrics" is just a calibration of extant economic theory, it will never make much of an independent contribution: in that sense, one must agree with Summers (1991) but for completely opposite reasons. Much of the observed data variability in economics is due to features that are absent from most economic theories, but which empirical models have to tackle. *Ceteris paribus* conditions can sometimes be justified for theoretical reasoning, but do not provide a viable basis for empirical modeling: only a "minor influence" theorem, which must be established empirically, will suffice.

This implication is not a tract for mindless modeling of data in the absence of economic analysis, but instead suggests formulating more general initial models

that embed the available economic theory as a special case, consistent with our knowledge of the institutional framework, historical record, and the data properties. Once a congruent encompassing general model is established, an automatic model selection approach based on general-to-simple principles could help bring objectivity and credibility to empirical econometric modeling.

Economic observations are far from perfect, being subject to revision, and even to conceptual changes, with important variables unobserved, and available proxies of unknown quality. Theory constructs (such as "consumption," or "user cost of capital") and their measured counterparts (consumers' expenditure or after-tax real interest rates adjusted for depreciation) can differ markedly, especially after aggregation. Thus, a "pure" data-based approach can lack substance.

Economics has delivered a range of invaluable insights into individual decision taking, market functioning, and system-wide economies, with a vast body of theory, which has made rapid technical and intellectual progress – and will continue to do so. Applied econometrics cannot be conducted without an economic theoretic framework to guide its endeavors and and help interpret its findings. Nevertheless, since economic theory is not complete, correct, and immutable, and never will be, one also cannot justify an insistence on deriving empirical models from theory alone. That paradigm encourages covert data mining, so the credibility of existing evidence is unclear.

Data "mining" does not have pernicious properties when using a structured approach, using appropriate significance levels that decline with both the number of candidate variables and sample size: at 1% significance, one irrelevant variable in 100 will be significant by chance, at the cost of raising the selection t-ratio from around ± 2.0 to ± 2.7. Parsimony is not a justification for arbitrarily excluding many potentially relevant contenders, not even when doing so to avoid more initial variables than observations. While it is essential that the final model is much smaller than the sample size, that does not preclude starting general and making the maximum use of our best available theory and econometrics to guide our empirical endeavors and then interpret their outcomes. Thus, Frisch (1933) remains our best advice: "mutual penetration', which entails using economic analysis to guide an applied study, but letting the empirical evidence play a real role.

Acknowledgments

Financial support from the ESRC under Research Grant RES-062-23-0061 is gratefully acknowledged. I am indebted to Gunnar Baardsen, Julia Campos, Jennifer Castle, Guillaume Chevillon, Jurgen Doornik, Neil Ericsson, Katarina Juselius, Søren Johansen, Bobby Mariano, Jaime Marquez, Terry Mills, Mary Morgan, Bent Nielsen, Ragnar Nymoen, Kerry Patterson, Duo Qin, James Reade, Aris Spanos and Pravin Trivedi for helpful comments.

Note

1. Atkinson (2008) notes Robbins' apparent dismissal of Richard Stone (1951) as "not economics."

2
How much Structure in Empirical Models?

Fabio Canova

Abstract

This chapter highlights the problems that structural methods and SVAR approaches have when estimating DSGE models and examining their ability to capture important features of the data. We show that structural methods are subject to severe identification problems due, in large part, to the nature of DSGE models. The problems can be patched up in a number of ways, but solved only if DSGEs are completely reparameterized or respecified. The potential misspecification of the structural relationships gives Bayesian methods an edge over classical ones in structural estimation. SVAR approaches may face invertibility problems but simple diagnostics can help to detect and remedy these problems. A pragmatic empirical approach ought to use the flexibility of SVARs against potential misspecification of the structural relationships but must firmly tie SVARs to the class of DSGE models which could have generated the data.

2.1 Introduction

The 1990s witnessed a remarkable development in the specification of stochastic general equilibrium models. The literature has added considerable realism to the popular workhorses of the 1980s; a number of shocks and frictions have been introduced into first-generation Real Business Cycle (RBC) models driven by a single

technological disturbance; and our understanding of the propagation mechanism of structural shocks has been considerably enhanced. Steps forward have also been made in comparing the quality of the models' approximation to the data. While a few years ago it was standard to calibrate the parameters of a model and informally evaluate the quality of its fit to the data, now full information likelihood-based estimation of the structural parameters has become common practice (see, for example, Smets and Wouters, 2003; Ireland, 2004; Canova, 2005; Rabanal and Rubio-Ramirez, 2005; Gali and Rabanal, 2005) and new techniques have been introduced for model evaluation purposes (see Del Negro *et al*., 2006). Given the complexities involved in estimating stochastic general equilibrium models and the difficulties in designing criteria which are informative about their discrepancy with the data, a portion of the literature has also considered less demanding limited information methods and focused on whether a model matches the data only along certain dimensions. For example, following Rotemberg and Woodford (1997) and Christiano, Eichenbaum and Evans (2005), it is now common to estimate structural parameters by quantitatively matching the conditional dynamics in response to certain structural shocks. Regardless of the approach a researcher selects, the stochastic general equilibrium model one uses to restrict the data is taken very seriously: in both estimation and testing, it is in fact implicitly assumed that the model is the data-generating process (DGP) of the actual data, up to a set of serially uncorrelated measurement errors. Despite the above-mentioned progress, such an assumption is still too heroic to be credibly entertained. As a consequence, estimates of the parameters may reflect this primitive misspecification and, as the sample size grows, parameter estimates need not converge to those of the true DGP.

The 1990s also witnessed an extraordinary development of vector autoregressive (VAR) techniques: from simple reduced form models, VARs have evolved into tools to analyze questions of interest to academics and policy makers. Structural VARs have enjoyed an increasing success in the profession for two reasons: they are easy to estimate and the computational complexities are of infinitesimal order relative to those of structural techniques; structural inference can be performed without conditioning on a single, and possibly misspecified, model. Clearly, there is no free lunch and robustness against misspecification comes at the cost of limiting the type of policy exercises one can entertain. One additional advantage of structural VARs needs to be mentioned. While techniques to deal with parameter variations are sufficiently well developed in this literature (see Cogley and Sargent, 2005; Primiceri, 2005; Canova and Gambetti, 2007), they are still at an infant stage when it comes to structurally estimating time variations in the parameters of a stochastic general equilibrium model (see Justiniano and Primiceri, 2008; Fernandez-Villaverde and Rubio-Ramirez, 2007).

When addressing an empirical problem with a finite amount of data, one has therefore to take a stand on how much theory one wants to use to structure the available data prior to estimation. If the former approach is taken (which we will call "structural" for simplicity), model-based estimation can be performed, but

inference is valid only to the extent that the model correctly represents the DGP of the data. If the latter approach is taken (which we call "SVAR" for simplicity), one can work with a class of structural models and use implications that are common to the members of this class to identify shocks and trace out their effects on the endogenous variables of the system, but cannot say much about preference or production function parameters, nor conduct certain policy exercises that involve changes in expectation formation. The choice between the two alternatives is easy in two extreme and unlikely situations: the stochastic models one writes down are in fact the DGP of the actual data; there is a unique mapping between the structural models to reduced form ones. Under these two conditions, direct (structural) or indirect (SVAR) estimation will give similar answers to a set of core questions investigators like to study (transmission of certain disturbances, effects of shocks to certain policy rules, and so on) and for these questions, accuracy and computational time become the most important factors that determine the choice of technique.

Unfortunately, the reality is far from the ideal and both approaches have important shortcomings. Current dynamic stochastic general equilibrium (DSGE) models, even in the large-scale versions that are now used in central banks and international institutions, are still too simple to capture the complexities of the macro-data. In addition, because they are highly nonlinear in the structural parameters and the mapping between structural parameters and the coefficients of the aggregate decision rules is analytically unknown – the exact mapping is known only in a few but uninteresting cases – the identification of the structural parameters from the data is far from clear. Structural VAR estimation also faces identification problems. The identification restrictions researchers use are often conventional, have little economic content, and are not derived from any class of models that macroeconomists use to interpret the results. Furthermore, there are DSGE models which do not admit a finite order VAR representation and others which cannot be recovered when the Wold decomposition is used to set up a VAR. Omitted variables may play an important role in SVAR results and the use of small-scale systems may distort the conclusions one draws from the exercise. In both cases, small samples, or samples which contain different regimes, may further complicate the inferential problem. All in all, the issues of misspecification, identification, low signal-to-noise ratio, invertibility, omitted variables and reduced number of shocks and, last but not least, small samples, should always be in the back of the mind of an investigator who is interested in studying an applied problem and/or suggesting policy recommendations from his/her analysis.

The scope of this chapter is to highlight the problems one faces when using either of the two methodologies to conduct policy analyses, and to address questions concerning the validity of models and their ability to capture features of the data and, in general, empirical issues of interest to academics and to policy makers. In particular, we discuss identification problems and problems connected with the potential non-representability of the aggregate decision rules with VARs. The problems we describe do not have a solution yet and standard approaches to deal with them may make the problems worse. We provide a list of "dos and

don'ts" which applied investigators may want to keep in mind in their work and outline a methodology, combining ideas from both types of approaches, which can potentially avoid some of the problems we discuss and allow useful inference on interesting economic questions. Nevertheless, it should be clear that asking too much from a model is equivalent to asking for trouble. One should use theory as a flexible mechanism to organize the data and to avoid questions that the data, the nature of the model, or the estimation approach employed cannot answer.

2.2 DSGE models

DSGE models are consistent theoretical laboratories where the preferences and the objective functions of the agents are fully specified, the general equilibrium interactions are taken into account, the stochastic structure of the driving forces is exactly defined, the expectations of the agents are consistently treated and the equilibrium of the economy is clearly spelled out. The economic decisions of the agents are derived under the assumption that they maximize their objectives in a rational, forward-looking manner. Individual optimality conditions are highly nonlinear functions of the parameters of agents' objective functions and constraints and of the variables that are predetermined and exogenous to their actions. Given the complicated nature of these conditions, explicit decision rules, expressing the choice variables as a function of the predetermined and exogenous variables and the parameters, are not generally available in a closed form. Hence, it is typical to use numerical procedures to approximate these functions, either locally or globally. The solutions to the individual problem are then aggregated into total demand and supply curves, the equilibrium for the economy is computed, and perturbations produced by selected disturbances are analyzed to understand both the mechanics and the timing of the adjustments back to the original equilibrium.

Under regularity conditions, we know that a solution to agents' optimization problems exists and is unique. Hence, one typically guesses the form of the solution, uses a particular functional form to approximate the guess and calculates the coefficients of the approximating function which, given the stationarity of the problem, must be the same for every t. For most situations of interest, (log-)linear or second-order approximations, computed around a carefully selected pivotal point, suffice. The optimality conditions of agents' problems in (log)-linearized deviations from the steady-state are:

$$0 = E_t[A(\theta)x_{t+1} + B(\theta)x_t + C(\theta)x_{t-1} + D(\theta)z_{t+1} + F(\theta)z_t] \tag{2.1}$$

$$0 = z_{t+1} - G(\theta)z_t - e_t, \tag{2.2}$$

where θ is a vector which includes the parameters of preferences, technologies, and policies; $A(\theta), B(\theta), C(\theta), D(\theta), F(\theta), G(\theta)$ are continuous and differentiable functions of θ; x_t are the endogenous variables of the model; and z_t the uncontrollable driving forces, which are typically assumed to follow an AR(1) process with possibly contemporaneously correlated errors e_t. These approximate individual optimality conditions are numerically solved to produce individual decisions rules which can

be equivalently written in a restricted state space format:

$$x_{1t} = J(\theta)x_{1t-1} + K(\theta)e_t$$
$$x_{2t} = G(\theta)x_{1t}, \tag{2.3}$$

where x_{1t} are the predetermined and exogenous variables and x_{2t} are the choice variables of the agents, or in a restricted VAR format:

$$A_0(\theta)x_t = H_1(\theta)x_{t-1} + H_2(\theta)E_t, \tag{2.4}$$

where:

$$A_0(\theta) = \begin{bmatrix} I & 0 \\ I & -G(\theta) \end{bmatrix},\ H_1(\theta) = \begin{bmatrix} J(\theta) & 0 \\ 0 & 0 \end{bmatrix},\ H_2(\theta) = \begin{bmatrix} K(\theta) & 0 \\ 0 & 0 \end{bmatrix},\ E_t = \begin{bmatrix} e_t \\ 0 \end{bmatrix}. \tag{2.5}$$

The solution of a log-linearized DSGE model therefore has the same format as well-known time series models and this makes it particularly attractive to applied macroeconomists with some time series background. However, several unique features of the individual decision rules produced by DSGE models need to be noted. First, (2.3)–(2.4) are nonlinear in the structural parameters θ, and it is θ and not J, K or G that a researcher is typically interested in. Second, the decision rules feature cross-equation restrictions, in the sense that the $\theta_i, i = 1, 2, \ldots$, may appear in several of the elements of the matrices J, K and G. Third, the number of structural shocks is typically smaller than the number of endogenous variables that the model generates. This implies singularities in the covariance of the x_ts, which are unlikely to hold in the data. Finally, H_1 and H_2 are of reduced rank. Note that if A_0 is invertible, (2.4) can be transformed into:

$$x_t = M_1(\theta)x_{t-1} + v_t, \tag{2.6}$$

where $M_1(\theta) = A_0(\theta)^{-1}H_1(\theta), v_t = A_0(\theta)^{-1}H_2(\theta)E_t$ and a (reduced form) VAR representation for the theoretical model could be derived. As we will see, the nonlinearity in the mapping between θ and J, K, G makes identification and estimation difficult, even when cross-equation restrictions are present. System singularity, on the other hand, is typically avoided by adding measurement errors to the decision rules or by considering only the implications of the model for a restricted number of variables – in this case the number of variables is equal to the number of exogenous variables. Finally, rank failures are generally avoided by integrating variables out of (2.4) and obtaining a new representation featuring invertible matrices. As we will see, such an integration exercise is not harmless. In fact, this reduction process will in general produce a VAR moving average (VARMA) representation for the individual decision rules of the DSGE model. Hence, aggregate decision rules may not be always representable with a finite order VAR.

Given the linearity of (2.3) or (2.4) in the predetermined and exogenous variables, aggregate decision rules will also be linear in predetermined and exogenous variables. Therefore, given values for the θ vector, time series can be easily simulated, responses to exogenous impulses calculated and sources of business cycle fluctuations examined.

How does one select the θ vector used in simulation exercises? Until a few years ago, it was common to calibrate θ so that selected statistics of the actual and simulated data were close to each other. This informal selection process was justified by the fact that DSGE models were too simple and stylized to be faced with rigorous statistical estimation. In recent years the complexity of models has increased; a number of frictions have been introduced on the real, the monetary and, at times, the financial side of the economy; a larger number of disturbances has been considered and a number of more realistic features added. Therefore, it has become more common to attempt structural estimation of the θ using limited information approaches, such as impulse response matching exercises, or full information ones, such as likelihood-based methods.

A clear precondition for any structural estimation approach to be successful is that the parameters of interest are identifiable from the chosen objective function. In the next sub-section we discuss why parameter identifiability may be hard to obtain in the context of DSGE models and why, perhaps, calibration was originally preferred by DSGE modelers.

2.2.1 Identification

Identification problems can emerge in three distinct situations. First, a model may face identification problems in population, that is, the mapping between the structural parameters and the parameters of the aggregate equilibrium decision rule is ill-conditioned. We call this phenomenon the "solution identification" problem. Since the objective functions are typically a deterministic transformation of either (2.3) or (2.4), failure to identify θ from the entries of the aggregated versions of the $J(\theta), K(\theta), G(\theta)$ matrices (or from the aggregate versions of the $A_0(\theta), H_1(\theta), H_2(\theta)$ matrices) is sufficient for having population identification problems for all possible choices of objective functions.

Second, it could be that identification pathologies emerge because the selected objective function neglects important model information – for example, the steady-states or the variance-covariance matrix of the shocks. In other words, one can conceive situations where all the structural parameters are identifiable if the whole model is considered, but some of them cannot be recovered from, say, a sub-set of the equations of the model or a sub-set of the responses to shocks. We call this phenomenon the "limited information identification" problem. As an example of why this may happen, suppose you have two variables, say output and inflation, and two shocks, say technology and monetary shocks. Obviously, the responses to technology shocks carry little information for the autoregressive parameter of the monetary shock. Hence, this parameter is unlikely to be identified from the dynamics induced by technology shocks. It should also be clear that limited information and solution identification problems are independent of each other and therefore may appear in isolation or jointly.

Finally, difficulties in identifying parameters may be the result of small samples. That is to say, even if the mapping between the structural parameters and the parameters of the aggregate decision rules is well behaved and even if the objective function considers all the implications of the model, it may be difficult to recover

structural parameters because the sample does not contain enough information to invert the mapping from $J(\theta)$, $K(\theta)$, and $G(\theta)$ or from the objective function to θ. To understand why this problem may emerge, consider the likelihood function of one parameter for a given dataset. It is well known that, as the sample size increases, the shape of the likelihood function changes, becoming more sharply peaked around the mode. Therefore, when the sample is small, the likelihood function may feature large flat areas in a relevant portion of the parameter space and this may make it difficult to infer the parameter vector which may have been generating the data.

Econometricians have long been concerned with identification problems (see, for example, Liu, 1960; Sims, 1980, among others). When models are linear in the parameters, and no expectations are involved, it is relatively straightforward to check whether the first two types of problems are present: it is sufficient to use rank and order conditions and look at the mapping between structural parameters and the aggregate decision rules. It is also easy to measure the extent of small sample issues – the size of the estimated standard errors or an ill-conditioned matrix of second-order derivatives of the objective function evaluated at parameter estimates give us an indication of the importance of this problem. For DSGE models none of these diagnostics can really be used. Since the mapping between θ and the parameters of (2.3) or (2.4) is nonlinear, traditional rank and order conditions do not apply. Furthermore, the size of estimated standard errors is insufficient to inform us about identification problems.

If identification problems are detected, what can one do? While for the first type of problems there is very little to be done, except going back to the drawing board and respecifying or reparametrizing the model, the latter two problems could in principle be alleviated by specifying a full-information objective function and by adding external information. If one insists on using a limited information criteria, one then needs to experiment with the sub-set of the model's implications to be used in estimation. Such experimentation is far from straightforward because economic theory offers little guidance in the search, and because certain variables produced by the model are non-observable (for example, effort) or non-measurable (for example, capital) by the applied researcher. Information from external sources may not always be available; it may be plagued by measurement errors or not very informative about the parameters of interest (see Boivin and Giannoni, 2005).

DSGE models face a large number of population identification problems. Canova and Sala (2005) provide an exhaustive list of potentially interesting pathologies. To summarize their taxonomy: a number of DSGE models, with potentially different economic implications, may be observationally equivalent in the sense that the aggregate decision rules they produce will be indistinguishable; they may be subject to under- or partial identification of their parameters, that is, a set of parameters may disappear from the aggregate decision rules or enter only in a particular functional form; and they may face weak identification problems – the mapping between structural parameters and the coefficients of the aggregate decision rules may display little curvature or be asymmetric in some direction. All these problems could occur locally or globally in the parameter space. However, given the common

practice of obtaining estimates using optimization routines which constrain the search of the maximum to an interval, we will consider only local problems in what follows. Also, while the econometric literature has often considered the latter as a small sample problem, weak identification problems easily occur in the population. In other words, while it is generally true that when the sample size is small the curvature of the mapping may not be sufficient to recover the underlying vector of structural parameters from the coefficients of the aggregate decision rules, there is nothing that ensures that such a mapping in DSGE models will be better behaved with an infinitely large sample.

Next, we present two examples which show the pervasiveness of population identification problems in standard DSGE models. While the models are of small scale, it should be remembered that most of the larger-scale DSGE models used in the literature feature the equations of these models as building blocks. Therefore, the problems we highlight are likely to emerge also in more complex set-ups.

2.2.1.1 Example 1: observational equivalence

Consider the following three equations:

$$y_t = \frac{1}{\lambda_2 + \lambda_1} E_t y_{t+1} + \frac{\lambda_1 \lambda_2}{\lambda_1 + \lambda_2} y_{t-1} + v_t \tag{2.7}$$

$$y_t = \lambda_1 y_{t-1} + w_t \tag{2.8}$$

$$y_t = \frac{1}{\lambda_1} E_t y_{t+1} \text{ where } y_{t+1} = E_t y_{t+1} + e_t, \tag{2.9}$$

where $\lambda_2 \geq 1 \geq \lambda_1 \geq 0$ and v_t, w_t and e_t are independent and identically distributed (i.i.d.) processes with zero mean and variance σ_v^2, σ_w^2, σ_e^2 respectively. It is well known that the unique stable rational expectations solution of (2.6) is $y_t = \lambda_1 y_{t-1} + \frac{\lambda_2+\lambda_1}{\lambda_2} v_t$ and that the stable solution of (2.8) is $y_t = \lambda_1 y_{t-1} + e_t$. Therefore, if $\sigma_w = \sigma_e = \frac{\lambda_2+\lambda_1}{\lambda_2}\sigma_v$, a unitary impulse in the three innovations will produce the same responses for $y_{t+j}, j = 0, 1, \ldots$, in the three equations, and these are given by $[\frac{\lambda_2+\lambda_1}{\lambda_2}, \lambda_1 \frac{\lambda_2+\lambda_1}{\lambda_2}, \lambda_1^2 \frac{\lambda_2+\lambda_1}{\lambda_2}, \ldots]$.

What makes the three processes equivalent in terms of impulse responses? Clearly, the unstable root λ_2 in (2.6) enters the solution only contemporaneously. Since the variance of the shocks is not estimable from normalized impulse responses (any value simply implies a proportional increase in all the elements of the impulse response function), it becomes a free parameter which we can arbitrarily select to capture the effects of the unstable root. Turning things around, the dynamics produced by normalized impulses to these three processes will be observationally equivalent because λ_2 is left underidentified in the exercise.

While equations (2.6)–(2.8) are stylized, it should be kept in mind that many refinements of currently used DSGE models add some backward-looking component to a standard forward-looking one, and that the current Great Moderation debate in the US hinges on the existence of determinate versus sunspot solutions (see, for example, Lubik and Schorfheide, 2004). What this example suggests is

that these features may be indistinguishable when one looks just at normalized impulse responses.

How can one avoid observational equivalence? Clearly, part of the problem emerges because normalized impulse responses carry no information for the unstable root λ_2. However, the variance of the shocks does have this information and, for example, the likelihood function of the first process will be different from those of the other two. Hence, adding information could help limit the extent of observational equivalence problems. In the case where one is not willing to or cannot use this information and only employs the dynamics in response to normalized shocks to recover structural parameters, information external to the models needs to be brought in to disentangle various structural representations (as it is done, for example, in Boivin and Giannoni, 2006).

2.2.1.2 Example 2: identification problems in a New Keynesian model

Throughout this sub-section we assume that the investigator knows the correct model and the restrictions needed to identify the shocks. Initially, we assume that he/she chooses as an objective function the distance between the responses in the model and in the data. Later on, we examine how identification is affected when additional information is brought into the estimation process.

We consider a well-known small-scale New Keynesian (NK) model, which has become the workhorse in academic and policy discussions and constitutes the building block of larger-scale models currently estimated in the literature. Several authors, including Ma (2002), Beyer and Farmer (2004), Nason and Smith (2005) and Canova and Sala (2005), have pointed out that such a structure is liable to identification problems. Here we discuss where and how these problems emerge.

The log-linearized version of the model consists of the following three equations for the output gap y_t, inflation π_t and the nominal rate r_t:

$$y_t = \frac{h}{1+h}y_{t-1} + \frac{1}{1+h}E_t y_{t+1} + \frac{1}{\phi}(i_t - E_t\pi_{t+1}) + \nu_{1t} \tag{2.10}$$

$$\pi_t = \frac{\omega}{1+\omega\beta}\pi_{t-1} + \frac{\beta}{1+\omega\beta}E_t\pi_{t+1} + \frac{(\phi+\nu)(1-\zeta\beta)(1-\zeta)}{(1+\omega\beta)\zeta}y_t + \nu_{2t} \tag{2.11}$$

$$i_t = \lambda_r i_{t-1} + (1-\lambda_r)(\lambda_\pi\pi_{t-1} + \lambda_y y_{t-1}) + \nu_{3t}, \tag{2.12}$$

where h is the degree of habit persistence, ϕ is the relative risk aversion coefficient, β is the discount factor, ω is the degree of price indexation, ζ is the degree of price stickiness, and ν is the inverse elasticity of labor supply, while $\lambda_r, \lambda_\pi, \lambda_y$ are monetary policy parameters. The first two shocks follow an AR(1) process with parameters ρ_1, ρ_2, while ν_{3t} is i.i.d. The variances of the shocks are denoted by $\sigma_i^2, i = 1, 2, 3$. For the sake of presentation, we assume that the shocks are contemporaneously uncorrelated even though, in theory, some correlation must be allowed for.

Since the model features three shocks and three endogenous variables, we can construct several limited information objective functions, obtained by considering

the distances of all the responses to only one type of shock, the distance of the responses of a sub-set of the endogenous variables to all shocks, and the distance of the responses of all variables to all shocks.

The model has 14 parameters: $\theta_1 = (\sigma_1^2, \sigma_2^2, \sigma_3^2)$ is underidentified from scaled impulse responses, just as in the previous example, the parameters of $\theta_2 = (\nu, \zeta)$ cannot be identified separately as they enter only in the slope of the Phillips curve (2.10) and in a multiplicative fashion, while $\theta_3 = (\beta, \phi, h, \omega, \lambda_r, \lambda_\pi, \lambda_y, \rho_1, \rho_2)$ contains the parameters of interest.

To construct aggregate decisions rules numerically, we set $\beta = 0.985, \phi = 2.0, \nu = 1.0, \zeta = 0.68, \omega = 0.75, h = 0.85, \lambda_r = 0.2, \lambda_\pi = 1.55, \lambda_y = 1.1, \rho_1 = 0.65, \rho_2 = 0.65$. With the aggregate decision rules we compute population responses and use 20 equally weighted responses to construct the distance function. We explore the shape of the distance function in the neighborhood of this parameter vector by tracing out how it changes when we change either one or two parameters belonging to θ_3 at a time, keeping the others fixed at their chosen values. As we have mentioned, identification problems could be due to solution or objective function pathologies. Here we convolute the two mappings, and directly examine how the shape of the objective function varies with θ, because the graphical presentation of these separate mappings is cumbersome.

Figure 2.1 plots the shape of the distance function when we vary β, ϕ, ω, h. Column 1 presents the distance function obtained using the responses of all three variables to monetary shocks; column 2 the distance function obtained using the responses of inflation to all shocks; and column 3 the distance function obtained using the responses of all variables to all the shocks. The range for the parameters considered is on the x-axis, while the height of the distance function for each parameter value is on the y-axis.

It is easy to see that monetary shocks have a hard time to identify the four structural parameters over the chosen intervals (the distance function is extremely flat in each of the parameters), that considering the responses of inflation to all shocks still leaves the coefficient of relative risk aversion pretty much underidentified, and that considering all the responses to all the shocks makes the distance function much better behaved. Still, asymmetries in the mapping between the risk aversion coefficient and the distance function remain even in this latter specification. Hence, taking a limited information approach, either in the sense of considering the responses of all variables to one shock or of one variable to all shocks, is problematic from an identification point of view.

One may wonder if this behavior is due to the choice of the parameters around which we map the distance function. The answer is negative. Canova and Sala (2005) construct the concentration statistic, defined as $C_{\theta_0}(i) = \int_{j \neq i} \frac{g(\theta) - g(\theta_0) d\theta}{\int (\theta - \theta_0) d\theta}, i = 1, \ldots, 9$, where g represents the distance function and θ_0 the pivot point, and let θ_0 vary over a reasonable range. Such a statistic synthetically measures how the multidimensional slope of the distance function changes around the selected parameter vector (see Stock, Wright and Yogo, 2002). Canova and Sala show that the minimum and maximum of this statistic in the range of θ_0 they consider varies

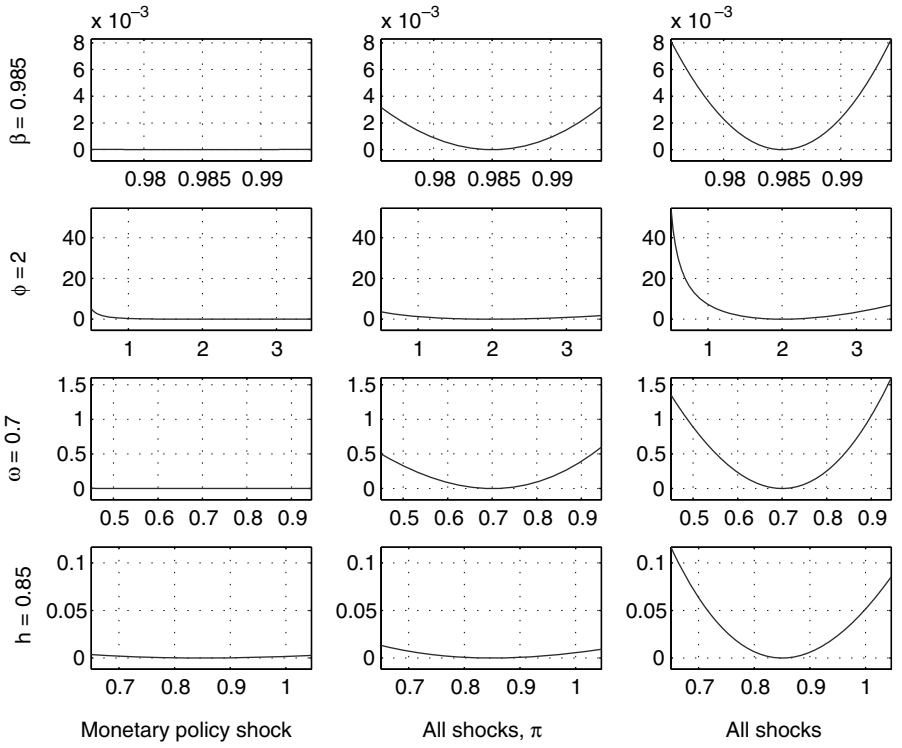

Figure 2.1 Shape of the distance function

very little, suggesting that the problems present in Figure 2.1 are not specific to the selected parameter vectors.

Since Figure 2.1 considers one dimension at a time, partial identification problems, where only combinations of parameters are identifiable, cannot be detected. Figure 2.2 shows that ridges indeed exist: for example, responses to monetary shocks carry little information about the correct combination of λ_y and λ_π; IS shocks cannot separately identify the risk aversion coefficient ϕ and the habit persistence parameter h, while Phillips curve shocks have little information about the discount factor β. What is interesting is that when the responses to all shocks are considered, some problems are reduced. For example, there appear to be fewer difficulties in identifying the parameters of the policy rule when all the responses to all shocks are considered – the distance function is more bell-shaped even though there is a significantly large flat area. However, even in this case, the true values of β, ϕ and h are difficult to pin down.

This model, in addition to partial, weak and underidentification problems, faces generic observational equivalence problems. For example, it would be hard to detect whether the data are generated by an indeterminate version of the model (which would be the case if $\lambda_\pi < 1$) or a determinate one ($\lambda_\pi > 1$), so long

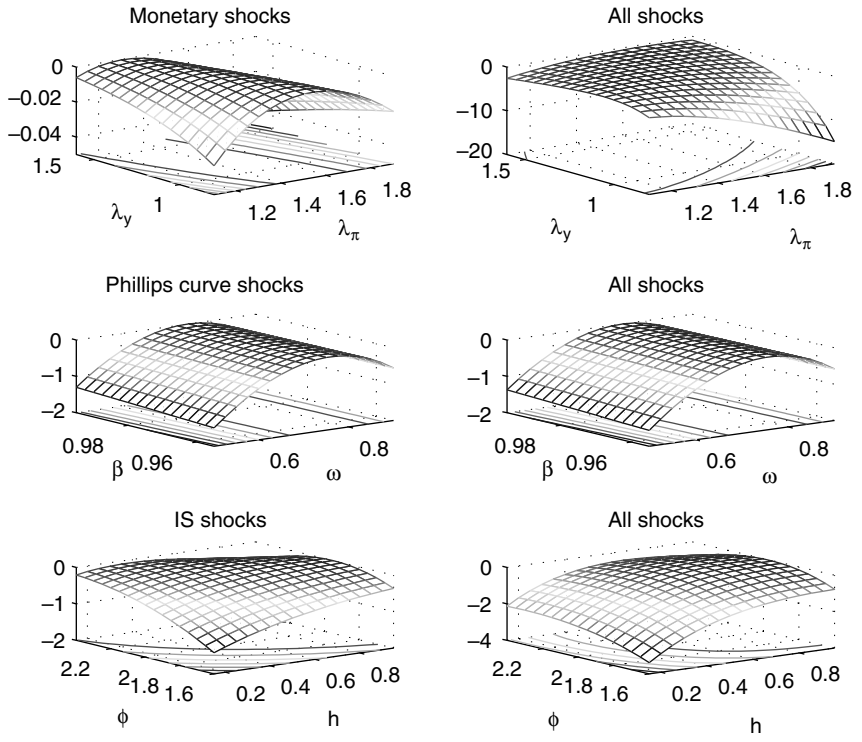

Figure 2.2 Distance function and contour plots

as the other parameters are allowed to be adjusted. Figure 2.3, which is reproduced from Canova and Gambetti (2007), shows that the shape and, in many cases, the size of the responses at almost all horizons to the three shocks are similar in the two regimes. Hence, if this were the only information available to the investigator, it would be difficult to detect which regime has generated the data.

This latter problem is a special case of a general pathology that applied investigators often face when dealing with DSGE models: the objective functions that one constructs from the aggregate decision rules may display multiple peaks, which may be clearly separated (as is the case in the above example; see also Lubik and Schorfheide, 2004) or not (see the example discussed in section 5 of Canova and Sala, 2005). Observational equivalence, probably more than any other identification problem, prevents attaching any meaningful economic interpretation to the outcomes of the estimation process and, obviously, conducting any meaningful policy analysis with the estimated model.

What generates the identification problems we have detected? All the nonlinear transformations, which are necessary to go from the structural parameters to the distance function, contribute. For example, consider the case of the price indexation parameter ω, which enters nonlinearly in the model and in several of

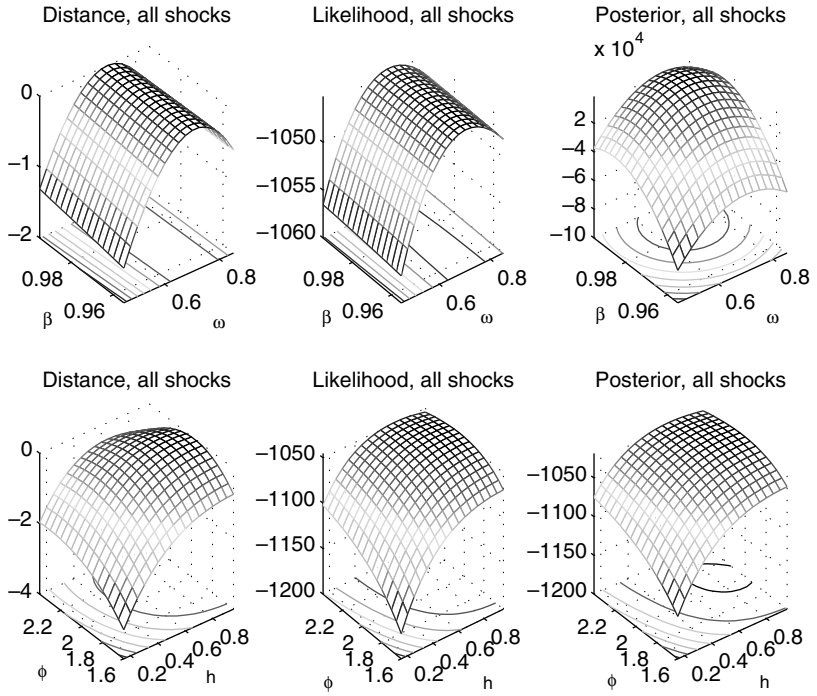

Figure 2.3 Impulse responses: determinate versus indeterminate equilibrium

the coefficients of the aggregate decision rules, but always in combination with other parameters. The coefficients of the restricted VAR solution are inverted to compute impulse responses and their distance from the "truth" is then squared and summed. One would guess that it is just by chance that such a complex set of operations will allow the mapping from ω to the objective function to be well behaved.

The standard answer to the problems shown in Figures 2.1 and 2.2 is to fix parameters with difficult identification features (after all, it does not matter what value we select) and estimate the remaining ones. While this approach is common, there is no guarantee that it will give meaningful answers to the questions of interest. In fact, while such a mixed calibration-estimation approach will be successful, at least in population, if the parameters that are treated as fixed are set at their true value, setting them at values which are only slightly different from the true ones may lead estimation astray. Intuitively this happens because, for example, setting β to the wrong value implies adjustments in parameters which enter jointly with β in the coefficients of the aggregate decision rules and this may move the minimum of the function in a somewhat unpredictable way. Canova and Sala (2005) show, in the context of a simple RBC example, that these shifts may be significant and may drive inference the wrong way.

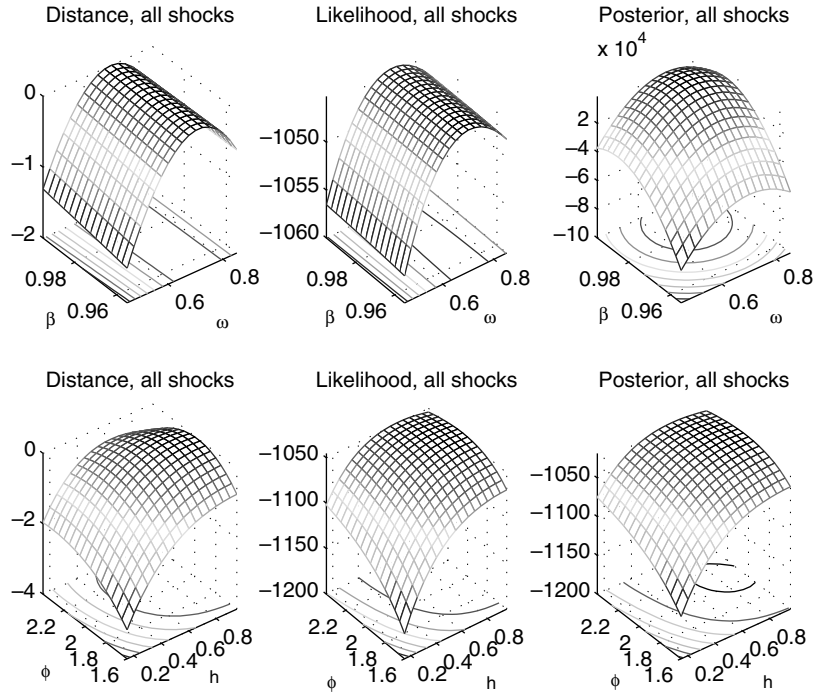

Figure 2.4 Distance function, likelihood and posterior plots

What can one then do to conduct structural estimation? The distance function we have employed can be obtained by approximating the likelihood function of the model. Therefore, the resulting estimators can be thought of as quasi-maximum likelihood (ML) estimators of the structural parameters. However, there is no reason to use such an approximation. Once the decision rules are written in a state space format, the likelihood function can be easily and efficiently computed with the Kalman filter. Therefore, identification problems could be reduced if information about the covariance matrix of the shocks or the steady-states of the model – which are not used when normalized impulse response matching is performed – are brought into the estimation. Figure 2.4, which plots the distance function when all the shocks are considered and the likelihood function in β and ω, and ϕ and h, indeed suggests that these parameters could be better identified from the likelihood than from the distance function – the curvature of the latter is much larger than the curvature of the former. Nevertheless, the problem with ridges remains. Since the likelihood has all the information that the model delivers, one can conclude that it is the solution mapping, rather than the objective function mapping, that induces under- and partial identification problems in this example.

It has become quite common to estimate the parameters of a DSGE model by Bayesian methods. Bayesian methods attempt to trace out the shape of the posterior

distribution of the structural parameters, which is proportional to the likelihood times the prior. The use of prior information could add curvature to the likelihood function, therefore making identification problems apparently disappear. We show how this can happen in the last column of Figure 2.4. A sufficiently tight prior has given the posterior a nice bell-shaped appearance with round contours in (β, ω). Clearly, the use of Bayesian methods are not the solution to the identification problems we have highlighted in this sub-section – it could, however, help when identification problems are caused by small samples. Achieving identification via prior restrictions does not change the fact that the likelihood function constructed through the lenses of the aggregate decision rules of the model has little information about the structural parameters. In this case the shape of the posterior distribution will, to a large extent, mimic the shape of the prior, so that structural estimation is nothing more than sophisticated calibration – rather than calibrating to a point, we calibrate to an interval, and within the interval we assume that some parameter values are more likely than others. When population identification problems exist and a researcher is interested in estimating the structural parameters, it is necessary to reparametrize the model. If this is infeasible or undesirable, then informal calibration is one simple and internally consistent device to make the model operative for inference and forecasting. The deep issue here is that DSGE models are not typically designed with an eye to the estimation of their parameters and this is clearly reflected in the identification problems they display.

Prior information on the parameters of macroeconomic models may come from different sources. It may be accumulated knowledge about a phenomenon repeatedly studied in the literature (for example, the properties of the transmission of monetary policy shocks), evidence obtained from micro-studies, or from the experience of other countries. All this information may be valuable to the applied investigator and should be formally introduced in the structural estimation of the model, if available. However, if the likelihood has little information about the structural parameters, and this additional information was all that was available to identify the parameters, structural estimation would not be particularly useful – it would resemble confirmatory analysis where prior expectations are verified *a posteriori*. In this situation, policy exercises are difficult to interpret, and the alternative of measuring the range of outcomes produced by the model using a selected range of parameters, as suggested in Canova (1995), is a feasible and more plausible approach.

What are the consequences of the identification problems we have described? For the sake of presentation, we will focus on estimates obtained by matching responses to monetary policy shocks, which appear to produce the distance function with the worst identification properties, and are those on which the literature has paid most attention. In this exercise we still assume that shocks are correctly identified – in our model, reduced-form interest rate innovations are the true monetary policy shocks. If this were not true, additional problems, such as those discussed in, for example, Canova and Pina (2005), would be compounded by those discussed here. We consider different sample sizes, on the one hand, to highlight some of the properties of the estimates of parameters

with problematic identification features and, on the other, to examine whether additional identification problems may emerge just because of small samples.

We simulate 200 time series for interest rates, the output gap and inflation for $T = 120, 200, 1000$, fixing $\nu = 1$ and $\sigma_i^2 = 1.0$ in all cases; we estimate an unrestricted VAR(2), which is the correct empirical reduced form model to use in this case, and compute impulse responses and bootstrap confidence bands which are then used to build a diagonal matrix of weights: the weights are inversely proportional to the uncertainty in the estimates. Table 2.1 presents a summary of the estimation results. It reports the true parameters, the mean estimate, the numerical standard errors computed across replications (in parentheses) and the percentage bias (in square brackets).

A few features of the table are worth commenting upon. First, biases are evident in the estimates of the partially identified parameters (λ_π, λ_y), the weakly identified parameters (ζ, ω, h), and the underidentified parameters $(\rho_1,\ \rho_2)$. Note that even with 250 years of quarterly data, major biases remain. Second, numerical standard errors are large for the partially identified parameters and invariant to sample size for the underidentified ones. Third, parameter estimates do not converge to population values as T increases. Finally, and concentrating on $T = 200$, estimates suggest economic behavior which is somewhat different from that characterizing the DGP. For example, it appears that price stickiness is stronger and central bank reaction to the output gap and inflation is equally strong.

In sum, identification problems lead to biased estimates of certain structural parameters (see also Choi and Phillips, 1992), to inappropriate inference when conventional asymptotic theory is used to judge the significance of estimated parameters, and, possibly, to wrong economic interpretations. For unconditional forecasting, identification problems are unimportant: as long as the fit and the forecasting performance is the same, the true nature of the DGP does not matter. However, policy analyses and conditional forecasting exercises conducted with estimated parameters may lead to conclusions which are very different from

Table 2.1 NK model: matching monetary policy shocks

	True	$T = 120$			$T = 200$			$T = 1000$		
β	0.985	0.984	(0.007)	[0.6]	0.985	(0.007)	[0.7]	0.986	(0.008)	[0.7]
ϕ	2.00	2.39	(2.81)	[95.2]	2.26	(2.17)	[70.6]	1.41	(1.19)	[48.6]
ζ	0.68	0.76	(0.14)	[19.3]	0.76	(0.12)	[17.5]	0.83	(0.10)	[23.5]
λ_r	0.20	0.47	(0.29)	[172.0]	0.43	(0.27)	[152.6]	0.41	(0.24)	[132.7]
λ_π	1.55	2.60	(1.71)	[98.7]	2.22	(1.51)	[78.4]	2.18	(1.38)	[74.5]
λ_y	1.1	2.82	(2.03)	[201.6]	2.56	(2.01)	[176.5]	2.16	(1.68)	[126.5]
ρ_1	0.65	0.52	(0.20)	[30.4]	0.49	(0.21)	[34.3]	0.50	(0.19)	[31.0]
ρ_2	0.65	0.49	(0.20)	[32.9]	0.48	(0.21)	[34.8]	0.48	(0.21)	[34.7]
ω	0.25	0.76	(0.39)	[238.9]	0.73	(0.40)	[232.3]	0.65	(0.38)	[198.1]
h	0.85	0.79	(0.35)	[30.9]	0.76	(0.37)	[32.4]	0.90	(0.21)	[21.3]

those obtained with the true one. Hence, it is generally unwise to attach any economic interpretation to the estimates or draw conclusions about how the economy works from structural exercises which are plagued by identification problems.

What is left for the applied investigator to do? Apart from attempting to reparametrize the model, not much. One interesting issue still unexplored in the literature is to take population identification problems as being the norm rather than the exception, and try to find estimation techniques or objective functions which, given a sample size, are able to minimize the distortions produced by identification pathologies. While some progress has been made in the context of moment estimation (see Stock and Wright, 2000; Rosen, 2006), these procedures are applicable only in restrictive situations (the weighting matrix must be chosen in a particular way) and are awkward to use in DSGE models, which are highly parameterized and nonlinear.

How does one detect identification problems? The univariate and bivariate exploratory analysis we have presented, for example, in Figures 2.1 and 2.2 can definitely help in spotting potential problems and this analysis could easily be complemented with local derivatives of the objective function in the dimensions of interest. Alternatively, numerically computing the Hessian of the objective function around particular parameter values and calculating the size of its eigenvalues can give more formal indications on how flat or how information-deficient the objective function is locally. For example, if the rank of the Hessian is less than the number of structural parameters, one of its eigenvalues is zero and at least one parameter is underidentified. If the rank of the Hessian is close to deficient, one or more of its eigenvalues is close to zero and either weak or partial identification problems, or both, are likely to be present. Experimentation with the number of shocks used to construct the objective function and the number of variables can also give useful information about what statistic may identify a particular structural parameter, as is experimentation with different objective functions and with different features of the data (for example, steady-state versus dynamics).

Clearly, diagnostics of this type have to be run prior to estimation, but such an exercise is not much more complicated or time consuming than the type of exercises one performs to measure the sensitivity of the results to the selection of calibrated parameters. In general, the following rules of thumb are useful to limit the extent of identification problems: given a model, always choose a likelihood-based objective function, which has the highest informational content; given a model and the likelihood function, and if it is the sample which is problematic, add information in the form of additional data or prior restrictions, which synthetically reproduces it.

It is important to stress that looking at the minimized value of the objective function, at standard errors of the estimates or at the resulting impulse responses, is not generally useful as an *ex post* device to detect identification problems. The distance function is within the tolerance level (10^{-7}) for all the parameter combinations generating Table 2.1, and the practice of blowing up the objective function by appropriately choosing the matrix of weights will not change the fact that the

gradient or the Hessian display problematic features. Furthermore, it can be shown that population responses fall within a 68% band centered around the estimates of the responses to monetary shocks computed with the parameter estimates, even when the sample size is $T = 120$. Therefore, the practice of showing that the model's responses computed using the estimated parameters lie within the confidence bands of the responses estimated from the data is not particular informative as far as identification problems are concerned. Large standard errors do emerge when identification failures exist, but also when other problems are present (for example, very noisy data or regime switches). Hence, associating large standard errors with identification issues is, in general, incorrect.

It is also important to stress that the addition of measurement errors for estimation purposes can distort the identification properties of structural parameters. It is not particularly difficult to conceive situations where a parameter that was identified by certain features of the model becomes free to move and fit other properties of the data it was not designed for, once measurement error is added. Therefore, while there is some logic in adding measurement errors to link the model variables to the observables, one should be careful and investigate the consequences that such a process has on the identification properties of the parameters.

2.3 Structural VARs

Structural VAR inference is typically perceived to be at the extreme opposite to structural model-based inference. SVAR models take a minimalist approach to the estimation problem and consider only a very limited sub-set of the large number of restrictions that DSGE models impose on the data. For example, the fact that the matrices H_1 and H_2 in (2.4) depend on θ is typically neglected and only a part of the information present in $A_0(\theta)$ is used. Furthermore, the singularity that the model imposes on the data is completely disregarded.

This minimalist approach has one obvious disadvantage: if less structure is imposed on the data, fewer interesting economic questions can be asked. However, such a limited information approach is advantageous when some of the model's restrictions are dubious, which would be the case if the model is misspecified in some dimensions, or fragile, which would be the case if the restrictions depend on the functional forms or the parameter values one specifies. In this case, neglecting these restrictions can robustify estimation and inference.

As we have mentioned in the introduction, and despite recent attempts to make them more realistic, the current generation of DSGE models is still far from reproducing the DGP of the actual data in many respects: models fail to capture, for example, the heterogeneities present in the actual world; important relationships are modeled with black-box frictions; timing restrictions are used to make them compatible with the dynamics observed in the data; and *ad hoc* shocks are often employed to dynamically span the probabilistic space of the data. Since misspecification is likely to be pervasive, system-wide and even limited-information classical structural methods are problematic, even when identification problems are absent.

Bayesian methods have an edge in structural estimation when model misspecification is present. Inference in this context, in fact, does not require the asymptotic correctedness of the model under the null. Furthermore, these methods can potentially deal with model misspecification, for example, by imposing prior distributions over models and weighting the posterior information contained in each of them by their posterior probability. However, this potential advantage of Bayesian methods is often unexpressed: except for Schorfheide (2000), it is very unusual for researchers to consider an array of models, all of which can potentially be useful to answer the question of interest. In this situation, one is often left wondering what posterior estimates obtained from a misspecified model mean in practice and whether policy makers could and should trust these estimates when taking important policy decisions.

The difficulties of the current generation of DSGE models in representing the DGP of the data have been highlighted by Del Negro *et al.* (2006), who take a workhorse model, popular among academics and central bankers, and show that it is possible to improve its fit by considerably relaxing the cross-equation restrictions that it imposes on the matrices $H_1(\theta)$ and $H_2(\theta)$. Their approach, which uses a DSGE model as a prior for a VAR, is useful for designing a metric to assess the distance between the model and the VAR of the data, and represents a promising way to evaluate model fit, to suggest ways to bring models in closer contact with the data and, in general, to conduct structural inference in misspecified models.

If one takes the inherent misspecification that the current generation of DSGE models display seriously and heavily weights inferential mistakes, one may then want to proceed in a more agnostic way. Rather than conditioning on one model and attempting to estimate its structural parameters, one could be much less demanding in the estimation process, and employ a sub-set of the model restrictions, which are either uncontroversial or likely to be shared by a class of economies with potentially different features, to identify structural shocks. One way of doing this is to neglect the restrictions present in the matrices H_1 and H_2, which are often not robust, and use some of those present in $A_0(\theta)$, for which a strong *a priori* consensus can be found in theory, and then trace out the dynamics of the variables of interest in response to disturbances or measure the relative importance of each shock for business cycle fluctuations. Therefore, with such an approach, most of the detailed cross-equation restrictions imposed by a model will be eschewed from the estimation process and only constraints which are likely to hold in many models are used to identify structural shocks. Unfortunately, it has become common in the literature to employ constraints which are unrelated to any specific class of models or are so generic that they lack economic content. While 20 years ago researchers spent considerable time and effort justifying their identification restrictions from a theoretical point of view (see, for example, Sims, 1986; Bernanke, 1986), now it is often the case that these restrictions are not even spelled out in detail, and the only justification for them a reader can find is that they are used because someone else in the literature has used them before. In general, delay-type restrictions, which use the flow of information accrual to agents in the economy, and placing zeros in the impact matrix of shocks, are the preferred identification devices.

Canova and Pina (2005) have shown that delay-type restrictions do not naturally arise in general equilibrium models, are often inconsistent with their logic, and one has to work hard to cook up general equilibrium environments with such features (see, for example, Rotemberg and Woodford, 1997). Long-run restrictions have been hailed in the past as the answer to these problems, since restrictions of this type are common to a variety of theories (for example, money neutrality or the idea that technological progress explains the long-run path of variables are features which are shared by macro-models with different micro-fundations) and allow inference without tying one's hand to a particular specification for the short-run dynamics around these long-run paths. However, this alternative identification approach is non-operative: long-run restrictions are scarce relative to the number of shocks researchers are interested in recovering. Therefore, when four or five shocks need to be identified, one is forced to use a mixture of long-run and delay restrictions. Furthermore, as pointed out by Faust and Leeper (1997), long-run restrictions are weak and prone to observational equivalence problems.

The sign and shape approach, suggested in Canova and De Nicoló (2002) and Uhlig (2005), is advocated in the next section and can bridge SVAR and DSGE models in a more solid way and provide a constructive answer to the quest for identification restrictions. Unfortunately, such an approach does not yet have widespread use in the profession (exceptions are, among others, Dedola and Neri, 2007; Pappa, 2005) and the science of identification in SVARs is still very much the craft of finding restrictions that would not bother anyone in the profession.

Apart from identification issues, which have received attention in the VAR literature since, at least, Cooley and LeRoy (1985), a number of authors have recently questioned the ability of structural VARs to recover the true DGP of the data, even when an appropriate identification approach is used. To see why this could be the case, consider the following alternative restricted state space representation for the log-linearized aggregate decision rules of a DSGE model:

$$\begin{aligned} x_{1t} &= J(\theta)x_{1t-1} + K(\theta)e_t \\ x_{2t} &= N(\theta)x_{1t-1} + M(\theta)e_t, \end{aligned} \tag{2.13}$$

where $e_t \sim iid(0, \Sigma_e)$. The questions we ask are the following: (i) Does a VAR representation for a subset of the variables of the model, say x_{2t}, exist? (ii) Would the resulting VAR be of finite order? (iii) What would happen to inference if only a sample of limited size is available? We have already mentioned that, if both x_1 and x_2 were observable, (2.12) is simply a restricted, though reduced rank, VAR(1). However, this is not a very realistic set-up: usually x_{1t} includes non-observable variables; furthermore, only a sub-set of the variables appearing in x_{2t} may be of interest, could be reasonably measured, or have relevant information for the exercises one may want to conduct. Therefore, it is legitimate to ask what the process of integrating out non-observable, uninteresting or badly measured variables would imply for the restricted time series representation of the aggregate decision rules of the model.

2.3.1 Invertibility

If $M(\theta)$ is a square matrix, and if $J(\theta) - K(\theta)M(\theta)^{-1}N(\theta)$ has a convergent inverse (for example, if all its eigenvalues are less than 1 in absolute value), it is easy to show that:

$$x_{2t} = N(\theta)\{[1 - (J(\theta) - K(\theta)M(\theta)^{-1}N(\theta)]^{-1}K(\theta)M(\theta)^{-1}\}x_{2t-1} + u_t, \qquad (2.14)$$

where $u_t \sim (0, M(\theta)'\Sigma_e M(\theta))$. Therefore, if only x_{2t} is observable, the aggregate decision rules have a restricted VAR(∞) representation. If instead $N(\theta)$ is a square matrix, then:

$$x_{2t} = N(\theta)J(\theta)N(\theta)^{-1}x_{2t-1} + (I + (N(\theta)K(\theta)M(\theta)^{-1} - N(\theta)J(\theta)N(\theta)^{-1})\ell)u_t, \quad (2.15)$$

where ℓ is the lag operator. Under this alternative assumption, the aggregate decision rule for x_{2t} therefore has a VARMA(1,1) representation.

Hence, if a reduced number of variables is considered, the aggregate decision rules of the model have a much more complicated structure than a restricted VAR(1). The question of interest is whether we can still use a VAR with a finite number of lags to approximate the aggregate decision rules for x_{2t}. Straightforward algebra can be used to show that if the exogenous driving forces are AR(1) and if both the predetermined states and x_{2t} are observed, then the correct representation for the vector of predetermined states and choice variables is a restricted VAR(2) with singular covariance matrix. On the other hand, if only x_{2t} is observable and the dimension of x_{2t} is the same as the dimension of e_t, Ravenna (2006) has shown that the aggregate decision rules for x_{2t} can be approximated with a finite order VAR if and only if the determinant of $\{I - [J(\theta)K(\theta)M(\theta)^{-1}N(\theta)]\ell\}$ is of degree zero in ℓ.

What does this all mean? It means that the aggregate decision rules for a sub-set of the variables of the model can be represented with a finite order VAR only under a set of restrictive conditions. These conditions include invertibility of the mapping between structural shocks and the variables included in the VAR, a fundamentalness condition, which implies that the information contained in the observables is the same as the information contained in disturbances of the model, and the condition that random perturbations produce fluctuations around the steady-state that are not too persistent.

Note that the condition we have used to derive (2.13), is never satisfied in practice. One can think, at best, of four or five truly structural sources of disturbances and this typically is much less than the size of the vector x_{2t}. Therefore, it is only after *ad hoc* disturbances and/or measurement errors are *ex post* included that $M(\theta)$ is a square matrix. Similarly, the restriction that $N(\theta)$ is a square matrix is difficult to satisfy in practice – the number of states is typically smaller than the number of endogenous variables. The other conditions clearly depend on the structure of the model but, for example, specifications in which agents react to news that may materialize in the future fail to satisfy the first condition – the resulting MA representation of the model is nonfundamental. Finally, the convergence of the

economy to its steady-state when perturbed by shocks depends on the details of the specification. Therefore, it is difficult to assess how important in practice this assumption is. Given that many DSGE models have fairly weak internal propagation mechanisms, and as long as the structural shocks are stationary, such a condition is likely to be satisfied in practice.

In sum, one should not be surprised to find DSGE models featuring aggregate decision rules for a sub-set of the variables that are not representable with a finite-order VAR (see Fernandez-Villaverde *et al.*, 2007, for examples). Nevertheless, a large class of models does have aggregate decision rules with these properties. To be sure that SVAR inference is valid, one must first select a class of models which could have generated the data and check whether the required conditions are satisfied for alternative parameterizations. While this requires a SVAR investigator to take a certain class of models much more seriously before drawing any inference from his/her analysis, it also makes SVAR estimation less straightforward and more time consuming since the number of parameters, functional form and friction permutations that need to be checked before the analysis is conducted is large. Furthermore, since bizarre counter-examples can always be found, it may become difficult for an applied macroeconomist to assess in practice whether a finite order VAR is a good approximation to the class of DSGE models one is interested in or not.

For the final question, Chari, Kehoe and McGrattan (2006) have recently shown that one may be led astray when evaluating the relevance of economic theories using SVARs simply because, with small samples, the population properties of the aggregate decision rules may be very poorly approximated with a VAR. That is to say, even when there exists a VAR representation for the variables in x_{2t}, when this representation is of finite order, and when identification of shocks is properly performed, small sample biases in the estimates of the reduced form parameters and the covariance matrix of the shocks may make inference whimsical. For example, they show that a short sample of data simulated from an RBC model driven by a neutral technology shock may lead a researcher to believe that it could have been generated by a model with different microfundations – in the population, hours worked increases in response to a technology shock, but in small samples hours may fall in response to the correctly identified technology shocks.

An applied investigator has to live with small sample biases. Long samples, even when they are available, are rarely used because causal relationships are often subject to important regime shifts, and when regime shifts are absent, changes in the definition or in the way the data is sampled or computed make empirical analysis difficult. Econometrics can help here: it is well known that in a variety of experimental designs and with samples of about 100 observations, estimates of the AR(1) coefficient are downward biased by up to 30%. While this type of analysis could be easily extended to more realistic and interesting economic models – for example, to measuring the size of the bias in the largest autoregressive root of the aggregate decision rule (which roughly determines the dynamics of the system) and in the eigenvalues of the covariance matrix of reduced form shocks (which determines the size of the impact effects) – one needs to consider models where the impact effect is fairly weak to have important sign reversals in small samples. Therefore,

while such an issue should be kept in mind, its practical relevance appears to be limited.

There is another way of seeing these representation problems from a different and probably more informative viewpoint – that of omitted variables and shock misaggregation, which have a long tradition in the VAR literature (see, for example, Braun and Mittnik, 1993; Faust and Leeper, 1997). Suppose the aggregate decision rules for the endogenous variables of a DSGE model can be written as a VAR(1):

$$\begin{bmatrix} I - A_{11}\ell & A_{12}\ell \\ A_{21}\ell & I - A_{22}\ell \end{bmatrix} \begin{bmatrix} y_{1t} \\ y_{2t} \end{bmatrix} = \begin{bmatrix} B_1 \\ B_2 \end{bmatrix} e_t,$$

where y_{1t} are the variables included and y_{2t} the variables excluded from the empirical model and where these vectors do not necessarily coincide with those of the state variables x_{1t} and the choice variables x_{2t}. Then the representation for y_{2t} is:

$$(I - A_{22}\ell - A_{21}A_{12}(1 - A_{11}\ell)^{-1}\ell^2)y_{2t} = [B_2 - (A_{21}(1 - A_{11}\ell)^{-1}B_1\ell]e_t \equiv \upsilon_t. \quad (2.16)$$

When y_{1t} and y_{2t} are of the same dimensions, this simplifies to:

$$[I - (A_{11} + A_{22})\ell + (A_{11}A_{22} - A_{21}A_{12})\ell^2]y_{2t} = [B_2 + (A_{21}B_1 - A_{11}B_2)\ell]e_t \equiv \upsilon_t. \quad (2.17)$$

What does this reduced system representation imply? First, it is easy to see that the model for y_{2t} is an ARMA(∞, ∞) and the lagged effect of the disturbances mixes up the contemporaneous effects of different structural shocks ($B_1 e_{t-1}$ has smaller dimension than e_{t-1}). Furthermore, it is clear that even if the e_ts are contemporaneously and serially uncorrelated, the υ_ts are contemporaneously and serially correlated and that two small-scale VARs featuring different y_{2t}s will have different υ_ts. Finally, since υ_t is a linear combination of current and past e_t, the timing of the innovations in y_{2t} is not preserved unless A_{11} and A_{21} are both identically equal to zero, which is true, for example, if y_{2t} includes the states and y_{1t} the controls of the problem.

In other words, (2.16) implies that shocks extracted from a SVAR featuring a reduced number of the model's variables are likely not only to confound structural shocks of different types, but also to display time series properties which are different from those of the true shocks to these variables. Hence, even if the correct identifying restrictions are used, VAR models which are small relative to the universe of variables potentially produced by a DSGE model are unlikely to be able to capture either its primitive structural disturbances or the dynamics they induce unless some strong and not very practically relevant conditions hold.

Contrary to the previous representation of the invertibility problem, which provides little guidance on how to check for failures, this latter representation does give researchers a way to measure the importance of potentially omitted variables. In fact, if omitted variables are important, reduced form VAR residuals will be correlated with them. Therefore, for any given set of variables included in the VAR, it is sufficient to check whether variables potentially belonging to y_{1t} display significant correlation with the residuals. If so, they should be included in the VAR and estimation repeated; if not, they can be omitted without further ado.

To conclude, we present two examples below illustrating the issues we have discussed in this section. In the first example, noninvertibility emerges because the model has a nonfundamental representation. In the second, the MA of the model is invertible, but the dynamics of the reduced system are different from those of the full one.

2.3.1.1 Example 3: a Blanchard and Quah economy

The example we present belongs to the class of partial equilibrium models popular in the late 1980s. While it is not difficult to build general equilibrium models with the required features, the stark nature of this model clearly highlights how invertibility problems could occur in practice. The model that Blanchard and Quah (1989) consider has implications for four variables (gross domestic product (GDP), inflation, hours and real wages) but the solution is typically collapsed into two equations, one for GDP growth (ΔGDP), the other for the unemployment rate (UN_t), of the form:

$$\Delta GDP_t = \epsilon_{3t} - \epsilon_{3t-1} + a(\epsilon_{1t} - \epsilon_{1t-1}) + \epsilon_{1t} \tag{2.18}$$

$$UN_t = -\epsilon_{3t} - a\epsilon_{1t}, \tag{2.19}$$

where ϵ_{1t} is a supply shocks, ϵ_{3t} a money supply shock and a is a parameter measuring the impact of supply shocks on aggregate demand. Hence, the aggregate decision rule for these two variables is a VMA(1). It is easy to check that a finite-order VAR may approximate the theoretical dynamics of this model only if $a > 1$.

To see this, we set $a = 0.1$ and plot in Figure 2.5 the theoretical responses of output and unemployment to the two shocks and the responses obtained using a VAR(1) and a VAR(4), where the econometrician uses the correct (but truncated) vector autoregressive representation of the model. Note that, while the signs of the responses are correct, the dynamics are very different. Also, while there is some improvement in moving from a VAR(1) to a VAR(4), some of the theoretical responses are very poorly approximated even with a VAR(4). Since a VAR(q), $q > 4$, has responses which are indistinguishable from those of a VAR(4) – as the matrices on longer VAR lags are all very close to zero – no finite-order VAR can capture (2.17) and (2.18).

What generates this result? When $a < 1$ the aggregate decision rules of the model are nonfundamental, that is, innovations to output growth and unemployment do not have the same information as the variables themselves. Therefore, there is no convergent VAR representation for these two variables where the roots of the VAR are all less than one in absolute value, and this is true even when an infinite lag length is allowed for.

2.3.1.2 Example 4: an RBC model

We work with the simplest version of the model since more complicated structures do not bring additional insights into the problem. The social planner maximizes:

$$E_0 \sum_{t=0}^{\infty} \beta^t \frac{c_t^{1-\phi}}{1-\phi} - AN_t, \tag{2.20}$$

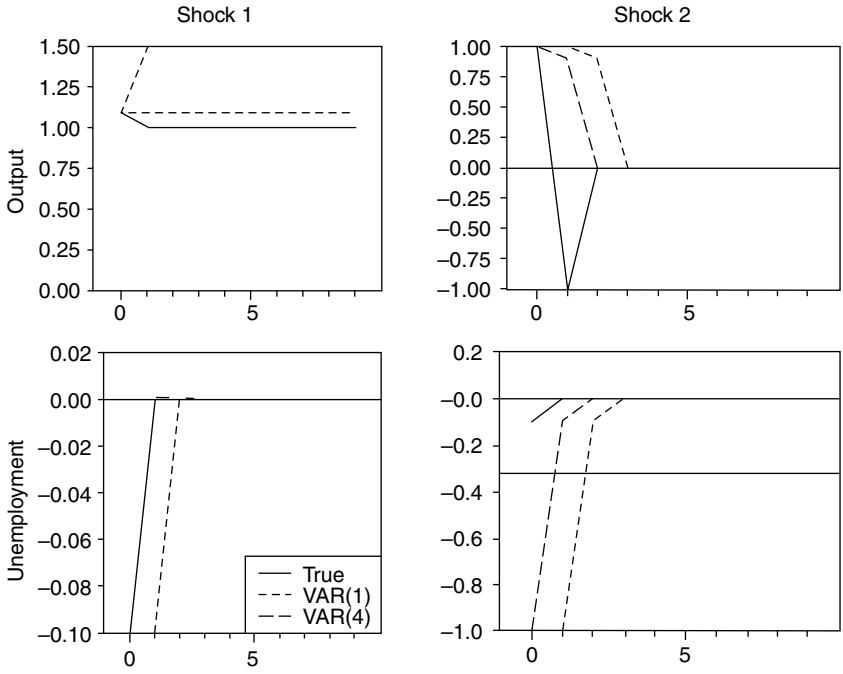

Figure 2.5 Responses in the Blanchard and Quah model

and the resource constraint is:

$$c_t + k_t + g_t = k_{t-1}^{\eta} N_t^{1-\eta} z_t + (1-\delta)k_{t-1}, \tag{2.21}$$

where c_t is consumption and ϕ is the risk aversion coefficient, A is a constant and N_t are hours worked; z_t is a first-order autoregressive process with persistence ρ_z, steady-state value z^{ss} and variance σ_z^2; g_t is a first-order autoregressive process with persistence ρ_g, steady-state value g^{ss} and variance σ_g^2; k_{t-1} is the current capital stock; η is the share of capital in production, and δ the depreciation rate of capital. Using the method of undetermined coefficients, and letting output be $y_t \equiv k_{t-1}^{\eta} N_t^{1-\eta} z_t$, and investment be $i_t = k_t - (1-\delta)k_{t-1}$, the aggregate decision rules for $(k_t, c_t, N_t, y_t, r_t, i_t)$, where r_t is the real rate, imply standard dynamics in response to the two shocks. In particular, as z_t increases, hours, consumption, output, the real rate and investment increase contemporaneously while the dynamics of the capital stock have a hump-shaped pattern. On the other hand, as g_t increases, consumption falls, hours, output, the real rate and investment increase contemporaneously and the capital stock has a hump-shaped pattern.

What would the dynamics induced by the two shocks in a system which includes only the interest rate and investment look like? That is, what would happen if we integrate out the effect of the shocks on the other four variables? Figure 2.6 plots the responses of the two variables of interest to the two shocks in the full and the

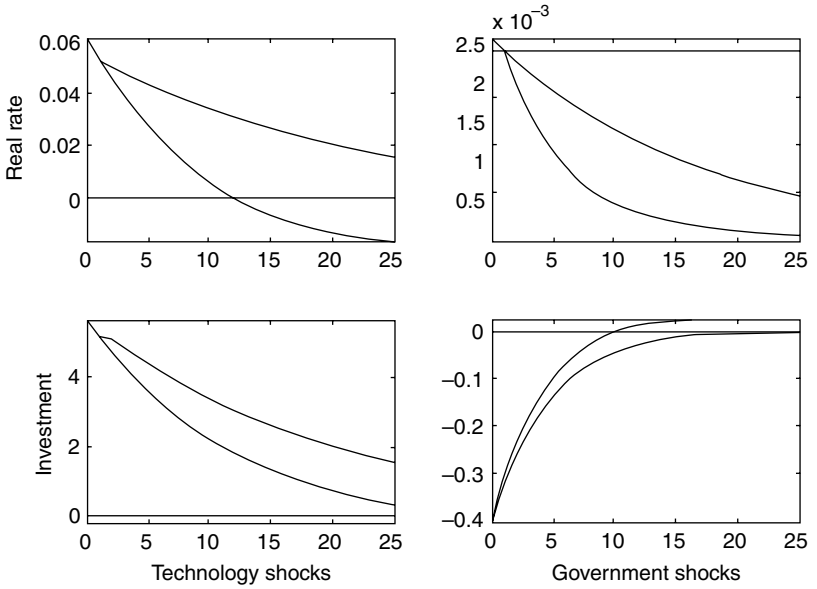

Figure 2.6 Dynamics in an RBC model

reduced systems. Clearly, while the impact effect is identical, lagged dynamics are very different.

What is the reason for this result? Mechanically, since A_{11} and A_{21} are not small, shocks last more than one period and persist for a number of periods. Notice that the persistence in the reduced system is strong (see, for example, the effect of technology shocks on the real rate), suggesting that the process of marginalizing part of the system has serious consequences on the responses of the variables to shocks, at least in this example.

It goes without saying that it makes a lot of difference which of the two systems one uses as a benchmark to represent the DSGE model and in trying to see whether actual and simulated data are similar or not.

2.4 Some final thoughts

The previous two sections may have given the reader a rather pessimistic view about the possibility of conducting meaningful inference with DSGE models and the impression that not many alternatives are left to the applied investigator. If structural estimation is pursued, misspecification of the structural relationships may make the interpretation of estimates difficult; identification problems are likely to be widespread and even in the unlikely case when they are not present, a number of additional statistical and specification assumptions need to be made, making it very difficult to judge what is causing what. The alternative of using SVARs seems to be equally problematic. While VARs are less prone to misspecification of the

structural relationships, identification problems are still present and noninvertibility of the DSGE models aggregate decision rules may also make SVAR analyses uninterpretable.

Chari, Kehoe and McGrattan (2007) have suggested using the so-called business accounting method to evaluate DSGE models, but the logic of the approach represents a step backward relative to what we discuss here – only reduced form relationships are used to judge what is missing from the model – and it is hard to avoid important observational equivalence problems when judging different structural models of the business cycle.

What, then, should one do? No matter which approach one takes, one should be very careful and learn how to interpret the information contained in the diagnostics obtained from experimenting with the structure of the model and investigating the properties of the data. If structural estimation is performed, methods which allow for misspecification should be preferred and extra information, in the form of micro-data or data from other countries, may help to break the deadlock of parameter identification when problems are due to small samples. We have suggested that to solve population identification problems it is necessary to reparameterize or respecify DSGE models, but obviously this is a more long-term goal, since such an approach brings us back to the very basic foundation of DSGE-based exercises. Nevertheless, if theorists would build models bearing in mind that they will be estimated, certain issues could be completely avoided.

If SVAR analysis is preferred, one should link the empirical model to DSGE theories much better than has been done so far, explicitly write down the class of models one will employ to interpret its results (as done, for example, in Canova and De Nicoló, 2002), and perform the preliminary analysis necessary to check whether the aggregate decision rules of such a class of models do have a finite-order VAR format for the sub-set of relevant variables used in the VAR. Identification should also be clearly linked to the class of structural models of interest and artificial delay restrictions avoided. One way of doing this is described in Canova (2002), where robust restrictions on the sign of responses to shocks derived from a class of models are used to identify shocks, and the results of the analysis are discussed through the lenses of such models. Canova and Paustian (2007) show that such an approach has good size and power properties against local alternatives and gives reasonable results in inappropriately marginalized systems.

Integrating structural and VAR analyses, as suggested by Del Negro and Schorfheide (2004, 2005, 2006), also provides an interesting avenue for future research, where structural models and empirical analyses can cross-fertilize each other.

From the point of view of policy makers, DSGE models are useful if they can forecast well, since it is much easier to tell stories with estimates of their parameters than with SVAR estimates or estimates of pure time series models. However, to forecast at least as well as more unrestricted models, the DSGE models popular in the academic literature must produce restrictions which are not rejected in the data, and this is pretty hard to do when one considers, for example, prices rather than

quantities and financial or monetary variables rather than real ones. In addition, to test the quality of these restrictions one needs substantial "cosmetic surgery" in the form of additional shocks, frictions and other black-box jingles, which are difficult to justify from a theoretical point of view and make any hypothesis a joint test of the restrictions and the chosen add-ons. Realizing these facts should probably lead academics and policy makers to be less demanding of the models they write down and use. Typically, small models forecast better than larger ones and different models can be used for different purposes. Having an array of models at one's disposal, which are built to answer different economic questions, and averaging their forecasting results may not only robustify the outcomes of the investigation but also give an entirely different perspective on the reasons driving certain economic phenomena.

While one can envision the disappearance of the "model" of the economy as conceived in the 1970s, constructed by patching up pieces of theoretical structures and a lot of empirical wisdom, and used to answer all possible questions policy makers may have, it is very likely that smaller scale, more or less structurally oriented models will coexist in the portfolio of research departments of central banks and international institutions for a while, serving different purposes and different objectives.

To go back to the main question of this chapter, how much structure should there be in an empirical model? The solomonic and, probably, obvious answer, is that it depends on the scope of the analysis and the information available in the data. Different models can have different structural content if they serve different purposes. Nevertheless, it should be clear that certain policy exercises can be conducted only in models where expectations and general equilibrium features are fully taken into account and where the predictive content of pure time series models is close to nonexistent as the horizon of the forecast surpasses one year. Small-scale structural models that allow a large number of policy exercises and at the same time offer some indication of the potential developments one to two years ahead are probably the ones that will survive the dust of time in the longer run.

Introductory Remarks on Metastatistics for the Practically Minded Non-Bayesian Regression Runner

John DiNardo

Abstract

It would appear that much debate among practically minded researchers in economics, social science, and in other fields, is rooted in (frequently) unstated assumptions about the underlying philosophical justification for the statistical procedures being debated. In this chapter, I try to provide a simple non-technical introduction to some long-standing debates about "metastatistical" questions, especially those that divide (some) "Bayesians" from (some) non-Bayesians while attempting to draw out some implications for the "practically minded non-Bayesian regression runner." Some of the issues which have prompted the most raucous debate in philosophical circles include: the meaning of "probability," the importance or unimportance of pre-designation (pre-specified research design), the role of "models," and the practical value of hypothesis testing and other common statistical practices. I discuss some of the links between these philosophical views and actual practice and consider two different case studies – one from medicine and another from labor economics.

3.1 Introduction

> "Everything has already been said, but perhaps not *by* everyone and *to* everyone."[1]

The purpose of the somewhat silly title of this chapter is to warn the reader what not to expect. This is not intended as a "proper" introduction to metastatistics, which I could not write, of which there are several very good ones.[2] Given the enormous amount of writing on the subject, it is not surprising then that none of the ideas or arguments will be original.[3]

An even sillier title that some might use to describe the following is: "A jaundiced appraisal of some extreme Bayesian views by someone who just doesn't get it."

That is, of course, not my intent. Rather, I think that it is sometimes useful for the practically minded non-Bayesian regression runner (like myself) to consider some of the basic "philosophical" issues at the heart of statistics and econometrics. My purpose is also to bring some of the issues debated in metastatistics or the "philosophy of induction" literature "back to earth" from the somewhat airy realms in which they often dwell and toward the more messy realms of the low sciences, addressing them to an audience, like myself, who aren't philosophers but don't think that philosophy is necessarily a synonym for "useless." It is true that the discussion is often very mathematical, sometimes filled with obscure polysyllabic words of Greek or Latin origin, and pages and pages of definitions where the reader is expected to suspend disbelief before something of practical import seems to enter the discussion. Partly as a consequence, I will talk about ideas that a philosopher would define with much more precision: if you have philosophical inclinations, consider yourself forewarned.

That discussion about metastatistics often dwells in the "airy realms" is unfortunate. First, many of the issues discussed in this literature are of practical import. In economics, Bayesian approaches are becoming increasingly popular: in the United States, for example, the Food and Drug Administration (FDA) issued a call for comments on a proposal about increased use of Bayesian methods (Food and Drug Administration, US Department of Health and Human Services, 2006). Second, it seems to me that much of the debate among practically minded researchers is rooted in (frequently) unstated assumptions about the underlying philosophical justification for statistical procedures being debated. Consider the following statement of the advantages of adopting a Bayesian approach to FDA testing:

1. If we turn to Bayesian methods, difficult issues will be discussed in the right way by the right people.
2. Some of the dilemmas that FDA decision makers face are artifacts of the (non-Bayesian) statistical methods they use, and not due to demands of the scientific method.
3. The Bayesian perspective provides the best way to think about evidence (Goodman, 2004).
4. (In contrast to the usual approach) the Bayesian approach is ideally suited to adapting to information that accrues during a trial, potentially allowing for smaller, more informative, trials and for patients to receive better treatment. Accumulating results can be assessed at any time, including continually, with the possibility of modifying the design of the trial: for example, by slowing (or stopping) or expanding accrual, imbalancing randomization to favour better-performing therapies, dropping or adding treatment arms, and changing the trial population to focus on patient subsets that are responding better to the experimental therapies (Berry, 2006).

Such arguments are becoming increasingly common in domains outside of medicine and are most easily understood by using some of the metastatistical background.

3.1.1 Life, death, and statistical philosophy: an example

The issue of whether to use Bayesian or non-Bayesian methods has sometimes quite literally involved life or death issues. The case of ECMO (extracorporeal membrane oxygenation) is a useful example for those skeptical of the potential importance of the debate.

ECMO was a therapy developed for use with infants with persistent pulmonary hypertension: an ECMO machine circulates blood through an artificial lung back into the bloodstream. The idea is described as providing adequate oxygen to the baby while allowing time for the lungs and heart to rest or heal. The mortality rate using conventional therapy was believed to be 40% (Ware, 1989), although there is debate about whether that number was reasonable.[4] A possibly important consideration is that the notion of providing additional oxygen for infants was not obviously "safe." See the *British Journal of Ophthalmology* (1974) and Silverman

(1980), for example, for a discussion of the case of "oxygen therapy" for infants which, far from being harmless, caused blindness.[5]

Concern about the ethics of a conventional randomized trial (RCT), where half the patients are randomized into treatment and half to control, led the surgeons who had developed the therapy to use a "randomized play-the-winner" statistical method to evaluate the treatment. The purpose of this convoluted randomization scheme was to evade

> the ethical problem aris[ing] from the fact that during a "successful" randomized clinical trial (i.e., one that demonstrates a significant advantage to one treatment) about half of the trial subjects will receive a treatment which, at the end of the trial, will be known to be inferior. The recipients of the inferior treatment are individuals whose own outcomes are, in some sense, sacrificed to the greater good of knowing, with far more certainty than before the trial, the value, lack of value, or actual harm of the treatments under investigation. (Paneth and Wallenstein, 1985)

The randomization procedure is too elaborate to be described fully, but this gloss should be sufficient.[6] The essence of their "modified randomized play-the-winner" method is that "the chance of randomly assigning an infant to one treatment or the other is influenced by the outcome of treatment of each patient in the study. If one treatment is more successful, more patients are randomly assigned to that treatment" (Bartlett *et al.,* 1985).

Call ECMO "Treatment A" and conventional treatment "Treatment B." Initially, a group of biostatisticians prepared a sequence of blinded random treatment assignments. When the outcome of a treatment was known, this information would be sent to the biostatisticians, who would then create another sequence of blinded random treatment assignments; the probability of being assigned to A or B, however, was now a function of the success or failure of the treatment. In their study,

1. The first infant – with even odds – was randomly assigned to ECMO and survived.
2. The second infant – again with even odds – was randomly assigned to conventional treatment and died.
3. The third infant – with better-than-even odds in favor of being placed in ECMO as a result of the first two experiences – was randomized to ECMO and survived.
4. With now even higher odds the next infant was randomized to ECMO and survived.

This continued until there was a (pre-specified) total of 12 events. The result of this unusual randomization was that only one child was randomized to the conventional treatment and the 11 others received the ECMO treatment.

The outcome of this experiment was that the 11 infants randomized to ECMO treatment survived; the one infant randomized to conventional treatment died.

The debate revolved around whether the evidence from that trial and the previous history of non-randomized studies was "sufficient" or whether any other studies involving randomization were necessary. The researchers were reluctant to conclude that the single trial and the previous studies using "historical controls" were enough. Ware (1989), among others, observed that the randomization wasn't satisfactory and that one couldn't rule out other explanations for the observed outcomes. For instance, the sole infant not randomized to treatment was, coincidentally, the most severely ill patient in the study. The implication was that, had this one patient been randomized to ECMO, it is quite likely the child still wouldn't have survived.

Berry (1989), an advocate of Bayesian methods, harshly condemned the decision to continue further study as unethical.[7]

Most of the debate focused on the structure of the randomization, and revolved around a very narrow "binary" question: "Did ECMO work?" or, possibly, "What was the probability that ECMO works?" Both sides focused on whether the answer was "yes" or "no." The debate did not include, for example, a heated discussion about the necessary prerequisites to be considered "eligible" for treatment. Even if the researchers had used a more conventional randomization scheme, the study would not have been able to provide a good answer to *that* much more difficult question.[8]

3.1.2 The metastatistics literature

It is likely that much of the philosophical discussion on "induction" or "metastatistics" is somewhat unfamiliar to regression runners – it was to me. Moreover, often the metastatistics debate seems to involve few participants of the practical sort. As a consequence, many of the case study examples debated by philosophers of induction or statistics are drawn from physics; I am sure this is true in large part because physics has had some success – it is easier to debate "how to get the answer right" in a science when a consensus exists that, at some point, someone got it right. Such cases are rare (non-existent?) for low sciences like medicine and economics. As part and parcel of this general tendency, the types of problems considered in the metastatistics literature often seem far removed from the types of problems confronted by economists of my stripe – the "practically minded regression runner."[9]

When (by accident) I began reading about the philosophy of statistics I was surprised to discover:

1. the vehemence of the debate, and
2. the almost near-unanimous consensus that almost everything someone like me – a "practically minded non-Bayesian regression runner" – understands about statistics is wrong or profoundly misguided at best.

Concerning (2), consider the "stupid" inferences people like myself are "supposed to draw" on account of not adopting a Bayesian point of view. One example is inspired by an example from Berger and Wolpert (1988). Consider computing the

standard error of a measurement that occurs in the following way:

Flip a fair coin.

- If heads, use measuring device A for which the measurement is distributed normally with variance one and expected value equal to the truth.
- If tails, use measuring device B which has zero measurement error.

What is the *right* standard error if B is chosen? Although I had not given the matter a lot of thought before, it seemed obvious to me, a non-Bayesian, that the answer would be zero. Thus it came as a surprise to learn that, on some accounts, a non-Bayesian is "supposed" to give an answer of $\frac{1+0}{2}$.[10] By way of contrast, the Bayesian is described as someone who "naturally" avoids this inference, being "allowed" to "condition" on whether the measurement was made with machine A or B.[11]

As to the vehemence of the debate, LeCam (1977), a thoughtful non-Bayesian, prefaced his (rare) published remarks on "metastatistics"[12] by observing:

> Discussions about foundations are typically accompanied by much unnecessary proselytism, name calling and personal animosities. Since they rarely contribute to the advancement of the debated discipline one may be strongly tempted to brush them aside in the direction of the appropriate philosophers. However, there is always a ghost of a chance that some new development might be spurred by the arguments. Also the possibly desirable side effects of the squabbles on the teaching and on the standing of the debated disciplines cannot be entirely ignored. This partly explains why the present author reluctantly agreed to add to the extensive literature on the subject.

It is also a literature which (until recently) seemed almost entirely dominated by "Bayesians" of various stripes – the iconoclastic Bayesian I.J. Good (Good, 1971) once enumerated 45,656 different varieties of Bayesianism. There are also "objective" Bayesians and radical subjectivists. We might also choose to distinguish between "full-dress Bayesians" (for whom estimation and testing is fully embedded in a decision-theoretic framework) as well as a "Bayesian approach in mufti" (Good and Gaskins, 1971). As I discuss below, this variety and depth results in part from the view that probability and statistics are tools that *can* and *should* be used in a much broader variety of situations than dreamed of by the usual non-Bayesian regression runner: "Probability is the very guide to life." The non-Bayesian rarely thinks of statistics as being an *all-purpose* way to *think* (see Surprising Idea 3 in section 3.2).

This is not to suggest that there is *no* non-Bayesian philosophy involving statistics. Most notably, Mayo (1996) has recently stepped in to present a broader view of the philosophical underpinnings of non-Bayesian statistics that I find helpful, especially her notion of "severe testing." And there is an older tradition as well: Peirce (1878a, 1878b) and Venn (1888) are notable examples. The latter still remains an exceptionally clear exposition of non-Bayesian ideas; the articles by Peirce in *Popular Science Monthly* are insightful as well, but probably a slightly more difficult read. Nonetheless, such examples are few and far between.

In what follows, when I describe something as "Bayesian" I do not mean to suggest any writer in particular holds all the views so attributed here. There is considerable heterogeneity: some view concepts like "the weight of evidence" as important, others do not. Some view expected utility as important, others do not. This is not intended to be a "primer" on Bayesian statistics. Neither is it intended to be a "critique" of Bayesian views. There are several very good ones, some dating as far back as Venn (1888) (although some of these arguments will appear in what follows). Indeed, I will admit that, given the types of questions *I* typically find interesting, I don't find Bayesian ideas particularly helpful (and sometimes harmful). On the other hand, I can imagine situations where others might find formal Bayesian reasoning helpful. Indeed, given the prominent role that "models" play in economics, I am frankly a bit surprised that Bayesian techniques are not more popular than they are.

My purpose is not to do Bayesian ideas justice (or injustice!) but, rather, to try to selectively choose some implications of various strands of Bayesianism and non-Bayesianism for actual statistical practice that highlight their differences so as to be clear to a non-Bayesian perspective.

After having surveyed the metastatistics literature, one feels it is almost impossible to use the English language to label or describe the practically minded non-Bayesian regression runner.[13] When not being dismissed as belaboring under fallacious reasoning (Howson, 1997), she has been variously described as a "frequentist" – someone who is congenial to the notion of probability being about "relative frequency," or an NP (Neyman–Pearson) statistician – even though, as Mayo and Spanos (2006) observe, there is a great deal of confusion about what this means. Indeed, in my experience, most regression runners are not entirely sure what it means to be a user of "NP theory" (which is not surprising given that it is not clear that either Neyman or Pearson practiced or believed NP statistical theory!) Most congenial is Mayo's (1996) term "error statistician" – someone engaged in "severe testing." On the other hand, as a firm adherent of LeCam's Basic Principle Zero – "Do not trust any principle" – I will settle on the term "non-Bayesian."[14]

My hope is that consideration of some of the underlying metastatistics will make it easier to detect some sources of methodological disagreement. Put differently, one focus of what follows is to consider a claim, from Mayo and Kruse (2002), that "principles of inference have consequences" for actual practice.

More on this subsequently, but to ground the discussion, let me list the types of research questions I would like to consider as the aims of the practically minded regression runner:

1. What is the "causal effect" of some new medical treatment?
2. What are the the iatrogenic effects of morphine use? Does the use of pain medicine cause more pain?
3. Does (US) unionization lead to business failures?
4. Do "unions raise wages?",

as well as the types of questions I am *not* going to consider:

1. What is a good estimate of next quarter's GDP?
2. Does this structural model of the US labor market provide representation adequate enough for the purposes of evaluating potential policies?
3. What are the causes and consequences of black culture?

In my experience, what type of questions one is interested in asking often suggests what type of statistics one finds useful. While both types of questions are routinely asked by economists, the types of problems entailed seem very different to me (even if they do not appear this way to some Bayesians). This is not to imply that the second set of questions are necessarily illegitimate: I wouldn't want to suggest that people stop trying to estimate next quarter's GDP!

Indeed, when and where probability and statistics are most "useful" is one subject which divides many Bayesian and non-Bayesians and one that we explore in section 3.3.2.

3.2 Six surprising ideas and one puzzle

It may seem hard to believe that one's views on the metaphysics of statistics have consequences. In this section I enumerate six "surprising ideas" that I think go to the heart of many differences between non-Bayesians and Bayesians. For my purposes, I will focus on suggestions for practice that are most frequently invoked by Bayesians or radical subjectivists that are at furthest remove from *my own* non-Bayesian views. Despite this, my goal isn't to criticize them. Indeed, if they strike *you* as sensible, perhaps you are a (closet) Bayesian!

3.2.1 Six surprising ideas

1. The absence or presence of data-mining strategies, specification mining, non-random sampling, or non-random assignment are (should be) irrelevant to the inference of a set of data. Put differently, what could have happened, but didn't, in an experiment should make no difference to the evidential import of the experiment:

   > considerations about samples that have *not* been observed, are simply not relevant to the problem of how we should reason from the one that has been observed. (Jaynes, 1976, p. 200)
   >
   > Unbiased estimates, minimum variance properties, sampling distributions, significance levels, power, all depend on something ... that is irrelevant in Bayesian inference – sample space. (Lindley, 1971, p. 426)

2. Pre-specified research design is a waste of time:

   > In general, suppose that you collect data of any kind whatsoever – not necessarily Bernoullian, nor identically distributed, nor independent of each other – stopping only when the data thus far collected satisfy some criterion of a

> sort that is sure to be satisfied sooner or later [such as the requirement that a "t-statistic" exceed some critical value], then the import of the sequence of n data actually observed will be exactly the same as it would be had you planned to take exactly n observations in the first place. (Edwards *et al.*, 1963, pp. 238–9).

3. The problem of "how to reason" has been solved:

> Determining which underlying truth is most likely on the basis of the data is a problem in inverse probability, or inductive inference, that was solved quantitatively more than 200 years ago by the Reverend Thomas Bayes. (Goodman, 1999)
>
> [They are mistaken,] those who have insinuated that the Doctrine of Chances . . . cannot have a place in any serious inquiry . . . [it can] shew what reason we have for believing that there in the constitution of things fixt laws according to which things happen, and that, therefore the frame of the world must be to the effect of the wisdom and power of an intelligent cause; and thus to confirm the argument taken from final causes for the existence of the Deity. It will be easy to show that the problem solved in this essay [by the Reverend Bayes] is more directly applicable to this purpose. (Bayes, 1958)

4. Usual (non-Bayesian) practice is very badly wrong:

> . . . almost every frequentist [non-Bayesian] technique has been shown to be flawed, the flaws arising because of the lack of a coherent underpinning that can only come through probability, not as frequency, but as belief. (Lindley, 2000)
>
> Why it is taking the statistics community so long to recognize the essentially fallacious nature of NP [Neyman–Pearson, or non-Bayesian] logic is difficult to say, but I am reasonably confident in predicting that it will not last much longer. Indeed, the tide already seems strongly on the turn. (Howson, 1997)
>
> I explore the historical and logical foundations of the dominant school of medical statistics, sometimes referred to as frequentist statistics, which might be described as error-based. I explicate the logical fallacy at the heart of this system. (Goodman, 1999)

5. Randomization rarely makes sense in those contexts where it is most often employed:

> Physicists do not conduct experiments as Fisher would have them do. For instance, a simple experiment to determine the acceleration due to gravity might, say, require a heavy object to be dropped close to the earth. The conditions would be controlled by ensuring that the air is still, that the space between the object and the ground is free of impediments, and so on for other factors that are thought to interfere with the rate at which the object

> descends. What no scientist would do is to divide the earth's surface into small plots and select some of these at random for the places to perform the experiments. Randomizers might take one of two attitudes to this behavior of scientists. They could either say it is irrational and ought to be changed or else claim that experiments in physics and chemistry are, in some crucial respect, unlike those in biology and psychology, neither of which would appear to be very promising lines of defence. (Urbach, 1985, p. 273)

6. Probability does not exist:

> The abandonment of superstitious beliefs about the existence of the Phlogiston, the Cosmic Ether, Absolute Space and Time, ... or Fairies and Witches was an essential step along the road to scientific thinking. Probability, too, if regarded as something endowed with some kind of objective existence, is no less a misleading misconception .... (deFinetti, 1974, p. 3)

3.2.2 An introductory puzzle

One of the most unusual aspects of metastatistics is that people on different sides of the debate cite *the same example* to make the case that the other side is wrong.

Consider the following example. Mayo (1979) and Mayo and Kruse (2002) have cited it as an example of a flaw in the usefulness of Bayesian reasoning while Bayesians routinely cite such examples (see Poirier, 1995) to argue that this is evidence of a flaw in non-Bayesian reasoning! It consists of a comparison of what inferences are justified in two different "experiments."

In both cases, suppose you are interested in the fraction of black balls μ in a huge urn (we ignore the complications arising from issues of sampling with or without replacement) that is "well-mixed" and has only red and black balls. Denote the null hypothesis as $\mathcal{H}_0 : \mu = 0.5$ and the alternative as $\mathcal{H}_1 : \mu > 0.5$. Denote the random variable "number of black balls" by X and the sample size as n.

Experiment A	**Experiment B**
Method: Declare in advance that you are going to pick 12 balls randomly from the urn.	*Method:* Instead of predesignating or deciding *in advance of the experiment* that you are going to draw 12 observations, you decide that you are going to keep drawing balls from the urn until you get at least 3 red balls.
Result: 9 of the 12 balls are black. The usual estimate is $\mu = \frac{3}{4}$.	*Result:* You draw the third red ball on the 12th attempt. 9 of the 12 are black and the usual estimate is $\mu = \frac{3}{4}$.

In both experiments, 12 balls were drawn. In both experiments, 9 of the 12 were black. There are several different "loaded" questions one can ask when comparing

the two experiments:

1. Are the two "experiments" different?
2. Does the "evidential import" of the two experiments for your beliefs about the true value μ differ when presented with either experiment A or B?
3. Does your evaluation of the experiment depend on the "mental state" of the investigator?

If your instinct is that "the evidential import" of both "experiments" is the same, you may be Bayesian. To many Bayesians such an example is a demonstration of a logical flaw in non-Bayesian statistics: in both cases someone has drawn 9 black balls and 3 red balls. Why should I bother to consider which experiment was being performed? If the "mental state" of the experimenter is "locked up" in his/her head and, say, inaccessible by someone else analyzing the data, doesn't such a case represent a fundamental problem for the non-Bayesian? I will return to this problem below, but before I do it will be helpful to sketch out some generalizations about the differences between Bayesians and non-Bayesians regarding the *role* of statistics.

3.3 What is statistics good for?

First, the Bayesian is typically more ambitious about the goals of statistics: "According to the Bayesian view, scientific and indeed much of everyday *reasoning* is conducted in probabilistic terms" (Howson and Urbach, 1993, p. 17).

John Maynard Keynes, for example, an exponent of "logical probability," deployed statistics to a very diverse range of subjects, including teleological questions – whether perceived order could be used to provide evidence of the existence of God. He concluded that, although such questions were well suited to study by Bayes' law, the problem was that such evidence could only make the existence of God more credible if it were supported by *other* evidence for God's existence (Keynes, 1921, p. 267).

To understand this point of view it is helpful to think of probability and statistics, for the Bayesian, as tools to bridge the gap between deductive and inductive logic.[15]

Deductive logic is about the validity of "risk-free" arguments.

All men are mortal.
John is a man.
Conclusion: John is mortal. (*)

Such an argument is deductively valid since *if* the premises are true, then so is the conclusion. A sound argument is a valid argument that has true premises. There are many types of risky arguments. Consider the following example. Imagine you are given the option of randomly selecting an orange from a box known to contain mostly good oranges and a few bad oranges.

Most of the oranges in the box are good.
Conclusion: The orange I randomly select will be good. (**)

This argument (**) is risky. Even if the premise is true, the conclusion may be wrong; you may be unlucky and draw one of the few bad oranges.

While probability seems of little value for non-risky arguments such as (*), even a non-Bayesian can easily see how probability might be *helpful* for arguments such as (**). For example, if we know 90% of the oranges in the box are good, the conclusion "There is a 90% chance that the orange I select will be good" seems less risky than the conclusion "There is a 90% chance that the orange will be bad." Probability and statistics for the Bayesian can be viewed as a way to tame risky arguments and make them amenable to the types of reasoning more commonly found in situations requiring merely deductive logic.

As I discuss in section 3.4.2, a Bayesian is typically more comfortable thinking about the probability of most *propositions* – which can be true, false, or uncertain – than a non-Bayesian. The non-Bayesian is most comfortable thinking about probability as the relative frequency of *events*. In the above example, neither the Bayesian nor the non-Bayesian is that uncomfortable talking about the event of a randomly chosen orange being good or bad. On the other hand, a non-Bayesian is more likely to feel unclear about a statement like "There is a 90% chance that an asteroid shower is the source of the Chicxulub impactor that produced the Cretaceous/Tertiary (K/T) mass extinction of the dinosaurs 65 million years ago."[16] The *proposition* that "The mass extinction of the dinosaurs was caused by a piece of an asteroid" is either true or false.[17] It is not a statement about relative frequency, or the fraction of times that the proposition is true in different "worlds."

The divergence between the two points of view becomes clearest when we begin discussing propositions much more generally. If probability is understood as being useful in induction – one version of the argument goes – it is a small step from this example to considering probability as useful *whenever* one is faced with making a risky decision. By these sorts of notions, most decisions in *life* become subject to the probability calculus because most *propositions* that are risky can and should be reasoned about using probability.

Indeed, once you've moved from reasoning about *beliefs* to reasoning about *decisions*, notions of "utility" can often become important. Many (including some Bayesians) have difficulty with this step: the relationship between "beliefs" and "actions" is not always obvious. I, for example, tend to think of them as rather distinct.[18] I think of Voltaire's quip – "I am very fond of truth, but not at all of martyrdom" – as a (perhaps extreme) example of the possible divergence between beliefs and actions. Hacking (1965, p. 16) observes that:

> beliefs do not have consequences in the same way in which actions do ... [For example] we say that a man did something in consequence of his having certain beliefs, or because he believed he was alone. But I think there is pretty plainly a crucial difference between the way in which his opening the safe is a consequence of his believing he was unobserved, and the way in which the safe's

> opening is a consequence of his dialing the right numbers on the combination. It might be expressed thus: simply having the belief, and doing nothing further, has in general no consequences, while simply performing the action, and doing nothing further does have consequences.

While the connections between Bayesian probability and Bayesian decision theory are a matter of debate as well, the connections seem tighter.[19] More importantly, an example from "decision theory" will, I think, highlight an important difference between Bayesians and non-Bayesians.

A useful case study comes from L.J. Savage, an important figure in the development of Bayesian ideas, who argued that the role of a mathematical theory of probability "is to enable the person using it to detect inconsistencies in his own real or envisaged behavior. It is also understood that, having detected an inconsistency, he will remove it" (Savage, 1972, p. 57). Indeed, the first seven chapters of Savage (1972) are an introduction to the "personalistic" tradition in probability and utility.

3.3.1 What's utility got to do with it?

To me, the idea of probability as primarily a tool for detecting inconsistencies sounds strange; nonetheless, it appears to be a view held by many. Savage himself provides an interesting example of "detecting an inconsistency" and then removing it. This case study was the result of a "French" complaint about crazy "American" ideas in economics. The Frenchman issuing the complaint, Allais (1953), wrote a hotly contested article arguing against the "American" School's view of a "rational man."[20]

Savage, like some Bayesians, argued that maximizing expected utility is good *normative* advice. Although the ideas will probably be familiar as the "Allais paradox," it may be a good idea to sketch the main idea. If we consider $x_1, x_2, \ldots x_k$ mutually exclusive acts that occur with probability $p_1, p_2, \ldots p_k$, respectively, where $\sum_{i=1}^{k} p_i = 1$, and we can define utility over these acts with a single utility function $U(x)$ with the "usual" properties (increasing in x, and so on), we can define expected utility as:

$$E[U] = \sum_{i=1}^{k} U(x_i)p_i.$$

If utility is, say, increasing in money, then a "rational" person "should" prefer the gamble that yields the highest expected utility. (Note we postpone a discussion of what probability is until the next section.)

One of the gambles Allais devised to demonstrate that maximization of Expected Utility (what Allais referred to as the "Principle of Bernoulli") wasn't necessarily a good idea went as follows:

Imagine 100 well-shuffled cards, numbered from 1 to 100, and consider the two following pairs of bets and determine which you prefer.

First gambling situation

[A.] You win \$500,000 if you draw a card numbered 1–11 (11% chance). If you draw a number from 12–100, you get the status quo (89% chance).
[B.] You win \$2,500,000 if you draw a card numbered 2–11 (10% chance.) Draw a number from 12–100 or 1 and you get the status quo (90% chance).

The second pair of gambles

[C.] You win \$500,000 for certain.
[D.] You win \$2,500,000 if you draw a card numbered 1–10 (10% chance), \$500,000 if you draw a card from 11–99 (89% chance), and the status quo if you draw the card numbered 100.

As Allais found (and has been found repeatedly in surveys posing such gambles), for most people $B \succcurlyeq A$ (B is preferred to A) and $C \succcurlyeq D$ and, as Savage reports, the same was true for him (Savage, 1972, pp. 101–4)!

As most economists will recognize, this is a "paradox" since, from $C \succcurlyeq D$:

$$U(500,000) \quad > \quad 0.1U(2,500,000) + 0.89U(500,000) + 0.01U(0),$$

and from $B \succcurlyeq A$:

$$0.1U(2,500,000) + 0.9U(0) \quad > \quad 0.11U(500,000) + 0.89U(0),$$

and it is obvious that both inequalities can't be true.[21] There are two ways to handle this "paradox."

1. One possibility (the one that appeals to me) is that – even after continued reflection – my original preferences are just fine. For me, the fact that at the stated sums of money, etc., the comparison is inconsistent with Expected Utility Theory is merely too bad for the theory, however plausible it sounds. Indeed, as is well-known, it is possible to axiomatize preferences so that Allais paradox behavior is consistent with "rational" behavior (Chew, 1983).
2. A second possibility is to conclude that something is "wrong" with your "preferences." That was Savage's conclusion; his solution was to "correct himself."

Indeed, as befits a Bayesian, Savage analyzed the situation by rewriting the problem in an equivalent, but different way:

		Ticket number		
		1	2–11	12–100
First pair	Gamble A	5	5	0
	Gamble B	0	25	0
Second pair	Gamble C	5	5	5
	Gamble D	0	25	5

After writing down the problem this way, he then observed that if he were to draw a number from 12 to 100 he would be indifferent between the outcomes, so he decided to "focus" on what would happen if he should draw between 1 and 11. By doing so, he decided that, in the case of a subsidiary problem – ignoring outcomes higher than 11 – the correct answer depended on whether he would "sell an outright gift of $500,000 for a 10 to 1 chance to win $2,500,000 – a conclusion that I think has a claim to universality, or objectivity." He then concluded that, while it was still true that $C \succcurlyeq D$, upon reflection $A \succcurlyeq B$, not the other way around.

As Savage himself noted: "There is, of course, an important sense in which preferences, being entirely subjective, cannot be in error; but in a different, more subtle sense they can be."

We put aside the frequently knotty subject of "prior beliefs" for the moment, and contrast this Bayesian view with a typical non-Bayesian view about "what statistics is good for."

3.3.2 What is statistics good for? A non-Bayesian view

> In its most restricted form [statistical] theory seems to be well adapted to the following type of problem. If two persons disagree about the validity, correctness or adequacy of certain statements about nature they may still be able to agree about conducting an experiment "to find out". For this purpose they will have to debate which experiment should be carried out and which rule should be applied to settle the debate. If one of them modifies his requirements after the experiment, if the experiment cannot be carried out, or if another experiment is used instead, or if something occurs that nobody had anticipated, the original contract becomes void. Since the classical theory is essentially mathematical and clearly not normative it is rather unconcerned about how one interprets the probability measures ... The easiest interpretation is probably that certain experiments such as tossing a coin, drawing a ball out of a bag, spinning a roulette wheel, etc., have in common a number of features which are fairly reasonably described by probability measures. To elaborate a theory or a model of a physical phenomenon in the form of probability measures is then simply to argue by analogy with the properties of the standard "random" experiments.
>
> The classical statistician will argue about whether a certain mechanism of tossing coins or dice is in fact adequately representable by an "experiment" in the technical stochastic sense and he will do that in much the same manner and with the same misgivings as a physicist asking whether a particular mechanical system is in fact isolated or not. (LeCam, 1977, p. 142)

A non-Bayesian doesn't view probability as a singular mechanism for deciding the probability that a proposition is true. Rather, it is a system that is helpful for studying "experimental" situations where it might be reasonable to assume that the experiment is well described by some chance set-up. Even when attempting to use "non-experimental" data, a non-Bayesian feels more comfortable when he/she has reason to believe that the non-experimental situation "resembles" a chance set-up. Indeed, from a strict Bayesian viewpoint it is hard to understand why, in the

low sciences, there is a great deal of interest in "natural experiments." Put another way, one wants to try to draw a contrast between "experience" and "experiment." In the case of the former, statistical tools may or may not be particularly helpful, and other methods for gaining insight might easily dominate. In the latter case, one generally feels more hopeful that statistical reasoning might help.

3.4 A few points of agreement, then ...

Statistics and probability, as we understand them today, got a surprisingly late start in the (European) history of ideas.[22] Before the seventeenth century a major use of the word "probability" in English was to describe a characteristic of an opinion and dealt with the authority of the person who issued the opinion. "Thus [it could be said] Livy had more of probability but Polybius had more of truth." Or, "Such a fact is probable but undoubtedly false," relying on the implicit reference of what is "probable" to authority or consensus (Barnouw, 1979).

A theme that will recur frequently is the notion that *everything* in metastatistics is a topic of debate. As I discuss in section 3.4.2, even the definition of probability is the subject of considerable debate. However, it will be helpful to have at least some terminology to work with before enjoining the metaphysics.

3.4.1 Kolmogorov's axioms

One place to begin is a review of a few of Kolmogorov's axioms which Bayesians and non-Bayesians (generally) accept, although they interpret the meaning of "probability" very differently. Though they can be defined with much more care and generality, we will define them crudely for the discrete case:

1. Given a sample space Ω of possible events $A_1, A_2, \ldots A_k$ such that:

$$\Omega \equiv \sum_{i=1}^{k} \bigcup A_i \quad \text{for} \quad i = 1, 2, \ \ldots \ k.$$

2. The probability of an event A_i is a number which lies between 0 and 1.

$$0 < P(A_i) < 1.$$

   An event which cannot happen has a probability of zero, and a certain outcome has a probability of 1.[23] Two events, A_1 and A_2, are mutually exclusive if $P(A_1 \bigcap A_2) = 0$.
3. For any two mutually exclusive events probability is additive:

$$P(A_1 \bigcup A_2) = P(A_1) + P(A_2).$$

The same is true for pairwise mutually exclusive events so, for example, we can write:

$$\begin{aligned} P(A_1 \bigcup A_2 \bigcup \ldots \bigcup A_k) &= \sum_{j=1}^{k} P(A_j) \\ &= 1. \end{aligned} \tag{3.1}$$

If we were intending a proper introduction to probability, even here complications arise. Is k finite, for example? To address that issue properly one would introduce a set of measure theoretic considerations, but there is no need to cavil about such issues at present.[24]

The most important observation to make is that these are, so far, simply *axioms*. At this level, they are mere statements of mathematics. Indeed, we don't even have to consider them to be "probabilities." They may or may not be readily associated with anything "real" in the world. As Feller (1950, p. 1) explains:

> Axiomatically, mathematics is concerned solely with relations among undefined things. *This property* is well illustrated by the game of chess. It is impossible to "define" chess otherwise than by stating a set of rules ... The essential thing is to know how the pieces move and act. It is meaningless to talk about the "definition" or the "true nature" of a pawn or a king. Similarly, geometry does not care what a point and a straight line "really are." They remain undefined notions, and the axioms of geometry specify the relations among them: two points determine a line, etc. These are rules, and there is nothing sacred about them. We change the axioms to study different forms of geometry, and the logical structure of the several non-Euclidean geometries is independent of their relation to reality. Physicists have studied the motion of bodies under laws of attraction different from Newton's, and such studies are meaningful if Newton's law of attraction is accepted as true in nature.[25]

In sum, these axioms don't commit you to believing anything in particular. One reason you might adopt such axioms (and the reason I do) is because they seem convenient and useful if you are interested in the properties of chance set-ups or things that resemble chance set-ups.

I belabor this obvious point because I think it useful to consider that we *could* begin with different axioms. A nice example comes from Hacking (2001). Consider representing the probability of a certain event, A, as $P(A) = \infty$, and if A were impossible, $P(A) = -\infty$. In such a system:

- If the event A and $\tilde{}A$ (the event "not A") have the same probability, then $P(A) = P(\tilde{}A) = 0$
- If the event A is more probable than $\tilde{}A$, then $P(A) > 0$
- If the event $\tilde{}A$ is more probable than A, then $P(A) < 0$.

This too could form the basis of a theory of probability, but it is one we choose not to adopt because it seems "inconvenient" to work with and makes it more difficult to study the behavior of chance set-ups.

3.4.2 Definitions of probability

DeFinetti's declaration in Surprising Idea 6 that "PROBABILITY DOES NOT EXIST" may, at minimum, appear to be a bit intemperate. Indeed, it presupposes that many practically minded non-Bayesian regression runners are in the grips of some bizarre hallucination. It will help to consider two broad classes of definitions of probability that are sometimes referred to as:

1. "aleatory" or frequency-type probabilities
2. "epistemic" or belief-type probabilities.

Aleatory probabilities are perhaps what is most familiar to the non-Bayesian. For many, the notion of any other type of probability may not have been seriously entertained. It is interesting to observe that criticism of aleatory probability began at the inception of modern statistics and, as Hacking (1975, p. 15) observes, "philosophers seem singularly unable to put asunder the aleatory and the epistemological side of probability. This suggests that we are in the grip of darker powers than are admitted into the positivist ontology."

I began my presentation with Kolomogorov's axioms since everyone seems to agree on something like these; disputants disagree on what they are useful for, or what, precisely, they are "about." I won't do a complete survey, but a few moments of reflection may be all that is required to consider how slippery a notion probability could be.[26]

3.4.3 Aleatory or frequency-type probabilities

When we say "the probability that a fair coin will land as heads is $\frac{1}{2}$" we could take it as a statement of fact, which is either true or not. When we do so, we are generally thinking about probability as describing something that results from a mechanism that tosses coins and the geometry of the coin, perhaps. This mechanism can be described as a "chance set-up." We might go on to describe the physics of the place containing our coin-toss mechanism. A mechanism that would be perfectly useful in Ann Arbor, Michigan, might not work somewhere in the deep reaches of outer-space.

Nonetheless, most non-Bayesians, it would seem, are content to harbor little doubt that, at some fundamental level – whether we know the truth or not – it is meaningful to talk about the probability of a tossed coin falling heads. When pressed to explain what they mean when they say that the probability is $\frac{1}{2}$ that a fair coin will turn up heads, such a person might say "In the long run, if I were to repeatedly toss the coin in the same way, the relative frequency of heads would be $\frac{1}{2}$." We've yet to worry about "the long run" but, even at this level, for example, we would like to exclude the following deterministic but infinite series as being a

prototype for what we have in mind:

$$H \quad T \quad H \quad T \quad H \quad T \quad \ldots H \quad T \ldots$$

In such an example, if we know the last coin toss was "H" we are certain that the next coin toss will be "T." An "intuitive" definition that excludes such a possibility was given by Venn (1888), who talked about a probability as a characteristic of a *series* as "one which exhibits individual irregularity along with aggregate regularity." If we denote the number of "Trials" by N and the number of times the event "Heads" occurs as $m(N)$, we might go on to define the probability of "Heads" as:

$$P(\text{Head}) = \lim_{N \to \infty} \frac{m(N)}{N}.$$

An apparent weakness of this definition is, of course, that infinity is rarely observed. The derisive term about such thought exercises is sometimes referred to as "asymptopia" – which suggests something both unrealistic and unattainable.[27]

3.4.4 Objective, subjective, or "it depends"

Whether such a concept corresponds to something "real" or "objective," or whether it is "in the mind," is a subject on which much has been written. Sometimes such probabilities have been described as "objective" in order to contrast them with Bayesian "probabilities." However, one Bayesian objection is that there is no such thing as an "objective probability" – any such probability depends on purely subjective beliefs:

> To calculate a frequency, it is necessary to consider a repetitive phenomenon of a standardized variety. The appropriate meaning of "repetitive" and "standardized" is not obvious. To calculate a relative frequency it is necessary to subjectively define (possibly only conceptually) a class of events (known as a *collective*) over which to count the frequency. The relative frequency of the event ["Heads"] should also tend to the same limit for all subsequences that can be picked out in advance.[28]
>
> To the extent that individuals agree on a class of events, they share an objective frequency. The objectivity, however, is in themselves, not in nature. (Poirier, 1995)

Poirier, a Bayesian, stresses the (implicit) "subjectivity" of the frequentist notion of probability, specifically the notion of a "collective." The non-Bayesian von Mises (1957, p. 12), for example, defines a collective as a "sequence of uniform events or processes which differs by certain observable attributes, say colours, numbers, or anything else. Only when such a collective is defined, then a probability can be defined. If it is impossible to conceive of such a collective, then it is impossible to talk about probability." For von Mises, the notion of collectives with infinite numbers of entities was an *abstraction* to make the mathematical representation of reality "tractable" (Gillies, 2000, p. 90). While an extensive discussion of a

"collective" is beyond our scope, it is important to acknowledge that there can be "legitimate" disagreements about whether certain probabilities can be said to "exist." Von Mises argues that the reason it is possible to talk about the probability of a tossed coin turning up "Heads" is because it is easy to think of the "collective"; it is not possible, he says, to consider "the probability of winning a battle . . . [which] has no place in our theory of probability because we cannot think of a collective to which it belongs."

I personally share von Mises discomfort with defining the "probability of winning a battle," but I imagine others do not. Whether or not it would be "meaningful" to do so, or whether it "has no place in our theory of probability," the ultimate criterion in the non-Bayesian context is: "Would doing so help in understanding?" The salient issue is not that different, in principle, from the qualms a physicist might feel about "whether a particular mechanical system is in fact isolated or not." Whether that is a "defect" of the theory of probability or whether it introduces an undisciplined element of "subjectivity" is a subject upon which there has been much philosophical debate.[29]

3.4.5 Epistemic probability

The difficulties that a non-Bayesian might feel about conceiving of the appropriate collective are largely avoided/evaded when we consider a different notion of probability – epistemic. A nice place to start is a description from Savage, often called a "radical subjectivist:"

> You may be asking, "If a probability is not a relative frequency or a hypothetical limiting relative frequency, what is it? If, when I evaluate the probability of getting heads when flipping a certain coin as .5, I do not mean that if the coin were flipped very often the relative frequency of heads to total flips would be arbitrarily close to .5, then what do I mean?" We think you mean something about yourself as well as about the coin. Would you not say, "Heads on the next flip has probability 0.5" if and only if you would as soon guess heads as not, even if there were some important reward for being right? If so, your sense of "probability" is ours; even if you would not, you begin to see from this example what we mean by "probability." (Savage, 1972)

What is also interesting is that instead of Kolomogorov's axioms reflecting a (possibly) arbitrary set of axioms about unknown concepts which (one hopes) resemble some real world situation, they can also be derived from "betting rules." Again quoting Savage:

> For you, now, the probability $P(A)$ of an event A is the price you would just be willing to pay in exchange for a dollar to be paid to you in case A is true. Thus, rain tomorrow has probability 1/3 for you if you would pay just \$0.33 now in exchange for \$1.00 payable to you in the event of rain tomorrow. (*ibid.*)

As when we encountered Expected Utility, viewing probability as a device that allows one to make sensible "bets" is not *necessary*. The important distinction between aleatory and epistemic probability is that epistemic probabilities are numbers which obey something like Kolmogorov's axioms but do not refer to anything "real" in the world, but to a (possibly) subjective "degree of belief." Here's one definition from Poirier (1995, p. 19):

> Let κ denote the body of knowledge, experience or information that *an individual* has accumulated about the situation of concern, and let A denote an uncertain event (not necessarily repetitive). Then the *probability* afforded by κ is the "degree of belief" in A held *by the individual* in the face of κ.

Given this definition of probability, stating that the probability that a fair coin lands heads is *not* stating some property of a chance set-up – rather, it is an expression of belief about what the coin will do.[30] It is important to point out that opinions about this subject vary amongst Bayesians. I.G. Good, for instance, maintains that "true" probabilities exist but that we can only learn about them by using subjective probabilities. DeFinetti, as we saw, believes that it is unhelpful to postulate the existence of "true" probabilities.

How does this differ from the aleatory- or frequency-type probability we discussed above? Again quoting from Poirier (1995, p. 19):

> According to the subjective ... interpretation, probability is a property of an individual's perception of reality, whereas according to the ... frequency interpretations, probability is a property of reality itself.

Among other things, in this view the probability that a fair coin-toss is heads differs across individuals.[31]

3.4.6 Conditional probability, Bayes' rule, theorem, law?

Is it Bayes' rule, law, or theorem? Is it one of the most powerful ideas of all time, or the source of much mischief? Dennis Lindley (as cited in Simon, 1997) observes that "[Bayes'] theorem must stand with Einstein's $E = mc^2$ as one of the great, simple truths." Putting aside the intractable issue of what the Reverend Bayes *meant*, this has been the subject of considerable controversy and study.[32]

For the typical non-Bayesian, R.A. Fisher and William Feller, for example, Bayes' rule is nothing but a manipulation of the law of conditional probability.

Everyone starts with a *definition* of conditional probability:

$$P(A_i|B) = \frac{P(A_i \bigcap B)}{P(B)} \text{ if } P(B) > 0. \tag{3.2}$$

Provided the necessary probabilities exist, we can do the same thing in reverse:

$$P(B|A_i) = \frac{P(A_i \bigcap B)}{P(A_i)} \text{ if } P(A_i) > 0. \tag{3.3}$$

Then there is the "conditional" version of the law of total probability: as before, let the A_j be mutually exclusive events, for $j = 1 \ldots k$ and $\sum_{j=1}^{k} P(A_j) = 1$ and, if $0 < P(B) < 1$:

$$P(B) = \sum_{j=1}^{k} P(B|A_j)P(A_j).$$

What this says is that if $P(B)$ is the probability of some event, and it can be accompanied by some of the k mutually exclusive events A_j in some way, then the probability that $P(B)$ occurs is merely the sum of the different ways B can occur with A_j times the probability of $P(A_j)$.

Using equations (3.2), (3.3) and (3.1), rearranging, and applying this last operation to the denominator yields:

$$P(A_i|B) = \frac{P(B|A_i)P(A_i)}{P(B)} \tag{3.4}$$

$$P(A_i|B) = \frac{P(B|A_i)P(A_i)}{\sum_{j=1}^{k} P(B|A_j)P(A_j)}. \tag{3.5}$$

So far, there seems nothing particularly remarkable. However, here the agreement ends. Consider a "Note on Bayes' rule" by the non-Bayesian Feller (1950, p. 125):

> In [the above formulas] we have calculated certain conditional probabilities directly from the definition. The beginner is advised always to do so and not to memorize the formula [Bayes' rule, equation (3.5)] ... Mathematically, [Bayes' rule] is a special way of writing [the definition of conditional probability] and nothing more. The formula is useful in many statistical applications of the type described in [the above] examples and we have used it there. Unfortunately, Bayes's rule has been somewhat discredited by metaphysical applications ... In routine practice this kind of argument can be dangerous. A quality control engineer is concerned with one particular machine and not with an infinite population of machines from which one was chosen at random. He has been advised to use Bayes's rule on the grounds that it is logically acceptable and corresponds to our way of thinking. Plato used this type of argument to prove the existence of Atlantis, and philosophers used it to prove the absurdity of Newton's mechanics. But for our engineer the argument overlooks the circumstance that he desires success and that he will do better by estimating and minimizing the sources of various types of errors in prediction and guessing.

Feller's suggestion that the engineer will do better by minimizing the various types of *errors* is one issue where, at least rhetorically, non-Bayesians differ from Bayesians. For Feller, the focus is on using statistics (or other methods) to put ideas to the test, rejecting those that fail and advancing provisionally with those that survive. Bayes rule is a formula about *revising* one's epistemic probabilities incrementally. This distinction will become apparent when we apply Bayes' rule to estimation.

3.4.7 Reasoning or estimating with Bayes' rule?

Not surprisingly, Bayes' rule is viewed differently by Bayesians: it is a multi- (or all-) purpose tool of reasoning. Consider first the version given by equation (3.4). To fix ideas, let us consider one example of "Bayesian inference." In the above notation, let A_i be a specific hypothesis about the world and let B refer to some "data" that has somehow come in to our possession. For example, A_i might be the hypothesis that a coin is fair and B is the fact that you observed a single toss of the coin and it landed "heads." *Your* job is to ascertain how you should revise your beliefs in light of the data.

1. The "model" or likelihood for the behavior of N tosses of a coin is given by the following likelihood:

$$\mathcal{L}(\theta|N,h) = \left(\begin{array}{c} N \\ h \end{array} \right) \theta^h (1-\theta)^{N-h}. \tag{3.6}$$

   As described by Poirier (1995), $\mathcal{L}$ is a "window" by which to view the world – perhaps an "approximation" to the truth. We might debate what window is appropriate but, in the usual context, it isn't something to be "tested" or "evaluated." Moreover, the likelihood is a function which tells us "how likely we were to have observed the data we did (N, h)" given the truth of the model and a specific value of θ. (NB: here the likelihood is a device that tells you, given the parameter θ, what is the probability of observing the occurrence of h heads in N tosses of a coin.)

   Instead of using the coin toss mechanism to help you randomize, you are going to study the coin (and the mechanism) and learn about it.
2. The next step is to specify a prior distribution – one particularly *convenient* choice is the beta distribution. Priors are subtle things, but let us consider our beliefs about the value of θ to be describable by the following two parameter distribution:

$$\begin{aligned} f(\theta;\alpha,\delta) &= \frac{\Gamma(\alpha+\delta)}{\Gamma(\alpha)\Gamma(\delta)} \theta^{\alpha-1}(1-\theta)^{\delta-1} \\ &= \frac{1}{B(\alpha,\delta)} \theta^{\alpha-1}(1-\theta)^{\delta-1}, \end{aligned} \tag{3.7}$$

   where $\Gamma(\cdot)$ is the gamma function and $B(\cdot)$ is the beta function. This is a very flexible distribution which can put weight on all values between 0 and 1. Figure 3.1 displays some of the wide variety of shapes the prior distribution can take for different values of α and δ.

   Different values of α and δ correspond to different beliefs. One way to get some intuition about what type of beliefs the parameters correspond to is to observe, for example, that the mode of the prior distribution (when it exists) occurs at:

$$\frac{\alpha-1}{\alpha+\delta-2}.$$

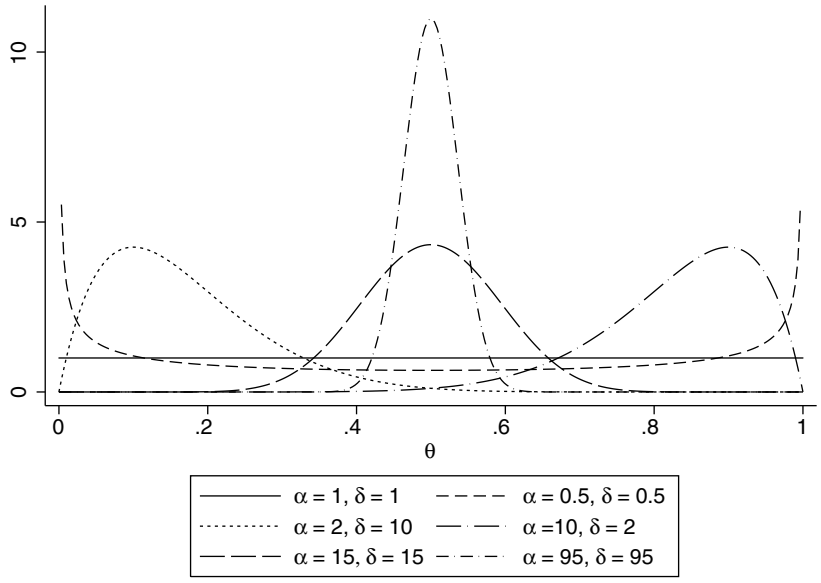

Figure 3.1 Different priors using the Beta distribution

It is sometimes helpful to think of $\alpha - 1$ as the number of heads "previously" observed, $\delta - 1$ the number of tails, and $\alpha + \delta - 2$ as the total number of coin flips previously observed from the experiment. On the other hand, it is not clear how someone could verify that a particular choice of prior was a good or bad description of one's beliefs.

3. In the third step, we merely plug our prior and our likelihood into Bayes' rule and what we come up with is[33]

$$\frac{1}{B((a+h),(\delta+(N-h)))}\theta^{\alpha+h-1}(1-\theta)^{\delta-1+N}. \tag{3.8}$$

Given the usual caveats, equation (3.8) is a statement of your personal beliefs about the value of θ, modified in light of the observed coin-toss. The beta distribution is a nice example because it is easier than usual to characterize the resulting "beliefs."

The left panel of Figure 3.2 shows two different prior distributions – one labeled "less informative" and the other "very informative." The first prior distribution corresponds to Beta(199,1) and the second to Beta(2,2). A convenient fiction to appreciate these prior beliefs is to imagine that, in the first case, you have previously observed 200 observations, 199 of which were heads. In the second case, you have previously observed four observations, two of which were heads. The first case corresponds to having "more prior information" than the second.

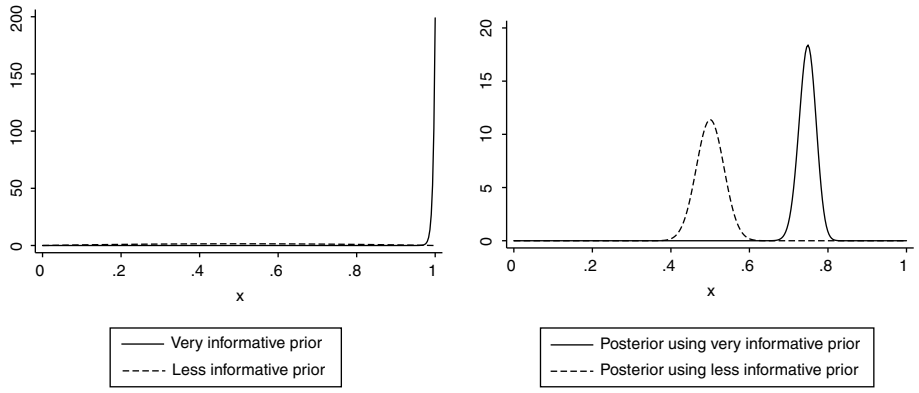

Figure 3.2 Different prior and different posterior distributions

The mode of the posterior distribution occurs at:

$$\frac{\alpha + h - 1}{\alpha + \delta + N - 2}.$$

This can be fruitfully compared to the usual non-Bayesian maximum likelihood (or method of moments) estimator, which is merely the sample mean:

$$\frac{h}{N}.$$

The difference between the posterior mode and the usual non-Bayesian estimator is that the former "adds" $\alpha - 1$ heads to the numerator and "adds" $\alpha + \delta - 2$ observations to the denominator.[34]

To see what effect this has, the right-hand panel of Figure 3.3 shows the resulting posterior distributions updated with 200 coin tosses, 100 of which are heads.

For a slightly different type of comparison one can consider two situations:

Prior	*Data*
Beta(99,99)	2 heads, 2 tails
Beta(2,2)	99 heads, 99 tails

In this case, although the experiments are very different, our conclusions are exactly the same (see Figure 3.3).

The role of the prior distribution and the sufficiency of the posterior distribution or likelihood are among the longest-standing debates in metastatistics. While a complete review is impossible, some of the most frequently enumerated difficulties are:

1. There is no way to verify whether the prior one has chosen adequately characterizes one's beliefs. Also, there is no unique way to translate ignorance or

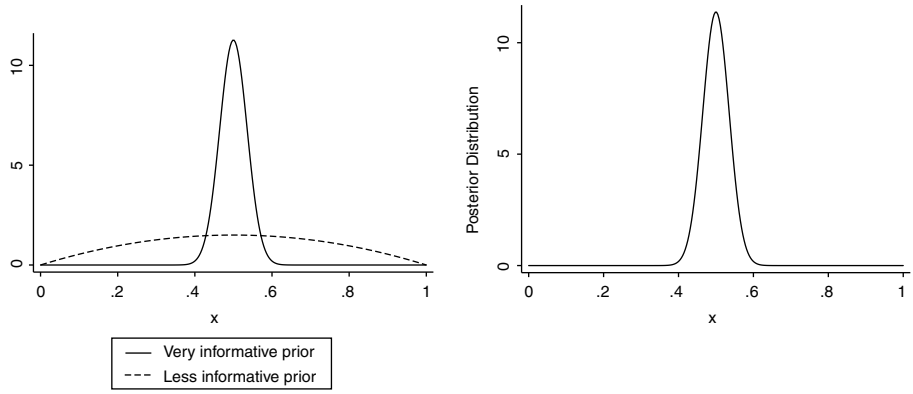

Figure 3.3 Different prior distributions, same posterior

"no information" into a prior distribution.[35] Consider the problem of estimating the length of a square garden which has sides of length between 1 and 5 feet. Based on this information, it seems "natural" to say that there is a 0.5 probability that the garden has sides of *length* between 1 and 3 feet. Equivalently, the information could be cast as saying that the area of the garden is between 1 and 25 square feet. In that case, it would appear just as natural to say that the probability is 0.5 that the *area* of the garden is between 1 and 13 square feet. This natural assignment of probability, however, implies that the probability is 0.5 that the length of the sides is between 1 and $\approx$ 3.61 feet ($\sqrt{13}$). However, it would be personally inconsistent to believe both claims and there is no principled method to reconcile the two different priors.

2. Even if a prior distribution is useful to the person holding it, it is not clear that it is useful to anyone else. LeCam (1977) observes that, for the binomial experiment, for arbitrary positive constant C, "if we follow the theory and communicate to another person a density $C\theta^{100}(1-\theta)^{100}$ this person has no way of knowing whether (1) an experiment with 200 trials has taken place or (2) no experiment took place and this is simply an *a priori* expression of opinion. Since some of us would argue that the case with 200 trials is more 'reliable' than the other, something is missing in the transmission of information."

3.5 The importance of the data-generation process

3.5.1 An idealized hypothesis test

Ultimately we would like to return to the "introductory puzzle," but before we do, let us introduce some context. The value of hypothesis testing has been frequently debated among non-Bayesians, but it may help to consider an idealized notion of how it is *supposed* to be done – this version is from Kmenta (2000) – when wishing

to make a statement about a *population* from a "random sample":

Preamble	State the maintained hypothesis [for example, the random variable X is normally distributed with σ^2 equal to ...].
Step 1	State the null hypothesis and the alternative hypothesis [for example, $\mathcal{H}_0 : \mu = \mu_0$ and $\mathcal{H}_A : \mu \neq \mu_0$].
Step 2	Select the test statistics [for example, $\overline{X}$ based on sample size $n = \ldots$].
Step 3	Determine the distribution of the test statistic under the null hypothesis [for example, $\sqrt{n}(\overline{X} - \mu_0)/\sigma$ is distributed $N(0, 1)$ – normal, with mean zero and variance 1].
Step 4	Choose the level of significance and determine the acceptance and the rejection region [for example, *"do not reject* $\mathcal{H}_0$ *if* $-1.96 \leq \sqrt{n}\frac{(\overline{X}-\mu_0)}{\sigma} \leq 1.96$*; otherwise reject it"*].
Step 5	Draw a sample and evaluate the results [for example, *"the value of* $\overline{X}$ *is ... which lies inside (outside) the acceptance region"*].
Step 6	Reach a conclusion [for example, *"the sample does (does not) provide evidence against the null hypothesis"*]. To distinguish between 5% and 1% levels of significance we may add the word "strong" before "evidence" when using the 1% level.

It will be worth noting Kmenta's observations about the procedure: "According to the above scheme, the planning of the test and the decision strategy are set *before* the actual drawing of the sample observations, which does not occur until step 5. This prevents rejudging the verdict to suit the investigator's wishes."

This observation comes up frequently in non-Bayesian discourse, but less frequently among Bayesians: does the investigator want to ensure him/herself against "rejudging the verdict?" Perhaps they should "rejudge the verdict?" As we will see, this points to a notion of **severity** as being primary, as opposed to merely a concern about the correctness of the various statistical tests (although the two are not unrelated).

3.5.2 The introductory puzzle revisited

With this in mind, we can now reintroduce the puzzle. Specifically, the puzzle arises because, by using some variant of the above procedure, under one experiment observing 9 black of 12 balls allows one to *reject* the null hypothesis; in the other, observing 9 black of 12 balls would not permit the researcher to reject the null. Some Bayesians point to this example as evidence of a flaw in non-Bayesian reasoning: why should what is "locked up in the head" of the researcher – his/her intentions about what he/she was going to do – matter? In both cases, he/she has the same "data." This problem appears in many guises: in clinical trials there is a debate about what should be done if, for example, "early" evidence from a trial suggests that a drug is effective. The non-Bayesian response is that the Bayesian view misconstrues the purpose of error probabilities.

First, let's illustrate the problem. In experiment A, the question is: "How often would we expect to see 9 black balls out of 12 balls under the null hypothesis?":

$$\begin{aligned} P(\widehat{\mu} \geq \frac{3}{4}|\mathcal{H}_0) &\equiv P(X \geq 9|\mathcal{H}_0) \\ &= \sum_{x=9}^{12} \left(\begin{array}{c} 12 \\ x \end{array} \right) \mu^x (1-\mu)^{12-x} \\ &= \left(\begin{array}{c} 12 \\ 9 \end{array} \right) \frac{1}{2}^9 (1-\frac{1}{2})^3 + \left(\begin{array}{c} 12 \\ 10 \end{array} \right) \frac{1}{2}^{10} (1-\frac{1}{2})^2 + \ldots \\ &= \frac{220+66+12+1}{2^{12}} \\ &= \frac{299}{2^{12}} \\ &= 0.073. \end{aligned}$$

In experiment B, the question is: "Under the null hypothesis, what is the probability of drawing 9 or more black balls before drawing a third red ball?" Let $r = 3$ be the pre-specified number of red balls to be drawn before the experiment is to be stopped. Let x index the number of black balls drawn, and let $n = x + r$.

This is a straightforward application of the negative binomial distribution where:

$$\begin{aligned} P(X \geq 9|\mathcal{H}_0) &= \sum_{x=9}^{\infty} \left(\begin{array}{c} r+x-1 \\ r-1 \end{array} \right) \mu^x (1-\mu)^r \\ &= \sum_{x=9}^{\infty} \left(\begin{array}{c} x+2 \\ 2 \end{array} \right) \mu^x (1-\mu)^r. \end{aligned}$$

It is very helpful to observe in doing the calculation that:

$$\sum_{x=j}^{\infty} \left(\begin{array}{c} x+2 \\ 2 \end{array} \right) (\frac{1}{2})^x = \frac{8+5j+j^2}{2^j}.$$

We can then write:

$$\begin{aligned} &= \sum_{x=9}^{\infty} \left(\begin{array}{c} x+2 \\ 2 \end{array} \right) \mu^x (1-\mu)^3 \\ &= \left(\frac{1}{2}\right)^3 \frac{8+5(9)+9^2}{2^9} \\ &= \frac{1}{8}\left(\frac{134}{512}\right) \\ &= 0.0327. \end{aligned}$$

There are several points to make about these "experiments" from a non-Bayesian perspective.

1. One point to emphasize is that in experiment A, the sample size is fixed. In experiment B, it was *possible* that the same experimenter would have continued to draw balls from the urn if a third red ball had not been drawn.
2. In neither case is it correct to make a statement such as "Given the experimental results (of 9 black and 3 red) there is a 7.3% probability in experiment A (3.3% probability in experiment B) that the null hypothesis is true." The hypothesis is presumably either true or false. The probability statements are statements about one particular "property" of a procedure. Whether it is a "good" procedure depends on a great deal more.
3. For many purposes, neither experiment is particularly "good." It depends on the alternative hypothesis that is the salient rival, but it is easy to come up with cases where Type I and II errors are going to be rather large. Figure 3.4 displays the sampling distribution of the two estimators. Neither experiment is going to be good, for example, at detecting the difference between a true mean of 0.5 and 0.51.

   Indeed, this was the non-Bayesian reaction to our earlier examination of ECMO: these experiments aren't likely to settle a well-meaning debate. Sometimes one is faced with a situation where one is trying to squeeze some inferential

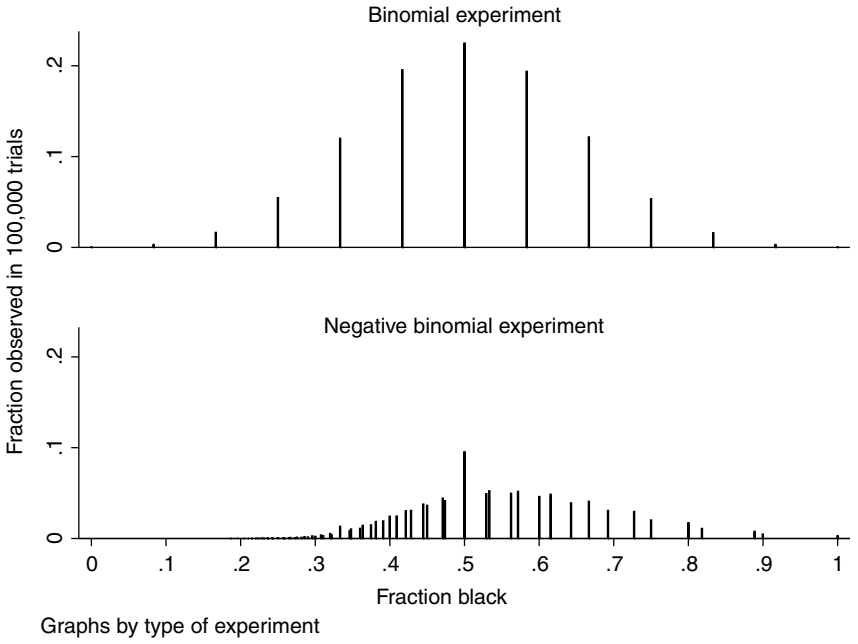

Figure 3.4 The introductory puzzle – which data-generation process?

blood from an experimental rock. In many such cases, we will not be able to put any proposition to a "severe test."

For the Bayesian the resolution of the problem is quite different – the data-generation process (DGP) doesn't (and shouldn't) matter. This if often referred to as "the likelihood principle." To see how this works, recall the statement of Bayes' rule in equation (3.5):

$$P(A_i|B) = \frac{P(B|A_i)P(A_i)}{\sum_{j=1}^{k} P(B|A_j)P(A_j)}.$$

Consider two different likelihoods such that:

$$zP(B|A_i) = P^*(B|A_i) \quad \forall A_i, z > 0.$$

Now use Bayes' rule to show that one's inference is unaffected by use of $P^*(B|A_i)$ instead of $P(B|A_i)$:

$$\begin{aligned} P(A_i|B) &= \frac{P^*(B|A_i)P(A_i)}{\sum_{j=1}^{k} P^*(B|A_j)P(A_j)} \\ &= \frac{zP(B|A_i)P(A_i)}{\sum_{j=1}^{k} zP(B|A_j)P(A_j)} \\ &= \frac{zP(B|A_i)P(A_i)}{z\sum_{j=1}^{k} P(B|A_j)P(A_j)} \\ &= \frac{P(B|A_i)P(A_i)}{\sum_{j=1}^{k} P(B|A_j)P(A_j)}. \end{aligned}$$

Indeed, because of this property, Bayes' rule is often written as:

$$\underbrace{P(A_i|B)}_{\text{Posterior}} \propto \underbrace{P(B|A_i)}_{\text{Likelihood}} \underbrace{P(A_i)}_{\text{Prior}}. \tag{3.9}$$

Consequently, how the data was generated does not matter for the typical Bayesian analysis. It is also why a Bayesian would view the information in the binomial versus negative binomial experiment as being the "same."

This property of Bayesian inference has been frequently cited as being one of the most significant differences between Bayesians and non-Bayesians.[36]

3.5.3 If the DGP is irrelevant is the likelihood really everything?

A great deal more follows from the Bayesian approach. Unlike the previous example, which might discomfit some non-Bayesians, another implication seems a bit more problematic. One significant difficulty with the simplest versions of Bayesian analysis concerns the distinction between "theorizing after the fact" and "predesignation."

There exist many discussions of this problem. Our discussion follows Sober (2002), who poses a problem involving a deck of cards with 52 different types of cards. Suppose 5 cards are randomly drawn from a typical 52-card deck. Call the configuration of cards that results X. We are now going to use data on X to revise our beliefs about various theories of the world.

Two theories that can "explain" X include:

1. *Theory A*. The particular 5 cards were randomly drawn from a deck of 52 cards.
2. *Theory B*. A powerful demon intervened to ensure that the configuration A was drawn.

The essence of Bayesian analysis requires calculating the likelihood of observing X if theory A is true and calculating the likelihood of observing X if theory B is true. Your actual priors aren't particularly important, but assume that $P(A) > 0$ and $P(B) > 0$, although the probability you attach to them can be small.

The problem arises because the likelihood of the second (silly) theory is higher in the second (false) theory than in the first (true) theory. Since there are 2,598,960 different 5-card hands that can result:

$$P[X|A] = 1/2,598,960$$
$$P[X|B] = 1.$$

Regardless of your prior beliefs about A or B, whatever you believed before, equation (3.9) instructs you to increase the "weight" you give to the demon hypothesis! (Of course, your posterior density might assign little weight to B, but our interest is merely in the fact that the "experiment" induces you to give more weight than you did before to B.) If we continued drawing 5-card hands, and continued to elaborate our demon hypothesis after the fact, we could in principle move you even closer to believing that hypothesis!

If that example strikes you as fanciful, consider a more familiar example, usually called the "optional stopping" problem. To fix ideas, imagine being interested in whether some normally distributed variable (with a known variance of 1) has a mean of zero or otherwise.

1. Take a sample of size 100 and do the usual non-Bayesian hypothesis test in the manner suggested by Kmenta earlier. In this case compute $z = \frac{\sum_{i=1}^{N} X_i}{\sqrt{N}}$.
2. Continue sampling until $|z| \geq k_{0.05}$ or $N = 1000$, whichever comes first, where $k_{0.05}$ is the appropriate 5% critical value.

As the non-Bayesian knows, the first procedure provides a far more reliable indicator that the mean is zero than the second test. With the sampling size fixed in advance, if $|z|$ turns out to be greater than the appropriate critical value, the usual conclusion is that either the null is false or "something surprising happened." Under the second DGP, the probability of Type I error is 53% (see Mayo and Kruse, 2002).

What the results of the experiment would do to a non-Bayesian's *beliefs* is a separate matter, but it is clear that he/she would find a "rejection" much more informative in the first case.

By contrast, for the Bayesian who adheres to the Likelihood Principle, both experiments provide the **same** information: the posterior probability assigned to the null hypothesis should be the same, regardless of which experiment is performed. The Bayesian is free to ignore the "intentions" of the experimenter (that is, the DGP), presumably "locked up" in the mind of the experimenter. Confronted with the evidence consistent with the usual rejection of the null for the non-Bayesian, the change in the posterior beliefs of the Bayesian would be the same under both experiments.

An interesting debate on "optional stopping" can be found in the famous Savage forum (1962, p. 70 ff.), where precisely this example is discussed. For Armitage, a non-Bayesian, the DGP is very important and a flaw of Bayesian reasoning:

> I think it is quite clear that likelihood ratios, and therefore posterior probabilities, do not depend on a stopping rule. Professor Savage, Dr Cox and Mr Lindley [participants in the forum] take this necessarily as a point in favour of the use of Bayesian methods. My own feeling goes the other way. I feel that if a man deliberately stopped an investigation when he had departed sufficiently far from his particular hypothesis, then "Thou shalt be misled if thou dost not know that." If so, prior probability methods seem to appear in a less attractive light than frequency methods, where one can take into account the method of sampling. (Savage *et al.,* 1962, p. 72)

G.A. Barnard, another forum participant – who originally proposed that the two experiments should be the same (Barnard, 1947a, 1947b) and introduced the notion to Savage – expressed the view that the appropriate mode of inference would depend on whether the problem was really a matter of choosing among a finite set of well-defined alternatives (in which case ignoring the DGP was appropriate) or whether the alternatives could not be so clearly spelled out (in which case ignoring the DGP was not appropriate.)[37]

3.5.4 What probabilities aren't – the non-Bayesian view

In a phrase, a Bayesian is more congenial to the notion that probabilities generated in the course of hypothesis testing represent the "personal probability that some claim is true or not," while such probabilities are merely devices that help "guide inductive behavior by assessing the usefulness of an experiment in revealing an 'error.'"[38] One problem sometimes cited by Bayesians is that non-Bayesians don't understand what "probability" means. To put it succinctly, a "*p*-value" is *not*:

- "The probability of the null hypothesis.
- The probability that you will make a Type I error if you reject the null hypothesis.
- The probability that the observed data occurred by chance."(Goodman, 2004)

The usual set-up begins with a "null hypothesis" and an "alternative hypothesis." Hypotheses can be simple or composite: an example of a simple hypothesis is "The population mean of a binomially distributed random variable is 0.5." That is, we can completely characterize the distribution of the random variable under the hypothesis. A "composite" hypothesis is a hypothesis that does not completely characterize the distribution of the random variable. An example of such a hypothesis is "The population mean of a binomially distributed variable is greater than 0.5." In addition to a set of "maintained hypotheses" ("the experimental apparatus is working correctly"), the next step is specifying a *test statistic.* In the usual hypothesis testing procedure, the distribution of this test statistic under the null hypothesis is known.

There are many ways to demonstrate that the probabilities that are used in hypothesis testing do not represent the probability that some hypothesis is true. A distinction that is sometimes made is "before trial" and "after trial" views of power and size. The following example comes from Hacking (1965).

Consider two hypotheses, a null ($\mathcal{H}_0$) and an alternative ($\mathcal{H}_1$), which are the only two possible states of the world. Let E_1, E_2, E_3, E_4 be the four possible outcomes and let the following be true about the world:

	$P(E_1)$	$P(E_2)$	$P(E_3)$	$P(E_4)$
$\mathcal{H}_0$:	0	0.01	0.01	0.98
$\mathcal{H}_1$:	0.01	0.01	0.97	0.01

We are interested in two tests, R and S, and specifically the power and size of the tests. Let the size of a test be the probability of incorrectly rejecting the null when it is true, and let the power of the test be 1 less the probability of Type II error (not rejecting $\mathcal{H}_0$ when it is false). For tests of a given size, more powerful tests are "better." The caveat about "a given size" is necessary since we can always minimize size by deciding on a rule that always rejects.

		Before trial	
		Size	*Power*
Test R	Reject $\mathcal{H}_0$ if and only if E_3 occurs	0.01	0.97
Test S	Reject $\mathcal{H}_1$ if and only if E_1 or E_2 occurs	0.01	0.02

If one takes a naive view of "power" and "size" of tests, the example is problematic. The size of both tests are the same, but test R is much more powerful – much less likely to fail to reject the null when it is false. *Before the trial*, we would surely pick test R.

What about *after* the trial? Consider the case when E_1 occurs. In that case test R instructs us to "accept" the null when *after* the trial we *know* with complete certainty that the null is false. The standard "evasion" of the problem for non–Bayesians is to observe (as Hacking, 1965, and Mayo, 1979, observe), that this is not a test that would usually be countenanced since there exist uniformly more powerful tests than R. This evasion, however, does not get to the heart of the problem.

3.5.5 What should "tests" do?

The previous discussion has attempted to be clear about why the "probabilities" of the usual hypothesis testing procedures should **not** be conflated with the "probability that the hypothesis is true."

What, then, is the "heart of the problem"? One argument, now associated with Mayo (1996), is that hypothesis tests should be used to put propositions to "severe" tests. The purpose of the probabilities for the non-Bayesian is to ascertain, as much as one can, how reliable specific procedures are at detecting errors in one's beliefs.

What is a severe test? In C.S. Peirce's words:

> [After posing a question or theory], the next business in order is to commence deducing from it whatever experimental predictions are extremest and most unlikely ...in order to subject them to the test of experiment. The process of testing it will consist, not in examining the facts, in order to see how well they accord with the hypothesis, but on the contrary in examining such of the probable consequences of the hypothesis as would be capable of direct verification, especially those consequences which would be very unlikely or surprising in case the hypothesis were not true. When the hypothesis has sustained a testing as severe as the present state of our knowledge ... renders imperative, it will be admitted provisionally ... subject of course to reconsideration. (Peirce, 1958, 7.182 and 7.231, as cited in Mayo, 1996)

Perhaps no better account can be given than Peirce's quotation. A nice quick gloss of a slightly more formal version of this idea is given in Mayo (2003):

Hypothesis H passes a severe test T with **x** *if*:

(i) **x** agrees or "fits" H (for a suitable notion of fit).
(ii) with very high probability, test T would have produced a result that fits H less well than **x**, if H were false or incorrect.

Mayo (1996) gives a nice example of why error probabilities *of themselves* are not enough, and why specification of an "appropriate" test statistic is a key ingredient. Mayo's example involves testing whether the probability of heads is 0.35 ($\mathcal{H}_0$) against the alternative that it is 0.10 ($\mathcal{H}_1$). It is an "artificial" example, but doesn't suffer the defect of the previous example – namely that the test is not the best in its class.

Suppose it is agreed that four coins will be tossed and that the most powerful test of size 0.1935 will be chosen. The following table shows the likelihood of observing various outcomes in advance of the experiment:

# Heads	*0*	*1*	*2*	*3*	*4*
$P(\mathcal{H}_0\|\cdot)$	0.1785	0.3845	0.3105	0.1115	0.0150
$P(\mathcal{H}_1\|\cdot)$	0.6561	0.2916	0.0486	0.0036	0.0001

Consider the following two tests:

Test 1	Reject $\mathcal{H}_0$	$\iff h = 0, 4$	Size = 0.1935	Power = $1 - 0.3438$
Test 2	Reject $\mathcal{H}_0$	$\iff h = 0$	Size = 0.1785	Power = $1 - 0.3439$

Given the set-up, the most powerful test of size 0.1935 is Test 1 – it is (slightly) more powerful than Test 2. But preferring Test 1 clearly doesn't make sense: if one sees all heads, it is surely more likely that $\mathcal{H}_0$ is true, yet Test 1 instructs you to reject. Mayo's solution is to observe that Test 1 fails to use an *appropriate* test statistic – one that measures how well the data "fits" the hypothesis. Even though one is searching for tests of size 0.1935 or better with the most "power," one chooses Test 1 at the cost of a nonsensical test statistic. The *usual* sort of test statistic might be the fraction of heads (F) less 0.35. Such a statistic has the property of punishing the hypothesis in a sensible way.

In this case, the test statistic takes on the following values:

# Heads	$F - 0.35$
0	-0.35
1	-0.10
2	0.15
3	0.40
4	0.65

In this account, Test 2 corresponds to the decision rule "Reject if $F - 0.35 < -0.1$" and the outcomes are now ordered by their departure from the null (in the direction of the alternative). The use of an appropriate sense of "fit" serves to show that the probabilities *per se* are not important – they don't directly correspond to a measure of belief. Rather, they are one step in assessing how good the test is at revealing an "error" (Mayo, 2003). The theory doesn't tell you in most non-trivial cases, however, how to generate a sensible test statistic – that depends on context.

While this example is admittedly superficial, it helps explain why, in constructing a good experiment, the importance of other (possibly not well defined) alternatives cannot be ignored. How *severe* a test is is always relative to some other possible alternatives. Suppose we collect data on unaided eyesight and the use of corrective glasses or contact lenses. If one proposed to "test" the theory that eye glass wearing **caused** unaided eyesight to get worse and found a "significant" rejection of the null of no correlation in favor of the alternative that the correlation was negative the "p-value" might be small but it would fail to be a **severe** test against the hypothesis that people with poor uncorrected vision are more likely to wear eye glasses.

3.5.6 Randomization and severity

One place where Bayesians and non-Bayesians differ is on the usefulness of randomization. Here, we can only introduce the problem.

Consider a case where the true state of the world can be characterized simply by the following:

$$y = \beta_0 + \beta_1 T + \beta_2 X + \epsilon, \tag{3.10}$$

where, for simplicity, the β are unknown parameters, the X are things that "cause" y and are observed, ϵ are things that "cause" y but are not observed, and $T = 1$(received treatment).

For the non-Bayesian, one of the benefits of randomization is that the X variables available are usually very inadequate. Also ϵ is some convolution of omitted variables and functional form misspecification: it is not generally plausible to make a statement like "ϵ follows the normal distribution," although statements like that are often found in the literature. Hence, though one could write down a "likelihood," it isn't necessary for the non-Bayesian.

A caricature might make this clear: it is **not** the case that "on the first day, God created y and made it a linear deterministic function of T and X; on the second day, in order to make work for econometricians, God appended a normally distributed error term with mean 0."

Indeed, in a randomized controlled trial (RCT), when the experimenter can intervene and assign T randomly, the "model" the experimenter estimates is often much less complicated:

$$y \quad = \quad \beta_0 + \beta_1 T + \epsilon. \tag{3.11}$$

For purposes of estimation one *could* write down a normal likelihood for this model:

$$y = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{y_i - \beta_0 - \beta_1 T_i}{2\sigma^2}\right). \tag{3.12}$$

With this likelihood, one could then specify prior beliefs about the fixed parameters β_0 and β_1, stipulate the form of heterokedasticity (that is, that the variance of ϵ was a constant for all observations, or model the heteroskedasticity), and so on. After seeing the data a Bayesian could update his/her beliefs about the values of these two parameters. Note that, in this formulation, there appears to be nothing special about the likelihood to distinguish it from any other comparison of means – nothing tells us, for example, that T was assigned randomly.

Nonetheless, writing down the likelihood seems a bit bizarre for the non-Bayesian. For example, if the treatment, T, was a nicotine patch and y was some outcome like "quit smoking successfully," no one thinks that only the patch matters and nothing else that can be observed matters – clearly the price of cigarettes, social norms, and so on, play a role. Indeed, available covariates are usually not used except to "test" the validity of the design. Specifically, in repeated samples:

$$E[\overline{y}_1] - E[\overline{y}_0] = \beta_1 \tag{3.13}$$

$$E[\overline{X}_1] - E[\overline{X}_0] = 0 \tag{3.14}$$

$$E[\epsilon_1] - E[\epsilon_0] = 0, \tag{3.15}$$

where $\bar{y}_1 \equiv \frac{1}{N_1}\sum_{i;T=1} y_i$, $\bar{y}_0 \equiv \frac{1}{N_0}\sum_{i;T=0} y_i$, the subscript 1 refers to the treatment group, the subscript 0 refers to the control group, and so on.

Taken literally, (3.14) suggests that, on average, in repeated samples, the mean for *any* pre-treatment variable should be the same. An auxiliary implication is that if one ran the regression but also included pre-treatment variables, the estimate of the effect of the treatment should not change. If it does change substantially, this is evidence against the design, and a cause for concern.

To fix ideas, suppose the treatment under consideration is ECMO (which we considered in section 3.1.1) and suppose a standard randomization scheme was employed on a large sample of children. A standard procedure is to report the averages for several variables. Table 3.1 is a hypothetical table.

Table 3.1 Hypothetical RCT on the efficacy of ECMO pre-treatment values of key variables (standard errors in parentheses)

Pre-treatment variable	*Treatment*	*Control*
Birth weight (grams)	3.26	3.21
	(0.22)	(0.23)
Age (days)	52	54
	(13)	(14)

Usually researchers report whether there are any "significant" differences between the treatment and control group means. The intended purpose is to ensure that the two groups satisfy a *ceteris paribus* condition: in ways we can observe, are the two groups roughly the same? – this is sometimes referred to as "balance." If sample sizes are large enough, more frequently than not the values in the two columns will not be "significantly" different. It serves as a "check" that the randomization achieved its intended purpose.

What variables should be included in this "check"? Presumably such a list does not include hair color, although this, in principle, should be balanced as well. The usual rule is to consider "pre-treatment variables which are predictive of the outcome." These may or may not be part of a proper "model" of infant death, but are there to assure one that, if there is a large difference in the groups after treatment, the researcher will not mistakenly attribute to the treatment what was really a failure of the *ceteris paribus* condition.

Bayesians frequently point to a flaw in this argument:

> My doubts were first crystallized in the summer of 1952 by Sir Ronald Fisher. "What would you do," I had asked, "if, drawing a Latin Square at random for an experiment, you happened to draw a Knut Vik square?" Sir Ronald said he thought we would draw again and that, ideally, a theory explicitly excluding regular squares should be developed ...

> The possibility of accidentally drawing a Knut Vik square or accidentally putting just the junior rabbits into the control group and the senior ones into the experimental group illustrates a flaw in the usual . . . argument that sees randomization as injecting "objective" or gambling-device probabilities into the problem of inference. (Savage *et al.,* 1962, p. 88)

Savage's example of having all the young rabbits in the control group and all the older rabbits in the treatment group is perhaps more recognizable than the distinction between Latin squares and Knut Vik squares, which come from classical agricultural experimentation. It is also related to the problem of random or pseudo-random number generation. If generating a sequence of random 0s and 1s, for instance, by chance (if only infrequently), some of these sequences will be undesirable – for example, if drawing a sequence of 1,000 numbers, it is possible that one draws all zeroes or all ones.

In the context of the RCT, the analogous problem, loosely based on our ECMO example, is described in Table 3.2. Assignment to the two groups was randomized but "bad luck" happened and the control group was comprised of the lightest birthweight babies (and viewed by the doctors as usually the least healthy) who were, on average, potentially in need of ECMO at much older ages (again, viewed by the doctors as an indicator of general frailty).

Table 3.2 Bad luck in a hypothetical RCT on the efficacy of ECMO pre-treatment values of key variables (standard errors in parentheses)

Pre-treatment variable	*Treatment*	*Control*
Birth weight (grams)	3.26	2.1
	(0.22)	(0.23)
Age (days)	52	140
	(13)	(14)

In this example, the problem is that the treatment and control groups are not "balanced." The treatment babies are (before treatment) healthier on average than the control babies. The typical non-Bayesian would generally find the numbers in Table 3.2 evidence against the validity of the design.[39]

For Bayesians, this suggests that the logic of randomization is flawed. If "balance" is the primary reason for randomization, why not deliberately divide into groups which look similar (and would "pass" a balancing test) without randomization *per se*. How does introducing uncertainty into treatment assignment help? Indeed, to some Bayesians, all it can do is lower the value of the experiment. From Berry and Kadane (1997):

> Suppose a decision maker has two decisions available, d_1 and d_2. These two decisions have current (perhaps posterior to certain data collection) expected

> utilities $U(d_1)$ and $U(d_2)$ respectively. Then a randomized decision, taking d_1 with probability λ and d_2 with probability $1 - \lambda$ would have expected utility $\lambda U(d_1) + (1 - \lambda)U(d_2)$. If the randomization is non-trivial, i.e. if $0 < \lambda < 1$, then randomization could be optimal only when $U(d_1) = U(d_2)$, and even then a non-randomized decision would be as good.

Savage goes further: "It has been puzzling to understand, why, if random choices can be advantageous in *setting up* an experiment, they cannot also be advantageous in its analysis."

There is much more to say: for instance, it may be useful to think about this class of problems in terms of the severity concept that we introduced earlier. However, it may be more instructive to consider two examples from real research. In one, I identify the problem as lack of severe testing. In the second, I identify the problem that the world is a "complicated place": assertions that were felt to be well-grounded by numerous studies seem less so in the face of a well-designed experiment.

3.6 Case study 1: "medication overuse headache"

In section 3.1.1 I briefly mentioned the case of ECMO – a treatment for infants with persistent pulmonary hypertension whose success was initially uncertain, but retrospectively seems of great benefit. Here I would like to consider a potentially "mirror-image" case: a treatment is being administered that, in my view, is potentially quite harmful. Also, I would argue, the literature is of unbelievably low quality. I locate the problem with the theory in the fact that, instead of behaving like Mayo's "error statistician" or engaging in "Peircean severe testing," the researchers began with a prior belief and then set about "updating" it. It should be noted that none of the studies involving this topic used "Bayesian statistics."[40] Rather, the question is "Is there enough evidence to proceed with the expert consensus or is more 'severe' testing necessary?"

This case is particularly useful because, as with many problems in medicine and social sciences (and elsewhere), it involves a problem of dubious ontology (is there "really" such a thing as medication overuse headache (MOH)?) as well as the problem of "new hypotheses" that "accommodate" the evidence instead of having a theory held in advance that "predicted" the evidence (much like our "demon" example in section 3.5.3).

A road map for what follows is:

1. During a period of time when the field was considered a "backwater" a diagnosis of MOH was developed. This theory argued that people with chronic severe headache pain caused their pain by taking pain medication "too frequently" and that, if they merely stopped taking the medication, their pain condition would improve.
2. The evidence for this theory was that patients who agreed to stop their pain medication had higher rates of improvement than those who didn't. These

studies typically ignore serious selection bias due to non-random attrition and regression to the mean.
3. In one of the few published critiques of the theory, it was noted that millions of users of analgesics, for reasons other than headache, do not develop migraine. In response, the theory evolved to state that only those individuals "predisposed" to migraine get MOH.
4. When a definition of the diagnosis that required improvement in pain after cessation of the offending medication was proposed it was strongly criticized. The definition was revised to empty it of potentially refutable content.

Every challenge to the theory that pain medication causes pain has been met by "accommodating" the evidence. Rather than reject the theory, at every turn the theory has accommodated the new evidence by making it more difficult to test. Furthermore, there is a complete absence of "severe testing."

3.6.1 What is medication overuse headache? Nosology and dubious ontology

The essence of "medication overuse headache" as a term for a certain class of chronic headache pain[42] is the idea that the patient *causes* his/her pain by taking pain (or other headache) medication in excess of arbitrary norms (set by researchers in the area) of appropriate use. The "offending" medication, as it is often referred to, can be any of a very diverse set with very different effects and mechanisms of action. These include ergotamine, caffeine, morphine, sumatriptan, and many other drugs. Opioids (morphine and related medications) are generally thought to be more of a problem than the other medications (Saper and Lake, 2006a).[42] Obermann and Katsarava (2007) cite a global prevalence rate of 1% and describe it as the "third most frequent headache type after tension-type headaches and migraine."[43]

> There are two ways to account for this phenomenon. The obvious one is that these people take chronic daily analgesics because they have chronic daily headaches. This is the explanation embraced by our patients and, until recently, by most physicians [who are not headache specialists]. (Edmeads, 1990)[44]

I believe this case study is illuminating because it suggests that the problem is *not* one of failing to view probability as epistemic, but is because researchers in the area have systematically *not* confronted their long-held views with severe testing.

3.6.2 Some salient background

3.6.2.1 Early history

In a recent review of the subject, Obermann and Katsarava (2007) date the first clear identification of MOH to a 1951 study, without a control group or randomization, which described 52 patients who took daily amounts of ergotamine and improved after "the ergotamine was withdrawn. A recommendation of the first withdrawal program followed and was introduced in 1963." The view that

medication overuse was a *cause* of migraine pain "became well-established" in the early 1980s (Capobianco *et al.,* 2001). It was first officially defined by the International Headache Society (1988) – the international association of neurologists with a specialty in headache – as "drug induced headache" in the International Classification of Headache Disorders (ICHD-1) (Obermann and Katsarava, 2007).

The view that medication use *caused* head pain was developed during a period of time when it was widely held that "migraine was a disorder of neurotic women" (Silberstein, 2004).[45]

3.6.2.2 The evidence

While a complete review of the evidence is not possible, let me take one representative example: Mathew *et al.* (1990).[46] Figure 3.5 is a modified version of a table from Mathew *et al.* The title of the table is also from the original article. Patients were assigned[47] to different treatment groups and their progress was observed.[48]

As Mathew *et al.* report, the data in the figure were based only on those patients who remained in the study – 90% in the group which continued to receive medication but only 50% in the group which had the medication withdrawn. With slight variations, Mathew *et al.*'s conclusions have become standard.[49] As far as I have

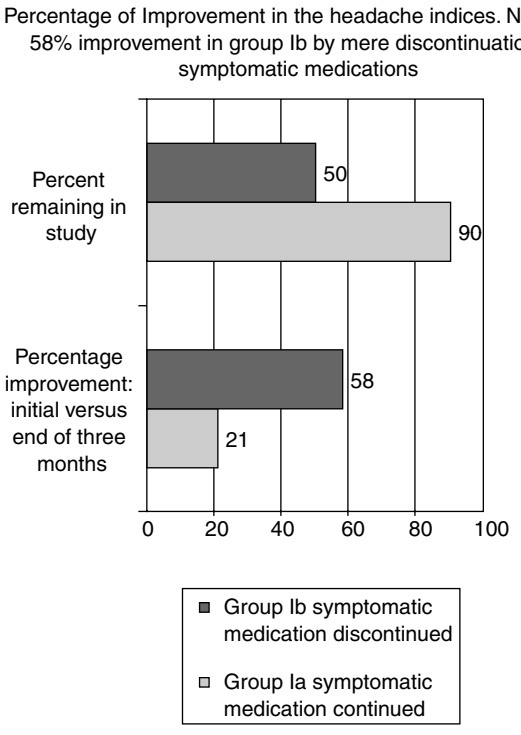

Figure 3.5 The evidence in a nutshell

been able to determine, the literature has not concerned itself with the problem of non-random attrition. One might expect that a patient who fails to improve after stopping the offending medication might be more likely to drop out than one who has improved (for some reason possibly unrelated to treatment). One possible reason for improvement might be mere "regression to the mean." For evidence that strongly suggests this is a problem see Whitney and Von Korff (1992).

3.6.2.3 First criticism

In one of the first (and extremely rare[50]) criticisms of research in this area, Fisher (1988) observed:

> As I understand it, analgesics beget more headache by making more brain serotonin available, which paradoxically increases the pain. My question is whether it holds only for headache or for other pains as well? In our arthritic clinic aspirin was used in doses of 8 to 14 tablets a day for about 15 years. I asked physicians who attended that clinic in those years whether they had ever noticed [the development of headache pain] . . . in any of the patients and they never had. Also 3 to 5 million people in the United States are taking aspirin daily to prevent arterial thrombosis. Should we expect headache . . . under these circumstances?[51]

As Fisher understood, the answer to his questions was "no" and advocated a randomized trial on the effect of withdrawal from headache medications where the control group would be subject to sham double-blind withdrawal. One can think of this as a proposal for a "severe test."

The response in the literature was to maintain that the theory was, in the main, correct and to merely amend the theory to accommodate the troubling fact highlighted by Fisher.[52] A typical amendment stated that "'analgesic abuse headache' may be restricted to those patients who are already headache sufferers [and that] individuals with . . . migraine, are predisposed to developing chronic daily headache in association with regular use of analgesic" (Bahra *et al.,* 2003).

3.6.3 Redefining MOH to avoid a severe test

The process of defining MOH provides a clear example of researchers avoiding a severe test. A useful place to start is the *initial* International Classification of Headache Disorders – 2 (ICHD-2).[53] The initial ICHD-2 definition of "medication overuse headache" is displayed in Table 3.3 (Headache Classification Committee of the International Headache Society, 2006).[54]

A key aspect of the definition is criterion C: the patient's *decision* to continue using analgesics at more than the approved rate.[55] This was immediately recognized to be a problem: existing standards of treatment for other forms of migraine, such as "menstrual migraine," *required* the use of analgesics at a rate which could then (inappropriately) be described as MOH.[56]

Another important aspect of the definition of MOH that was the subject of great dispute was item D – the requirement that, after removing the patient from the

Table 3.3 Initial 2004 International Headache Society classification criteria for analgesic-overuse headache

A. Headache present on ≥ 15 days/month with at least one of the following characteristics and fulfilling criteria C and D: 1 bilateral 2 pressing/tightening (non-pulsating) quality 3 mild or moderate intensity
B. Intake of simple analgesics on ≥ 15 days/month for > 3 months
C. Headache has developed or markedly worsened during analgesic overuse
D. Headache resolves or reverts to its previous pattern within 2 months after discontinuation of analgesics

Table 3.4 Revised ICHD-2 criteria for MOH

A. Headache present on ≥ 15 days per month
B. Regular overuse for > 3 months of one or more acute/symptomatic treatment drugs as defined under sub forms of 8.2 1. Ergotamine, triptans, opioids, or combination analgesic medication on ≥ 10 days/month on a regular basis for ≥ 3 months 2. Simple analgesics or any combination of ergotamine, triptans, analgesic, opioids on ≥ 15 days/month on a regular basis for ≥ 3 months without overuse of any single class alone
C. Headache has developed or markedly worsened during medication overuse

offending medication, the patient would improve. As reported in the literature, the problem was that such a requirement vitiated using MOH as a "diagnosis" in the traditional sense: "the problem is that medication overuse headache cannot be diagnosed until the overuse has been discontinued and the patient has been shown to improve. This means that when patients have it, it cannot be diagnosed. It can be diagnosed only after the patient does not have it any more."

After a meeting of experts in Copenhagen, this offending section (D of Table 3.3) – requiring improvement after going off the "causal" medications – was quickly removed to produce a revised version (Table 3.4). Whatever their intent, however, this redefinition seemed to make a MOH diagnosis impossible to refute.[57] Indeed, it was immediately noted that "the revision [to the definition of MOH] has eliminated the need to prove that the disorder is caused by drugs, that is, the headache improves after cessation of medication overuse" (Ferrari *et al.,* 2008). Although they suggested that "probable MOH" be introduced, their main focus was that sub-forms of MOH be defined for different types of medications, with opioids singled out as particularly problematic.[58]

The case of opioids is especially interesting since it is generally believed that opioid-related MOH is more worrisome and it has been argued that "sustained opioid therapy should rarely be administered to headache patients" (Saper and Lake, 2006b). This case is also useful since it might be falsely assumed that individuals doing research in this area (and supporting the idea of MOH) are incapable of, or not disposed to, putting hypotheses to severe testing. As noted previously,

researchers in this area routinely make no adjustment of any sort for the high rates of attrition in studies looking at chronic headache pain.

An illustrative exception to non-severe testing involves, not a test of MOH, but rather a study of the efficacy of sustained opioid therapy – opioids being considered a particularly pernicious cause of MOH (Saper and Lake, 2006a, 2006b). Although Saper *et al.* (2004) had no control group, the researchers treated individuals who dropped out for *any* reason, died for non-opioid related reasons, were suspected of "cheating" (using more opioids than allowed by the doctors), and so on, as *treatment failures*. This also included some patients who reported a substantial improvement but were considered to have "failed" to satisfy the *researchers'* definition of a significant reduction in functional impairment. In defining treatment failure more broadly, the researchers were essentially using a "worst case" bound.[59] While the use of "worst case bounds" is infrequent (or nonexistent) in the MOH literature, the argument for doing so has validity: it is entirely consistent with the notion of "severe testing." Indeed, leading researchers in MOH are aware of the potential value of such bounds. Saper and Lake (2006b), for example, harshly criticize a meta-analysis of RCTs on the efficacy of opioids for non-cancer pain for failure to adhere to "intent-to-treat" principles. In this instance, this meant treating as failures those individuals who began opioid treatment but then stopped for *any* reason.[60]

The severity of the tests to which opioid efficacy has been confronted is in sharp contrast to extant studies of MOH (sometimes by the same researchers), where a failure of a patient to reduce his medications is not treated as a failure of MOH therapy. Indeed, where attrition rates of 40% or higher are common, were the literature to treat those who were unwilling or unable to abstain from the offending medication as failures of "MOH therapy," it would appear that few, if any, of the studies in Zed *et al.* (1999) that purport to provide evidence favorable to the existence of MOH would continue to do so. Indeed, although plagued by non-random attrition and written by advocates of MOH, it has been observed that patients with MOH who "lapse" and re-establish medication overuse have higher measured "quality of life" on average than those with MOH who do not lapse (Pini *et al.*, 2001).

It might fairly be argued that an intelligent Bayesian might not have moved his/her posterior much in light of the foregoing discussion. Moreover, it is certainly the case that no formal Bayesian analysis has been employed. At least superficially, the "usual" statistical analysis was employed. What this literature *doesn't* do, however, is:

1. test the theory in such a way that the observed result would be unlikely if the obvious alternative (the one "favored by patients") was true – that it is chronic pain that causes use of pain relieving medication, not the other way around
2. employ the "usual" techniques to make tests more "severe" – the failure to use worst-case bounds, for instance, to deal with the problem of non-random attrition
3. react to each threat to the theory as potential reason to abandon the theory. Instead, the reaction of researchers has been continued modification of the theory until it is no longer capable of being refuted by evidence.

3.7 Case study 2: "union wage premium"

I would now like to consider an econometrically sophisticated literature – the literature on union wage effects. Two comprehensive and influential surveys are Lewis (1963, 1986). In these works, Lewis literally cites hundreds of studies attempting to estimate the causal effect of union status on wages.[61] See also the useful discussion in Heckman (1990).

3.7.1 Early history

The idea that labor unions might raise wages is one of the oldest debates in economics and was one of the earliest motivating examples for the famous "supply and demand" cross in a study by Jenkin (1870) (see Humphrey, 1992, for a short history). Ironically, although Jenkin (1868) concluded that the supply and demand analysis wasn't particularly relevant for explaining the consequences of union wage-setting, subsequent neoclassical theorizing in the main focused on the simple model depicted in Figure 3.6, where W is the real wage, L is the quantity of labor, D is the employer demand curve, S_c is the supply curve without unionization and S_u is the supply curve with unionization. Until Lewis' influential survey, opinions diverged between those who believed that unions could rarely control the supply of labor, such as Milton Friedman, and those that thought they could and therefore acted to create unemployment, such as Paul Samuelson (see Friedman, 1950).

3.7.2 A battery of severe tests

The analysis of union wage effects has become more sophisticated with the advent of large micro-datasets, but let me highlight some of the comparisons researchers

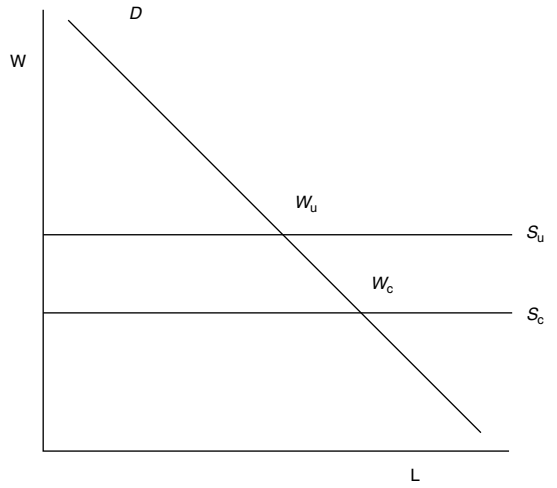

Figure 3.6 Union wage effects in the neoclassical model

have employed to analyze the question:

- Ashenfelter (1978) constructs control groups based on industry, race, and worker type (that is, craftsmen, operatives, laborers).
- Freeman (1984) compares wage rates for the same individual at *different points in time*. At one point in time the worker is in a unionized job; at a different point in time the worker is in a non-unionized job.
- Lemieux (1998) compares wage rates for the same individual who holds *two jobs*, one of which is unionized, the other which is not.
- Krashinsky (2004) compares wage rates of *identical twins*, one who is unionized and one who is not.
- Card (1992) constructs control groups, based on observable characteristics, which tend to receive the same wage in the non-union sector, as well as controlling for differences in permanent characteristics (that is, person-specific fixed effects).
- DiNardo and Lemieux (1997) and Card *et al.* (2003) compare US and Canadian workers, exploiting differential timing in the decline of unionization in the two countries.

Depending on the precise context, the union wage effect as measured in these studies ranges from 5% to 45%, with the vast majority of studies being at the higher end. All of the aforementioned studies adopt a distinctly non-Bayesian approach to the econometric analysis. The variety of research designs was not motivated by an attempt to "refine" posterior beliefs, but to put the hypothesis that unions raise wages to the most severe test possible with existing data. Each of the papers described above tried to "rule out" other explanations for the difference in union and non-union wages. (Perhaps this is why the posterior distribution of estimates of the union wage effect are as tight as they are – a survey of labor economists found remarkable unanimity on the average size of the effect (Fuchs *et al.,* 1998). The posterior mode of the economists surveyed was that unions raised wages 15% relative to similar non-union workers.)

What is also useful about this example is that there exists at least one Bayesian analysis, Chib and Hamilton (2002), which helpfully contrasts some unsophisticated non-Bayesian estimates from a small sample of workers. These non-Bayesian estimates vary from about 16% to 25%. If one treats these as "average treatment effects on the treated (ATOT)," these estimates are similar to their Bayesian posterior distributions.[62]

To put it a bit too simply, the basic empirical model has long been some variant of the following:

$$\begin{aligned} \log w_i &= X\beta_0 + \alpha_i + \epsilon_0 \quad \text{if } U_i = 0 \\ &= X\beta_1 + \psi\alpha_i + \epsilon_1 \quad \text{if } U_i = 1 \\ P(U_i = 1) &= F(Z\gamma), \end{aligned}$$

where U_i is the union status indicator for worker i, w_i is the wage of worker i, β and γ are parameters – the first two differ depending on whether the worker is unionized or not – X and Z are observed covariates, the ϵ are unobserved terms, and ψ is the ratio of the return to unobserved time invariant individual specific characteristics in the union to the non-union sector. The function $F(\cdot)$ is some type of cumulative density function and the elements of Z may overlap with X.

The Bayesian analysis of Chib and Hamilton (2002) takes a variant of the above model and is focused on how the effect of unions on wages varies across *individuals*. As has long been recognized, however, to a great extent unionization in the US occurs at the *establishment* level (this is in contrast to unionization in Europe, which frequently adheres to most workers in an industry). As Krashinsky (2004) observes, this has meant that the aforementioned empirical work has been unable to rule out the possibility of a "firm or enterprise specific fixed effect": a worker's union status could merely be a marker, for instance, for the profitability or generosity of the employer.[63] Put in other words, the list of "*ceteris paribus*" conditions considered in previous research did not include "working at the same firm."

As Freeman and Kleiner (1990) observe about the estimates of union wage effects with individual data, the "treatment effect" of most interest comes from an experiment on "firms" and not on "individuals" *per se*:

> While it is common to think of selectivity bias in estimating the union wage effect in terms of the difference between the union premium conditional on the observed union (and nonunion) sample and the differential that would result from random organization of a set of workers or establishments, we do not believe that this is the most useful way to express the problem. What is relevant is not what unionization would do to a randomly chosen establishment but rather what it would do to establishments with a reasonable chance of being unionized – to firms close to the margin of being organized rather than to the average nonunion establishment.

DiNardo and Lee (2004) use a regression discontinuity design, which, in their context, provides a very good approximation to an RCT of the sort discussed in the quote from Freeman and Kleiner (1990). Like previous work in this area, one of the motivating ideas was to put the hypothesis "do unions raise wages" to a more **severe** test, one that would allow for, among other things, a firm-specific effect.

This was possible in this research design since it used data on "firms." The research design essentially focused on comparing firms where the union "barely won" to those who "barely lost."

We can only be brief here, but the experiment is a "regression discontinuity design" based on an aspect of (US) labor law. Workers most often become unionized as the result of a highly regulated secret ballot. If more than 50% of the workers vote for the union, the workers win collective bargaining rights. If 50% or fewer do so, the workers do not win the right to collective bargaining. By comparing outcomes for employers at *firms* where unions barely won the election (for example, by one vote) with those where the unions barely lost, one comes close to the idealized RCT.

The test is severe against the hypothesis that unobserved differences in the *firms* that are unionized versus those that are not unionized can explain the different wages, and soon, of unionized workers.

It is rather easy to display the data from regression discontinuity designs. Figure 3.7 plots an idealized version of the key displays: in each, the average value of some outcome, where these averages are computed for different values of the vote share. The figure on the left corresponds to the case where unionization has an effect on the outcome in question. In the figure on the right (and one that resembles the figures in DiNardo and Lee, 2004), there is no detectable effect of unionization.

Figure 3.8 plots an idealized version of the key displays that correspond to ensuring the validity of the research design or "balance": in each the average value of some pre-treatment outcome (in the study by DiNardo and Lee this included firm size and measures of the health of the firm) are plotted for different values of the vote share. The graph on the left corresponds to the good case: firms in establishments where the union barely lost the election look the same as those where the union barely won. This corresponds to what was found in DiNardo and Lee. The figure on the right corresponds to a situation which is evidence against the design: firms in establishments where the union barely lost look much different than firms where the union barely won. In this case, the *ceteris paribus* conditions would seem to be violated.

To summarize the results of the study, the authors find (perhaps surprisingly given the huge literature documenting significant union wage effects) **no** effect of

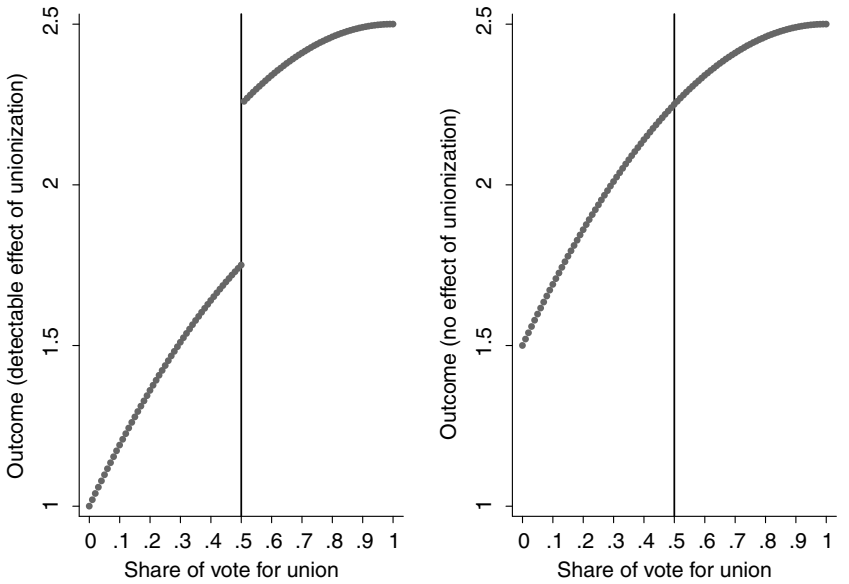

Figure 3.7 Two types of findings in a regression discontinuity design

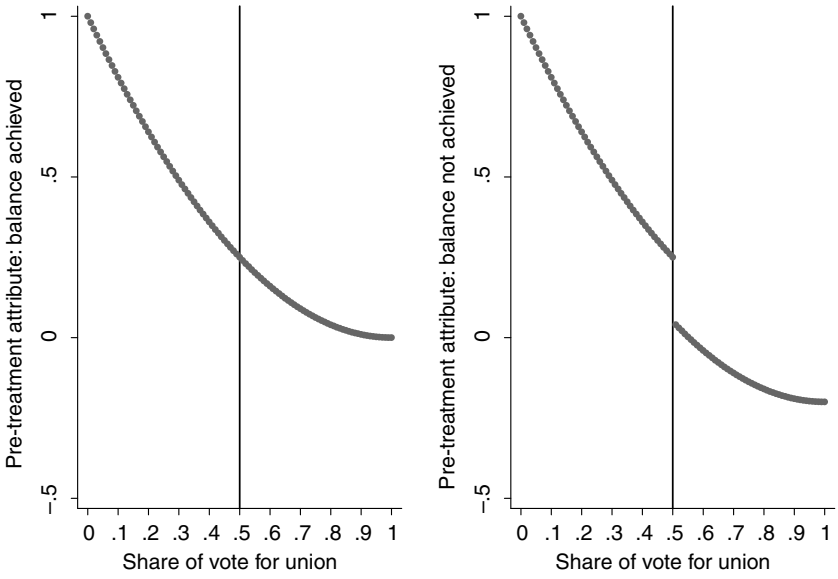

Figure 3.8 Evidence for or against "balance" in a regression discontinuity design

unionization on the myriad of outcomes they examine, such as wages, enterprise solvency, productivity, and so on. Limitations of scope prevent elaborating in more detail, but the study by DiNardo and Lee points to an important problem with any "non-severe" test of a hypothesis – Bayesian or non-Bayesian. If one takes the results from DiNardo and Lee seriously, it is hard to see how the problem could even be *addressed* with individual data – irrespective of whether Bayesian or non-Bayesian statistics were employed.

3.8 Concluding remarks

What I have written has only scratched the surface of longstanding disagreements. For any suggestion of dissent with any "Bayesian" views discussed in this chapter, there exists volumes of counter-arguments. Likewise, the debates among those who do not employ Bayesian methods are no less voluminous. I, myself, don't have a single "theory of inference" to which I adhere.

As I have sought, for reasons of clarity, to highlight the *differences* between Bayesian and non-Bayesian perspectives, I risk overstating them. It seems fitting, therefore, to conclude by illustrating that one can often find "non-Bayesian features" in Bayesian work and "Bayesian features" in non-Bayesian work.

3.8.1 Bayesian doesn't have to mean "not severe"

The idea that only non-Bayesians look for "severe tests," or "try to learn from errors," is not correct. One nice example comes from a recent careful study by Kline

and Tobias (2008), which is interested in estimating the "effect" of the Body Mass Index (BMI) on earnings.

Their point of departure is a two-equation model:

$$y_i = f(s_i) + x_i\beta + \epsilon_i \tag{3.16}$$

$$s_i = z_i\theta + u_i, \tag{3.17}$$

where y_i is log average hourly wages, x is a vector of demographic characteristics (schooling, experience, and so on) thought to have an effect on wages, s_i is the BMI of an individual, and $f(\cdot)$ is some continuous function of s which the authors introduce to allow for the reasonable possibility that, if BMI has an effect on wages, it is not necessarily linear.[64]

The most obvious possible problem is "confounding" – the relationship we observe between BMI and wages might merely represent the influence of other omitted factors that are correlated with BMI: in their model this is represented by a correlation between ϵ and u.[65] One such confounder they consider is "preferences for long-term investments, which we mean to represent characteristics that simultaneously impact decisions affecting both health and human capital accumulation."

One solution to this confounding problem is the identification of an "instrumental variable" that provides "exogenous" variation in BMI (that is, a variable which is correlated with BMI but not correlated with the unobserved determinants of wages). The authors discuss two possible instrumental variables for BMI – mother's BMI and father's BMI – and argue for their validity in several ways, including references to other literature.

In the case where $f(s)$ is linear in s, usual non-Bayesian practice is two-stage least squares or the method of instrumental variables. One test which sometimes seems to capture the notion of a"severe" test of the hypothesis that the instrumental variables are valid is an "overidentification test." Specifically, if both instrumental variables are valid, the estimated effect of BMI should be similar whether mother's BMI is used alone as an instrumental variable, father's BMI is used alone, or both are used (Newey, 1985). If the test rejects, it is unclear how to proceed, but as the authors note:

> From a theoretical perspective, however, it seems reasonable that the BMIs of the parents are either jointly valid as instruments, or jointly invalid, thus potentially calling into question what is actually learned from this procedure. On the empirical side, however, the correlation between parental BMI was found to be reasonably small (around .16), suggesting that something can be learned from this exercise, and that its implementation is not obviously redundant or "circular."

The authors' observation that the correlation between parental BMI is small seems, to me, to suggest the importance of "severity." Had the correlation been much higher, one might have been tempted to conclude that the proposed test was "obviously redundant" or "circular."

Consequently, Kline and Tobias (2008) provide an "informal test" of the validity of the "exclusion restriction" by asking whether, after using *one* instrumental variable, a model which excludes the other instrumental variable from the "structural equation" (equation (3.16) above) is well supported. Indeed, they calculate the Bayes factor associated with the hypothesis that the effect of father's BMI on wages is zero while maintaining the validity of mother's BMI as an instrumental variable and find strong support for that hypothesis. They also find strong support for the reverse.

While this does not exhaust the "specification testing" performed in the study, it does indicate an attempt to put a hypothesis to the severest test possible. Interestingly, although the study is clearly a "Bayesian" analysis, the authors found it useful to conduct such a test in an "informal" way – without attempting to "shoehorn" the specification testing into a complete Bayesian analysis.[66]

3.8.2 Non-Bayesian doesn't have to mean "severe"

My personal view is that statistical theory is often useful for situations in which we are attempting to describe something that looks like a "chance set-up." How one might go from information gleaned in such situations to draw inferences about other *different* situations, however, is not at all obvious. Some Bayesians might argue that one merely needs to formulate a prior, impose a "window on the world" (a.k.a. a likelihood) and then use Bayes' rule to revise our posterior probability. I am obviously uncomfortable with such a view and find LeCam's summary to the point: "The only precept or theory which seems relevant is the following: 'Do the best you can'. This may be taxing for the old noodle, but even the authority of Aristotle is not an acceptable substitute" (LeCam, 1977). This view also comports well with C.S. Peirce's classic description of a "severe test" I discussed earlier.

However, even at this level of vagueness and generality, it is worth observing that such views are not shared by non-Bayesians, or if they are, there is no common vision of what is meant by severe testing. Except for the most committed Bayesians, nothing in statistical theory tells you how to "infer the truth of various propositions." As I have argued elsewhere (DiNardo, 2007), often the types of theories economists seem interested in are so vague that it is often impossible to know what, in principle, would constitute "evidence" even in an "ideal" situation.

Certainly it is the case that non-Bayesian researchers are frequently unwilling to use statistical tools to change their views about *some* assessments. For one clear example, compare Glaeser and Luttmer (1997) and Glaeser and Luttmer (2003). The latter paper is a revised version of the former paper. The paper "develops a framework to empirically test for misallocation. The methodology compares consumption patterns for demographic subgroups in rent-controlled and free-market places. [They] find that in New York City, which is rent-controlled, an economically and statistically significant fraction of apartments appears to be misallocated across demographic subgroups"(Glaeser and Luttmer, 2003, p. 1027).

A significant difference between the two papers is that the latter, Glaeser and Luttmer (*ibid.*), includes an interesting falsification test (not included in Glaeser

and Luttmer, 1997). If the methodology works as intended, then when performing the same analysis on data from cities without rent control – they consider Chicago, Illinois, and Hartford, Connecticut – they should consistently estimate no welfare loss due to rent control. Contrary to such a presumption, however, for both cities they estimate large amounts of apartment misallocation (although these estimates are smaller than their estimate for New York City) that are statistically quite precise. Indeed, they acknowledge that "strictly interpreted, the results reject the identifying assumptions. In both cities, the procedure finds statistically significant misallocation" (Glaeser and Littmer, 2003, p. 1044). Nonetheless, while there are differences between the two versions of the paper, it is not clear whether such a rejection played any role in changing the inferences they draw. Indeed, they argue: "While this is disturbing, the large difference between our New York results and the results for these placebo cities suggests that even though our identifying assumptions may not exactly be true, the failure of the assumptions is unlikely to fully account for the observed misallocation in New York" (*ibid.*, p. 1044). What does it mean to say a set of assumptions fails to "fully account for the observed misallocation" and why should the results be viewed as "disturbing" (if indeed they should be)? In such a case, I think it is fair to say that we should have little confidence that their proposed *methodology* has a "truth preserving virtue." Note, however, this is only weakly related to one's views about the merits of rent control in New York City.

Much of the variation among non-Bayesians in their reaction to such statistical information seems to involve the "primacy" of certain types of (economic) *models*. Very roughly speaking, one can point to "a design-based approach" which focuses on creating or finding situations which resemble "chance set-ups" and where an analysis of the DGP proceeds separately from a single, specific, highly articulated, theoretical economic model. Historically, this approach has been associated with an emphasis on such issues as pre-specified analysis, "serious" specification testing, replicability, avoiding "confounding," identification, and so on.[67]

By contrast, one can also identify at least one strand of so-called "structural approaches" where there is little or no distinction between a DGP and a highly articulated "theoretical economic model."[68] An archetypal example of this approach, perhaps, is the multinomial logit of McFadden (1974) in which the consumer choice model – utility function, specification of heterogeneity in tastes, and so on – delivers a complete DGP in the form of a likelihood function. A feature of such an approach is that, in principle, once the model has been estimated, one can study "counterfactual policy simulations" or "experiments" which may have never been performed but can be described within the model.

This line of research gave birth to further developments which have yielded a wide variety of attitudes toward what might be called "severe testing." At one extreme, some researchers, such as Edward Prescott, apparently "completely reject econometrics as a useful scientific tool. Instead [Prescott] promotes *calibration* as the preferred method for 'uncovering' the unknown parameters of structural models and for evaluating and comparing their ability to fit the data" (Rust, 2007, p. 4).

While not rejecting the usefulness of statistics outright, Keane argues:

> that determinations of the usefulness of …"well-executed" structural models – both as interpreters of existing data and vehicles for predicting the impact of policy interventions or changes in the forcing variables – should rest primarily on how well the model performs in validation exercises. By this I mean: (1) Does the model do a reasonable job of fitting important dimensions of the historical data on which it was fit? (2) Does the model do a reasonable job at out-of-sample prediction – especially when used to predict the impact of policy changes that alter the economic environment in some fundamental way from that which generated the data used in estimation?
>
> My use of the word "reasonable" here is unapologetically vague. *I believe that whether a model passes these criteria is an intrinsically subjective judgment, for which formal statistical testing provides little guidance. This perspective is consistent with how other sciences treat validation*. (Keane, 2007, p. 32; emphasis added)

Indeed, Keane provides an illuminating illustration of this view by discussing an example of estimating the parameters of a life-cycle human capital investment model. After describing how the simplest version of the model fails to fit the data, he goes on to explain:

> by adding a number of extra features that are not essential to the model, but that seem reasonable (like costs of returning to school, age effects in tastes for schooling, measurement error in wages, and so on), we were able to achieve what we regard as an excellent fit to the key quantitative features of the data – although formal statistical tests still rejected the hypothesis that the model is the "true" data generating process (DGP). Despite these problems, there is nothing to indicate that the profession might be ready to drop the human capital investment model as a framework for explaining school and work choices over the life-cycle. (*ibid.,* p. 33)

As one might expect, Keane does not set forth a specific context in which one might find estimates of such a model "useful," or to what extent, if any, the inferences drawn from such an approach should influence the choices we make or what we advocate to others. Surely the model with or without amendments can't be "reasonable" for *all* contexts.

The "metastatistical" question is "How much confidence should one have in a judgment supported by such an approach?" The answer, to say the least, is not obvious.

Notes

1. The original author(s) of the quote are unknown. "The very model of the anonymous aphorism" (Koenker, 2007).
2. The number of Bayesian discussions are too numerous to list; nearly every book by a Bayesian has some discussion of metastatistics. A few books I found helpful: Berger and

Wolpert (1988), deFinetti (1974), Earman (1992), Good (1983), Howson and Urbach (1993), Joyce (1999), Keynes (1921), Savage (1972). Economists in particular may find Poirier (1995) useful for it's comparative approach, as well as Zellner (1984). Non-Bayesian discussions are not nearly as numerous but there are still many useful ones. Hacking (1965, 2001) are excellent introductions, as are Mayo (1996) and Venn (1888). Mayo (1996) has helped inspire a large literature trying, among other things, to provide a "philosophy of experiment." Useful articles with a broad focus include Freedman (1995) and LeCam (1977). The former includes some nice examples where economists and sociologists come off rather badly.

Occasionally all sides agree to get together and sometimes even agree to discuss issues. The famous "Savage Forum" (Savage *et al.,* 1962) is a nice introduction to a lot of the issues. Kyburg and Thalos (2003) has a nice collection of different approaches.

3. Even the term "introductory" is not mine. Hacking (1983) wrote: "Introductory topics should be clear enough and serious enough to engage a mind to whom they are new, and also abrasive enough to strike sparks off those who have been thinking about these things for years."
4. Paneth and Wallenstein (1985) observe, for example, that the survival rate among the 34 children who were considered for the trial, but did not enter because of a failure to meet one of the threshold criteria, was 100%.
5. It is also helpful to observe that the "prior" view of most ophthalmologists was that supplemental oxygen therapy was not a potential cause of Retrolental Fibroplasia (RLF) (now referred to as Retinopathy of Prematurity). From the *British Journal of Ophthalmology* (1974): "In the early days of research into the cause of RLF it was not uncommon at any meeting where oxygen was suggested as the cause, for an indignant ophthalmologist to rise from the floor and report a typical case where to his certain knowledge no supplemental oxygen was given. He would then sink back convinced that he had delivered the coup de grace to the oxygen theory. Equally challenging were those who claimed to have seen the condition in full-term infants, which seemed to deny any special vulnerability of growing retinal vessels. Although we now know these claims to have been valid, at the time they were stumbling blocks to the early acceptance of the vital importance of prematurity and oxygen."

   Much like the case of ECMO, the debate continues, as does the need for randomized controlled trials. Also, like ECMO, the debate has moved to more subtle questions, for example, about the appropriate threshold for starting oxygen in very low birth-weight children (Askie and Win, 2003; Silverman, 2004; Davis *et al.,* 2004; Hansmann, 2004; Shah, 2005; Vanderveen *et al.,* 2006).
6. See Bartlett *et al.* (1985), Wei and Durham (1978) and Zelen (1969) for a complete description of the variant of the "randomized play-the-winner" statistical method used.
7. See the several comments in *Statistical Science* **4**(4), 1989, and Ware's rejoinder in that issue. See Bartlett (2005) for a review of some of the history by one of the surgeons. The ethical issues don't end there; see also Couzin (2004): "Some companies seek out Berry Consultants [a small company founded by Bayesian advocate Donald Berry and his son] in the wild hope that a drug or device that's performed poorly in traditional trials can somehow undergo a Bayesian resurrection. (Such a 'rescue analysis' is rarely a possibility, both Berrys agree.)"
8. Indeed, while ECMO is used much more liberally today, *who* should get ECMO is a subject of considerable controversy (Allan *et al.,* 2007; Lequier, 2004; Thourani *et al.,* 2006). ECMO is now frequently employed but is still considered risky: "ECMO can have dangerous side-effects. The large catheters inserted in the baby's neck can provide a fertile field for infection, resulting in fatal sepsis" (Groopman, 2007). See *ibid.* for a case study where ECMO was begun, but then stopped because it was the "wrong treatment."

9. As it turns out, not even this sentiment is original. From Bickel and Lehmann (2001): "A chemist, Wilson (1952), [considering some issues in inference] pleads eloquently that 'There is a great need for further work on the subject of scientific inference. To be fruitful it should be carried out by critical original minds who are not only well-versed in philosophy but also familiar with the way scientists actually work (and not just with the way some of them say they work).' Wilson concludes pessimistically: 'Unfortunately the practical nonexistence of such people almost suggests that the qualities of mind required by a good philosopher and those needed by a working scientist are incompatible.' "
10. Of course, a non-Bayesian would feel that $\frac{1}{2}$ is a perfectly good estimator of the variance if you can't know which machine produced the measure.
11. Apparently, many examples of this specific type of inference can be avoided if one is a "conditional frequentist" (Poirier, 1995, p. 344).
12. The subtitle of LeCam's remarks "Toward Stating a Problem in the Doctrine of Chances" in part was an ironic twist on the title of Bayes' 1763 classic, "Toward Solving a Problem in the Doctrine of Chances" (Bayes, 1958).
13. A term frequently employed instead of "metastatistics" is the philosophy of "induction," and there is even debate on whether it is meaningful to talk about inductive inference. See Neyman (1957) and LeCam (1977), as well as Hacking (2001) and Mayo (1982).
14. LeCam's Basic Principle Zero (LeCam, 1990) was also intended to apply "in particular to the principles and recommendations listed below and should be kept in mind any time one encounters a problem worth studying." LeCam's principles seem quite sensible to me, and capture a lot of what I think non-Bayesians have in the back of their minds, including problems with the use of asymptotic approximations:

    1. Have clear in your mind what it is that you want to estimate.
    2. Try to ascertain in some way what precision you need (or can get) and what you are going to do with the estimate when you get it.
    3. Before venturing an estimate, check that the rationale which led you to it is compatible with the data you have.
    4. If satisfied that everything is in order, try first a crude but reliable procedure to locate the general area in which your parameters lie.
    5. Having localized yourself by (4), refine the estimate using some of your theoretical assumptions, being careful all the while not to undo what you did in (4).
    6. Never trust an estimate which is thrown out of whack if you suppress a single observation.
    7. If you need to use asymptotic arguments, do not forget to let your number of observations tend to infinity.
    8. J . Bertrand said it this way: "Give me four parameters and I shall describe an elephant; with five, it will wave its trunk."
15. A nice and more complete discussion can be found in Hacking (2001). Much of what follows is an abbreviated version of Hacking's discussion.
16. The Cretaceous/Tertiary Boundary is the boundary between the Cretaceous period and the Tertiary period. The Cretaceous period is the last period of the Mesozoic Era, which ended with the sudden extinction of the dinosaurs *inter alia.*
17. Even here, there is a possible non-Bayesian version of characterizing the probability: if we could re-run the world 100,000 times, in about 90% of cases an asteroid of size necessary to lead to mass extinction of the dinosaurs occurs. Perhaps ironically, on this precise question Bottke *et al.* (2007, p. 52) seem to arrive at their conclusion this way: "Using these [estimated] impact rates as input for a Monte Carlo code, we find there is a $\leq 10\%$ chance that the K/T impactor was derived from the background and a $\geq 90\%$ chance it came from the BAF [Baptistina Asteroid family]. Accordingly, we predict that the most

likely cause of the K/T mass extinction event was a collision between the Earth and a large fragment from the Baptistina asteroid shower."

18. In this regard, it is notable that there is a considerable body of non-Bayesian decision theory, the "Neyman–Pearson" framework being the best known. What is frequently referred to as the "Neyman–Pearson" statistical framework, however, is rarely *explicitly* invoked in most micro-empirical research, even though discussions about the "power" and "size" of tests are sometimes themselves the subject of debate. See, for example, McCloskey (1985), McCloskey and Ziliak (1996) and Hoover and Siegler (2008a, 2008b) for one debate on the subject.
19. There are many subtleties about the distinctions between beliefs and actions that I am ignoring. For instance, in describing Pascal's thesis, Joyce (1999, p. 21) – a "Bayesian" – is "careful to formulate [the thesis] as a *norm of rational desire* that governs the fair pricing of risky wagers [those that obey conventional axioms of probability]." In doing so he is explicit that he is making a statement about *desires* and *not actions* (*ibid.*, p. 19). "The old guard still insists that the concept of a fair price can only be understood in terms of behavioral dispositions, but it has become clear that the theoretical costs far outweigh benefits."
20. Ragnar Frisch's remarks, which accompanied Allias' article, suggest a fairly heated debate (emphasis added): "The problem discussed in Professor Allais' paper is of an extremely subtle sort and it seems to be difficult to reach a general agreement on the main points at issue. I had a vivid impression of these difficulties at the Paris colloquium in May, 1952. One evening when a small number of the prominent contributors to this field of study found themselves gathered around a table under the most pleasant exterior circumstances, it even proved to be quite a bit of a task to clear up in a satisfactory way misunderstandings in the course of the conversation. The version of Professor Allais' paper, which is now published in *ECONOMETRICA* emerged after many informal exchanges of views, including work done by editorial referees. Hardly anything more is now to be gained by a continuation of such procedures. *The paper is therefore now published as it stands on the author's responsibility. The editor is convinced that the paper will be a most valuable means of preventing inbreeding of thoughts in this important field. – R.F."*
21. By simple rearranging of terms, $B \succcurlyeq A$ yields:

$$0.11U(500,000) < 0.10U(2,500,000) + 0.01U(0),$$

and from $C \succcurlyeq D$ we get:

$$0.10U(2,500,000) + 0.01U(0) < 0.11U(500,000).$$

Hence, a contradiction.
22. For example, although games of chance greatly antedate anything resembling modern notions of probability – "someone with only modest knowledge of probability mathematics could have won himself the whole of Gaul in a week" – anything like our modern notions of probability did not "emerge permanently in discourse" until 1660 (see Hacking, 1975, 1990). Perhaps not surprisingly, the history of probability is the subject of much debate as well. For one criticism of Hacking's account see Garber and Zabell (1979).
23. Even at this point a fuller treatment would include a discussion of the problem of "logical omniscience." All I can do is cite a statement from Savage (1967): "For example, a person required to risk money on a remote digit of π would have to compute that digit, in order to comply fully with the theory [of personal probability], though this would really be wasteful if the cost of computation were more than the prize involved. For the postulates of the theory imply that you should behave in accordance with the logical implication of all that you know. Is it possible to improve the theory in this respect, making allowance within it for the cost of thinking, or would that entail paradox, as I am inclined to believe

but unable to demonstrate?" (As cited in Hacking, 1967. The published versions seems to have omitted some of the text.) See Hacking (1967) for a very useful discussion of the issue.

24. For instance, although it is easy to see how to partition a set of *events*, it is not always possible to see how to partition a set of *propositions*.
25. See Einstein (1920) for a thought-provoking discussion of Euclidean geometry as mathematical statements versus Euclidean geometry as statements about things in the world. As to Feller's observation about alternatives to Newton's law of attractions, see Cartwright (1984) for a provocative discussion of how even "the laws of physics lie" and physicists often fruitfully use different and mutually inconsistent models that makes a related point.
26. For a marvelous introductory exposition see Ch. 21 of Hacking (2001). For a more complete discussion that includes a bit more mathematical formalism and may be congenial to economists, see 2.1 of Poirier (1995).
27. There is much debate about the utility of *defining* probability as the limiting behavior of a sequence. This debate is intimately related to the debate about commending an estimator because, in repeated applications and in the long run, it would do well. The canonical problem is the "single case" exception (Hacking, 2001, Ch. 22) in which we are asked to consider a situation where, for example, there are two decks of cards: one, "the redder pack," has 25 red cards and 1 black card. The other "blacker pack" has 25 black cards and 1 red card. You are presented with two gambles. In the first gamble, you "win" if a red card is drawn randomly from the "redder" pack and lose otherwise ($P(\text{Win}) = 25/26$). In the second gamble, you "win" if a red card is drawn randomly from the "blacker" pack ($P(\text{Win}) = 1/26$). If you "win" you will be transported to "eternal felicity" and, if you lose, you will be "consigned to everlasting woe." As Hacking (and C.S. Peirce) and most people would choose the first gamble and hope, but *not* because of the long run; if we are wrong, there will be no comfort from the fact that we *would have been right most of the time*! Peirce's "evasion of the problem of induction" is to argue that we should not limit ourselves to merely "individualistic" considerations. "[Our interests] must not stop at our own fate, but must embrace the whole community. This community, again, must not be limited but extend to all races of beings with whom we can come in to immediate or mediate intellectual relation. It must reach, however vaguely, beyond this geological epoch, beyond all bounds. He would not sacrifice his own to save the whole world is, as it seems to me, illogical in all his inferences collectively. Logic is rooted in the social principle" (Peirce, 1878b, pp. 610–11).
28. Such a condition rules out, for example, the deterministic series $(H, T, H, T \ldots H, T)$ discussed above.
29. See Gillies (2000) for a nice discussion.
30. It is thus easier to understand Poirier's emphasis in the quotation above on whether the probability is "in nature" or "in themselves": that "to the extent that individuals agree on a class of events, they share an objective frequency. The objectivity, however, is in themselves, not in nature."
31. Again I have ignored "logical" probabilities, which are a class of epistemic probabilities which incorporate the notion of evidence. In this view, a probability is a "rational degree-of-belief" about a proposition or a measure of the degree of "credibility" of a proposition.
32. For three mutually exclusive analyses of what Bayes meant, and whether or not he succeeded in proving what he set out to establish, see Hacking (1965, Ch. 12). On whether Bayes' understanding is consistent with subsequent Bayesian interpreters (beginning with the rediscovery by Laplace, 1795), see Stigler (1982).
33. We have omitted one detail in this exposition, which is that the expression we are required to evaluate is:

$$\frac{\mathcal{L}(\theta|N,h)f(\theta)}{\int_0^1 \mathcal{L}(\theta|N,h)f(\theta)}.$$

In our previous notation, the denominator corresponds to $P(B)$ or $\sum_{j=1}^{k} P(B|A_j)P(A_j)$. One "nice" feature of the beta distribution is that it serves as the "natural conjugate prior" for the binomial distribution. Loosely speaking, the functional form of the prior and the likelihood are the same, which means one can treat the denominator as an *integrating constant* and it does not have to be computed directly.

34. The posterior mode can be rewritten as a weighted average of the sample mean and a prior mean, with the role of the prior vanishing as the number of actual sample observations grows large.
35. There are many variants of the following example. This particular variant is slightly adapted from Sober (2002).
36. Poirier (1995) provides a useful parody of the non-Bayesian view as he depicts a satistician's constantly evolving inference changing as he discovers more about the intent of the investigator.
37. Savage, before becoming familiar with the arguments in Barnard (1947a, 1947b), viewed the DGP as relevant ("I then thought it was a scandal that anyone in the profession could advance an idea – [that the DGP was irrelevant] – so patently wrong"). By the time of the forum he had come around to exactly the opposite point of view – "I [can] scarcely believe that people resist the idea [that the DGP was irrelevant] that is so patently right."
38. It should be noted than many Bayesians would argue that hypothesis testing *per se* is not a terribly sensible framework. They would also probably argue, nonetheless, that hypothesis tests are best interpreted in a Bayesian way.
39. There are many solutions to the problem of "inadmissible" samples in practice (unbalanced samples; see Jones, 1958, for example). One could merely conduct two experiments with more homogeneous samples. That is, one could conduct an experiment on low birth-weight babies and a separate experiment on high birth-weight babies. Sometimes block randomization is employed: the children might be sub-divided into groups according to their "healthiness" and the randomization might be performed separately within blocks.
40. See Zed *et al.* (1999) and Headache Classification Committee of the International Headache Society (2004) for extensive bibliographies.
41. The nosology of headache is elaborate and I can only coarsely define two types of headache here. According to the National Headache Foundation (http://www.headaches.org/consumer/tension_type.html, accessed December 10, 2007), "Tension-type headache is a nonspecific headache, which is not vascular or migrainous, and is not related to organic disease. The most common form of headache, it may be related to muscle tightening in the back of the neck and/or scalp [and is] characterized as dull, aching and non-pulsating pain [that] affect[s] both sides of the head.

    Symptoms … may include:

    - Muscles between head and neck contract
    - A tightening band-like sensation around the neck and/or head which is a 'vice-like' ache
    - Pain primarily occurs in the forehead, temples or the back of head and/or neck."

    Migraine headaches are most commonly associated with severe unilateral head pain, often accompanied by nausea and vomiting, photophobia (fear of light) and phonophobia (fear of sound), that can last from a few hours to several days. In some fraction of migraine patients the head pain is preceded or accompanied by visual disturbances called auras.
42. In the US, opioids were the standard of care as late as the nineteenth century until they were supplanted by aspirin in the early twentieth century at roughly the same time as over-the-counter use of such medications was made illegal (Meldrum, 2003). Moreover,

outside of the MOH literature it is generally viewed that opioids are under-prescribed because of (sometimes irrational) fears of promoting addiction, censure by police, and so on (Lipman, 2004). "The history of opioid use (or nonuse) in neuropathic pain is instructive. The natural reluctance to prescribe opioids to patients with neuropathic pain of benign cause was, for many years, reinforced by the received wisdom that opioids were ineffective in neuropathic pain [such as headache], based on weak evidence. It took many years before this 'truth' was questioned. Reexamination in the later 1980s was followed by controlled studies that clearly substantiated an important analgesic action of morphine and fentanyl and, later, other opioids in neuropathic pain" (Scadding, 2004).

43. Medication overuse headache has gone by several different names, including *analgesic rebound*, *ergotamine rebound*, *medication induced headache*, *transformed migraine*, *chronic migraine*, *daily headache*, *drug-induced headache*, *painkiller headache*, *medication-misuse headache*, *analgesic-dependent headache* (Obermann and Katsarava, 2007; Silberstein *et al.*, 1994, and so on).
44. As is widely recognized, severe chronic daily migraine occurred before the use of offending medications was common or even possible. The most widely cited example comes from the important neurologist Thomas Willis (1683), who recorded his treatment of Viscountess Anne (Finche) Conway in the seventeenth century.
45. Even current scholars in the field are negative about early developments in the field of headache. "Prior to the 1980s, the field of headache was rarely influenced by what would be generally accepted as scholarly, credible research" (Saper, 2005).
46. In describing the work as "representative," however, the view among experts in the field is considerably more favorable. Ward (2008) describes it as "his favorite article" in a recent review. Mathew (2008) responds by noting: "The impact of this article on the American and European headache communities was substantial. Until then, the Europeans had not appeared to appreciate the clinical significance of medication overuse or the existence of chronic daily headache ... One enduring fact continues to disappoint me. In spite of the extensive effort made to emphasize the importance of medication overuse in managing the headache population, many practitioners – including neurologists – continue to overprescribe symptomatic medications, thereby condemning their patients to treatment failure." For a more recent systematic review, see Zed *et al.* (1999).
47. No randomization appears to be involved. The patients were merely "grouped."
48. The measurement of "improvement" is not clear, but it appears to have been asymmetric. Improvement was measured as a percentage change in a headache index if the patient improved, and was given a value of zero if the patient did not improve.
49. One definition of MOH is:

    1. Occurs in a patient with a primary headache disorder who uses symptomatic or immediate relief medications very frequently (daily), often in excessive quantities.
    2. Tolerance to symptomatic medications develop and headaches become worse on continuing the treatment.
    3. The patient may show symptoms of withdrawal on discontinuing the medication, with increased headache lasting for a variable period of time, as long as three to four weeks.
    4. Headache ultimately improves after stopping the offending medications even though the primary headache disorder needs continuing prophylactic treatment.

50. The only other criticism I have been able to locate are letters to the editors (Gupta, 2004a, 2004b, 2004c).
51. Using language evocative of severe testing, Fisher remarked that "Claude Bernard, in speaking of an hypothesis, said that it is not sufficient to merely gather all the facts that support it but even more importantly, one must go out of one's way to find every means of refuting it."

52. While Fisher's challenge has never been even approximately met, the question of whether headaches arise *de novo* from analgesic headache has been investigated and substantiates Fisher's claim. It has been conceded that Fisher was correct (Bahra *et al.,* 2003; Lance *et al*., 1988).
53. For a brief history of the ICHD, see Gladstone and Dodick (2004).
54. Boes and Capobianco (2005) and Ferrari *et al*. (2007) describe some of the tangled history as well. It should be noted that the history is a matter of some dispute.
55. The rate of analgesic use is *usually* defined in terms of treatment days per month, such that treatment occurs at least two or three days each week, with intake of the drug on at least ten days per month for at least three months.
56. From Schuster (2004): "The definition does not apply to headache in women who take medications for five or six consecutive days for menstrually associated migraines but are treatment-free the rest of the month, acknowledged Fred D. Sheftell, MD, who participated in updating the classification. He said that if a woman took medications just four other days of the month, she would inappropriately meet the 10-days-a-month rule. For that reason, she must also be taking the drugs at least two to three days each week to meet the criteria."
57. Among the reasons given was the fact that "patients could become chronic due to medication overuse, but this effect might be permanent. In other words, it may not be reversible after discontinuation of medication overuse. Finally, a system whereby medication overuse headache became a default diagnosis in all patients with medication overuse would encourage doctors all over the world to do the right thing, namely, to take patients off medication overuse as the first step in a treatment plan."
58. See, for example, Saper and Lake (2006a) for a proposal to distinguish opioid using MOH patients from the remaining "less complicated" cases.
59. See Horowitz and Manski (1998) for a detailed discussion of such bounds. It should be noted that where such bounds are used, common practice is to report both "best case" *and* "worst case" bounds.
60. Indeed, the notion of "intent-to-treat" can be seen as part of an attempt to test a hypothesis **severely** and not a notion that is an inevitable consequence of adopting "frequentist" probability notions. See Hollis and Campbell (1999) for a discussion.
61. He referred to the union premium in wages between otherwise identical workers as the wage "gap" to distinguish it from what might obtain in a world without unions.
62. The distinction between ATOT and other estimands is important since it isn't particularly meaningful to consider the effect of union status on, say, the CEO of a large multinational, to take a stark example (US law, for example, prohibits this possibility). The paper, unfortunately, takes a naive approach to characterizes the treatment heterogeneity: in considering the variation in the effect of union status, it characterizes it by the estimated probability of being unionized. That is, the effect of unionization is allowed to vary across workers whose demographic characteristics put them at the same "risk" of being unionized. This conflates the treatment effect for workers with extremely low levels of observed human capital (who typically have very low probabilities of being unionized) with the treatment effects for those who can't be unionized (bosses) or those with high levels of education who are generally hostile to unionization. For an arguably much more sensible characterization of the heterogeneity in treatment effects, see Card (1992), for example. Card (*ibid*.) also deals with the problem of measurement error in union status, which is ignored in the empirical example in Chib and Hamilton (2002) but has long been an important issue in non-Bayesian analyses: see Freeman (1984), Jakubson (1991), or Card (1992) for three examples.
63. This possibility wasn't ignored, however. The problem was the lack of data. See, for example, Abowd and Farber (1982), Freeman and Kleiner (1990, 1999), who take the possibility quite seriously.

64. Although this is an important focus of their paper, it is one that I will not focus on since my interests in using this example lie elsewhere. To quote from their paper: "again, it is important to recognize that many applied studies in the treatment-response literature, and to our knowledge all of those that have been conducted on this specific topic, assume the relationship between the treatment variable and the outcome variable is linear (i.e., $f(s) = \alpha_0 + \alpha_1 s$), and define the slope of this function as the causal effect of interest. The assumption of linearity is likely made on computational considerations, as IV [instrumental variables] is simple to use in this context."
65. Again because my interests lie elsewhere, one might not wish to stipulate that it is possible to talk clearly about a "causal effect" of BMI on wages, because such an effect seems to presuppose that, in whatever manner we "manipulate" an individual's BMI, we would expect that the "effect" of BMI on wages would be the same. However, it is possible to imagine that the causal arrow runs *from* BMI *to* wages because (1) high BMI is equivalent to "bad health" and "bad health" lowers wages, or (2) high BMI is equivalent to "unattractive," and employers discriminate against those who are "unattractive" for reasons possibly unrelated to "productivity." If the latter were true, a "successful" but "unhealthy diet" that lowered BMI would *raise* wages; if the former were true, such a diet would *lower* wages. See DiNardo (2007) for a discussion.
66. It is also interesting to observe that this Bayesian "overidentification test" is arguably better-suited to "severity" than recent non-Bayesian interpretations of such overidentification tests. In the linear instrumental variables model, for example, the failure of the overidentification test has been recently reinterpreted *not* as a rejection of the premises of the estimated model but as evidence of "treatment effect" heterogeneity (Angrist, 2004). In this context, one possible cause (though not the only possible cause) of "treatment effect heterogeneity" is that the true relationship between BMI and wages is, say, quadratic but the investigator specifies a linear relationship. In such a case, one could no longer ensure that the estimated relationship would be invariant to the choice of instrumental variables even if the instrumental variables were "valid." The informal test proposed by Kline and Tobias (2008), however, easily accommodates such a situation since it allows $f(s)$ to be nonlinear without exhausting any overidentification.
67. Some of this discussion draws from a brief discussion in unpublished lecture notes by David Card, although for reasons of focus and brevity my account is not the same (Card, 2007).
68. It should not be surprising that the term "structural model" encompasses a wide array of activities which have very different emphases, including – to take just one example – classic studies of demand systems, and so on (see, for example, Deaton and Muellbauer, 1980). Moreover, some work involving "structural estimation" occurs in studies that also involve a design-based approach. For a simple illustration see DiNardo and Lemieux, (1992, 2001). Consequently, I use the phrase "single strand" advisedly.

Forecast Combination and Encompassing

Michael P. Clements and David I. Harvey

Abstract

Forecast combination is often found to improve forecast accuracy. This chapter considers different types of forecast combination and tests of forecast encompassing. The latter indicate when a combination is more accurate than an individual forecast *ex post*, in a range of circumstances: when the forecasts themselves are the objects of interest; when the forecasts are derived from models with unknown parameters; and when the forecast models are nested. We consider forecast encompassing tests which are framed in terms of the model's estimated parameters and recognize that parameter estimation uncertainty affects forecast accuracy, as well as conditonal tests of encompassing. We also look at the conditions under which forecast encompassing can be established irrespective of the form of the loss function.

4.1 Introduction

In this chapter we consider the closely related topics of forecast combination and tests of forecast encompassing. A test for forecast encompassing is just one of the many tests of predictive ability that might be considered. For example, one might test whether a set of forecasts are unbiased, or efficient (e.g., Mincer and Zarnowitz, 1969; Figlewski and Wachtel, 1981; Zarnowitz, 1985; Keane and Runkle, 1990) or as accurate given some loss function as a rival set of forecasts. Assuming a squared-error loss function, the approach of Granger and Newbold (1977) (sometimes known as the Morgan–Granger–Newbold test in recognition of Morgan, 1939) is one such test of whether differences between rival forecasts can

be attributed to sampling variability, or whether the differences are statistically significant once sampling variability has been taken into account. If we assume that the forecast errors are zero mean, normally distributed and serially uncorrelated (implying one-step-ahead forecasts), the Morgan–Granger–Newbold test is uniformly most powerful unbiased. A test of equal accuracy that dispenses with the restrictive assumptions that underpin this test, including that of squared-error loss, is due to Diebold and Mariano (1995). Although assessing the relative accuracy of forecasts is fundamental to forecast evaluation, from a practical or operational perspective the most useful way of doing this is not to test the null of equal accuracy but to test whether one set of forecasts encompasses the rival set. A set of forecasts is said to encompass a rival set if the rival set of forecasts do not contribute to a statistically significant reduction in forecast loss when used in combination with the original set of forecasts. Forecast encompassing is due to Chong and Hendry (1986) and is an application of the principle of encompassing (see, e.g., Mizon and Richard, 1986; Hendry and Richard, 1989) to the evaluation of forecasts, although it is formally equivalent to the earlier notion of conditional efficiency of Nelson (1972) and Granger and Newbold (1973).

The importance of testing for forecast encompassing (as opposed to equal accuracy) is that forecast combination is often found to improve forecast accuracy. That is, a linear combination of two or more forecasts may often yield more accurate forecasts than using a single forecast. If one is prepared to take a combination of forecasts rather than requiring that only one is selected, then it matters little whether one forecast is more or less accurate than another. Regression-based tests of forecast encompassing are a way of testing whether *ex post* a linear combination of forecasts results in a statistically significant reduction in (say) mean squared forecast error relative to using either individual forecast. Such tests can also be used as an indicator of when combinations might be useful *ex ante*. If neither set of forecasts encompasses the other, then subsequent forecasts should be constructed as a combination of those of the two individual sets.

If the goal is forecasting (as opposed to some other econometric endeavor, such as building a model that describes or quantifies the relationships between economic variables), then we suspect it would seldom be the case that the forecaster would be unwilling to take a combination of the available forecasts and would instead insist on selecting the single best forecasting model, or set of forecasts. Granger and Jeon (2004) present forecast combination as an example of "thick modeling," whereby the investigator pools the values of estimates of interest (parameter estimates, impulse responses, or forecasts, etc.) from a number of alternative specifications rather than seeking to select a single specification. Forecast combination has a long history: Granger and Jeon (2004) advocate the principle of thick modeling more generally. The principle of encompassing would suggest forecast encompassing be used to improve the forecasting model in the sense of re-specifying the model in an attempt to match the process that generated the data as closely as possible. However, it has been established that, even if this goal were attainable, it would not necessarily be beneficial from a forecasting perspective when there are breaks (see, e.g., Clements and Hendry, 2006).

There are a number of explanations as to why forecast combination works. Perhaps the most common is the portfolio diversification argument that underpinned the original analysis of Bates and Granger (1969), as recently discussed by Granger and Jeon (2004) and Timmermann (2006), amongst others. The idea is simply that the individual forecasts are each based on partial, and incompletely overlapping, information sets, as might be the case if they reflect private information, for example. The degree of overlap in the information sets is key, as is apparent in the discussion of Bates and Granger (1969) in section 4.2. An explanation stressed by Hendry and Clements (2004) is that of forecasts based on misspecified models when there are structural breaks and, as noted by Timmermann (2006, p. 138), a number of other papers discuss the roles of model misspecification and structural breaks. Hendry and Clements (2004) and Timmermann (2006) discuss a number of other reasons that would justify pooling.

Our survey is the latest of a number of recent reviews of the large literatures on the topics of forecast combination and on forecast encompassing. These include Clemen (1989), Diebold and Lopez (1996), Newbold and Harvey (2002) and Timmermann (2006). One of the key ways in which it differs from the others is the emphasis on the testing of forecast encompassing alongside the treatment of forecast combination. We are also able to include some of the important developments that have only recently found their way into the literature. For expositional convenience we focus on two forecasts, but in general more than two forecasts may be combined, and the notion of forecast encompassing can be generalized to the case of multiple forecasts (see Harvey and Newbold, 2000).

The plan of the rest of the chapter is as follows. Section 4.2 outlines the historical development of forecast combination and encompassing, and fills in some of the details. Section 4.3 describes the key developments when the forecasts are based on models and one wishes to compare the forecasting models. As the forecasts are generated from models in which the unknown parameters are replaced with estimates, an allowance is made for the true values having been replaced by random variables when the forecasts are compared. Section 4.4 considers forecasting from nested models, which is not covered by the analysis in section 4.3 and requires a separate treatment. Section 4.5 describes forecast encompassing tests within a framework of conditional testing of predictive ability, and where the emphasis shifts to testing forecasting *methods* rather than *models*. Thus far, we have maintained an assumption of symmetry of the loss function: the implications of dispensing with this assumption form the material of section 4.6. Section 4.7 offers some concluding remarks.

4.2 Historical development

4.2.1 Forecast combination

The notion of combining different forecasts of the same quantity in order to improve predictive accuracy was first proposed by Bates and Granger (1969). Suppose we have available two h-steps-ahead forecasts, f_{1t} and f_{2t}, of the quantity y_t. In this section, in line with the early literature on forecast combination (and

encompassing), we take the forecasts as given, and do not consider issues related to the method employed in obtaining the predictions, for example those of model estimation uncertainty and nesting considered in later sections. Assuming the forecasts to be unbiased, i.e., that the forecast errors $e_{it} = y_t - f_{it}$ $(i = 1, 2)$ have zero mean, Bates and Granger (1969) suggest the use of a combined forecast, f_{ct}, of the following form:

$$f_{ct} = (1 - \lambda) f_{1t} + \lambda f_{2t}. \tag{4.1}$$

When $0 \leq \lambda \leq 1$, f_{ct} comprises a simple weighted average of the two individual forecasts.

The optimal choice for the weighting parameter λ depends on the relative accuracy of the individual forecasts f_{1t} and f_{2t}, and can easily be obtained for a given loss, or cost of error, function. By far the most commonly assumed cost of error function in the literature is that of squared error loss, with forecast accuracy determined by the mean squared forecast error (MSFE) measure. Denoting the forecast error associated with f_{ct} by $\varepsilon_t = y_t - f_{ct}$, we obtain the following expression for the MSFE of the combined forecast:

$$E(\varepsilon_t^2) = (1 - \lambda)^2 \sigma_1^2 + \lambda^2 \sigma_2^2 + 2\lambda(1 - \lambda)\rho\sigma_1\sigma_2, \tag{4.2}$$

where σ_1^2 and σ_2^2 denote, respectively, the MSFEs of f_{1t} and f_{2t}, and ρ denotes the correlation between the forecast errors e_{1t} and e_{2t}. The optimal combination weight associated with a squared error loss function is then derived by choosing λ to minimize (4.2), i.e.:

$$\lambda_{opt} = \frac{\sigma_1^2 - \rho\sigma_1\sigma_2}{\sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2}. \tag{4.3}$$

The expected squared error associated with the optimal combination weight λ_{opt} is given by:

$$E\big(\varepsilon_t^2(\lambda_{opt})\big) = \frac{\sigma_1^2\sigma_2^2(1 - \rho^2)}{\sigma_1^2 + \sigma_2^2 - 2\rho\sigma_1\sigma_2},$$

where, of necessity, $E\big(\varepsilon_t^2(\lambda_{opt})\big) \leq \min\left\{\sigma_1^2, \sigma_2^2\right\}$. Suppose that f_1 and f_2 are equally accurate, i.e., $\sigma_1^2 = \sigma_2^2$. Then:

$$E\big(\varepsilon_t^2(\lambda_{opt})\big) = \frac{1}{2}\sigma_1^2(1 + \rho).$$

Given that $|\rho| \leq 1$, $\frac{1}{2}\sigma_1^2(1 + \rho) < \sigma_1^2$ for all values of ρ other than $\rho = 1$. So there are diversification gains when the forecasts are equally accurate unless the forecasts are perfectly correlated.

In practice the optimal weight parameter, and its constituent parameters ρ, σ_1^2 and σ_2^2, will not be known. However, given time series data on past forecasts and actuals, these quantities can be estimated, resulting in a sample analogue of the population weight parameter (4.3). Denoting the time series of past h-steps-ahead

forecast errors by e_{1t}, e_{2t}, $t = 1, \ldots, n$, the obvious estimator is given by:

$$\hat{\lambda}_{opt} = \frac{\sum_{t=1}^{n} e_{1t}^2 - \sum_{t=1}^{n} e_{1t}e_{2t}}{\sum_{t=1}^{n} e_{1t}^2 + \sum_{t=1}^{n} e_{2t}^2 - 2\sum_{t=1}^{n} e_{1t}e_{2t}}. \tag{4.4}$$

This estimated weight can then be used in the future to produce out-of-sample combined forecasts. The above estimator could equally be obtained from ordinary least squares estimation of the regression:

$$e_{1t} = \lambda(e_{1t} - e_{2t}) + \varepsilon_t, \tag{4.5}$$

or, equivalently:

$$y_t = (1 - \lambda)f_{1t} + \lambda f_{2t} + \varepsilon_t, \tag{4.6}$$

which is essentially a rearrangement of (4.1) with the error of the combined forecast, ε_t, now interpreted as a regression error.

The above analysis assumes that the individual forecasts are unbiased. However, it may well be the case that the individual forecasts are biased, as has been observed empirically for some macroeconomic forecasts (see, e.g., Zarnowitz and Braun, 1993; Stekler, 2002; Harvey and Newbold, 2003). In order to allow for bias in the forecasts, an intercept can be added to the regression (4.5) or (4.6):

$$e_{1t} = \alpha + \lambda(e_{1t} - e_{2t}) + \varepsilon_t,$$

which ensures that the implied combination:

$$f_{ct} = \alpha + (1 - \lambda)f_{1t} + \lambda f_{2t}, \tag{4.7}$$

is unbiased.

In addition to the possibility of biased forecasts, forecasts may also be inefficient in the sense of Mincer and Zarnowitz (1969). A generic forecast f_t is said to be Mincer–Zarnowitz efficient if $\alpha = 0$ and $\beta = 1$ in a regression $y_t = \alpha + \beta f_t + \varepsilon_t$, which implies that the forecast and forecast error are uncorrelated (see, e.g., Clements and Hendry, 1998, Ch. 3, for a discussion). If the individual forecasts are inefficient, the appropriate generalization of the combined forecast involves relaxing the implicit assumption that the combination weights sum to one. This results in an efficient combined forecast, with the more general formulation advocated by Granger and Ramanathan (1984):

$$f_{ct} = \alpha + \beta_1 f_{1t} + \beta_2 f_{2t}. \tag{4.8}$$

The weights are now obtained from the corresponding regression:

$$y_t = \alpha + \beta_1 f_{1t} + \beta_2 f_{2t} + \varepsilon_t. \tag{4.9}$$

Clearly (4.7) and (4.1) are special cases of (4.8), where the restrictions $\beta_1 + \beta_2 = 1$, and $\alpha = 0, \beta_1 + \beta_2 = 1$ are imposed, respectively. Note that when the actuals and forecasts are non-stationary integrated processes, (4.9) should be specified using actual and predicted changes, rather than levels.

The above methods of combining forecasts are simple and straightforward to implement, but the literature also contains many extensions to these simple approaches, the relatively early contributions of which are summarized by Clemen (1989). For example, Diebold (1988) and Coulson and Robins (1993) argue that, when estimating weights based on (4.9), account should be taken of the likely autocorrelation present in ε_t, either by allowing for ARMA residuals or including y_{t-1} as an additional regressor. The possibility of time-varying combination weights could also be entertained, reflecting the potentially evolving behavior of the process governing the actuals, and also of the individual forecasters. At a simple level, this might involve using recent data only to estimate the combination weights, while more sophisticated approaches are proposed by Diebold and Pauly (1987), LeSage and Magura (1992), and Deutsch, Granger and Teräsvirta (1994).

Relatively sophisticated methods of forecast combination inherently entail a greater data requirement, and are therefore most applicable when a reasonably long history of forecast performance is available. When, as is very often the case, only small samples of historical data exist, sampling variability plays a significant role in the estimation of the combination weights. This can temper the gains that could be realized relative to when the weights are known, potentially even giving rise to forecast combinations that are less accurate than simpler approaches that do not require combination weight estimation. For example, many authors (see, e.g., Makridakis and Winkler, 1983; Stock and Watson, 1999; Fildes and Ord, 2002) have found that simple averaging of individual forecasts very often outperforms more elaborate combination techniques, while Harvey and Newbold (2005) demonstrate that situations exist where the optimal weight on, say, f_{2t} is non-zero, but sampling variability affects the weight estimates to the extent that the resulting combination has a larger MSFE than that associated with just f_{1t} alone. The Bayesian combination methods of, *inter alia*, Clemen and Winkler (1986), Diebold and Pauly (1990) and Min and Zellner (1993) provide a means of formally estimating the combination weights, while mitigating the effects of sampling variability by shrinking the weights towards some prior mean. The widely observed robust performance of simple averages of forecasts motivates a prior of equal weights in this setting.

Another extension to combining forecasts is to allow nonlinear combination methods. Such methods may be useful when relatively large samples of forecasts are available, and/or when the nature of the forecasts suggests methods other than linear combination. Given a large number of forecasts, an attractive way of considering nonlinear combination schemes is via Artificial Neural Networks (ANNs), as ANNs are able to approximate large classes of nonlinear functions. Donaldson and Kamstra (1996) use single hidden-layer ANNs to combine forecasts of the volatility of daily stock returns from GARCH and moving-average variance models, and compare the results to traditional linear combination. Specifically, the ANNs are of the form:

$$f_{ct} = \alpha + \sum_{j=1}^{k} \beta_j f_{jt} + \sum_{i=1}^{p} \delta_i \Psi\left(z_t \gamma_i\right),$$

where:

$$\Psi\left(z_t\gamma_i\right) = \left(1 + \exp\left[-\left(\gamma_{0i} + \gamma_{1i}z_{1t} + \gamma_{2i}z_{2t}\right)\right]\right)^{-1},$$

and $z_{it} = s_y^{-1}\left(f_{it} - \bar{y}\right)$, $i = 1, 2$, i.e., the f_{it} are normalized by the in-sample mean and standard deviation of y_t. When $p = 0$ and $k = 2$, the ANN specializes to standard linear combination of the two sets of forecasts. Donaldson and Kamstra (1996) allow values of p up to $p = 3$, and find values of 1 or 2 are typically selected by their cross-validation procedure. The combinations are estimated by choosing the γ_i as random drawings from a $U(-1, 1)$ distribution, and then estimation of α, β, δ can be carried out by ordinary least squares (OLS).

Finally, for forecasts other than point forecasts, other forms of combination are used. For example, experts' subjective probability distributions are often combined using the logarithmic opinion pool, or LoOP (see, e.g., Genest and Zidek, 1986; Clemen and Winkler, 1999), which for discrete probability distributions is given by:

$$f^j = \frac{\prod_{i=1}^N \left(f_i^j\right)^{\beta_i}}{\sum_{j=1}^M \prod_{i=1}^N \left(f_i^j\right)^{\beta_i}} = \frac{\exp\left(\sum_{i=1}^N \beta_i \log f_i^j\right)}{\sum_{j=1}^M \exp\left(\sum_{i=1}^N \beta_i \log f_i^j\right)},$$

where f_i^j is individual i's probability of "class c_j," where there are M classes. The denominator is a scaling factor, and typically $\sum_{i=1}^N \beta_i = 1$. Clements and Harvey (2007) consider a form of LoOP for probability forecasts ($M = 2$) and two rival forecasts ($N = 2$), and Kamstra and Kennedy (1998) (henceforth, KK) suggest a form of combination for probability forecasts that involves the combining of log odds ratios by logit regressions. The KK combination of f_{1t} and f_{2t} is:

$$\begin{aligned} f_{ct} &= \frac{\exp\left[\alpha + \beta_1 \ln\left(\frac{f_{1t}}{1-f_{1t}}\right) + \beta_2 \ln\left(\frac{f_{2t}}{1-f_{2t}}\right)\right]}{1 + \exp\left[\alpha + \beta_1 \ln\left(\frac{f_{1t}}{1-f_{1t}}\right) + \beta_2 \ln\left(\frac{f_{2t}}{1-f_{2t}}\right)\right]} \\ &= \frac{\exp(\alpha)\left(\frac{f_{1t}}{1-f_{1t}}\right)^{\beta_1}\left(\frac{f_{2t}}{1-f_{2t}}\right)^{\beta_2}}{1 + \exp(\alpha)\left(\frac{f_{1t}}{1-f_{1t}}\right)^{\beta_1}\left(\frac{f_{2t}}{1-f_{2t}}\right)^{\beta_2}}, \end{aligned} \tag{4.10}$$

where β_1 and β_2 are the maximum likelihood estimates of the slope coefficients from a logit regression of y_t on a constant, $\ln\left(\frac{f_{1t}}{1-f_{1t}}\right)$ and $\ln\left(\frac{f_{2t}}{1-f_{2t}}\right)$. Clements and Harvey (2007) show that the KK combination is optimal when the data-generating process has the form:

$$\begin{aligned} y_t &= 1\left(\frac{\exp(\delta_1 X_{1t} + \delta_2 X_{2t})}{1 + \exp(\delta_1 X_{1t} + \delta_2 X_{2t})} > v_t\right) \\ f_{1t} &= \frac{\exp(\theta_{11} X_{1t})}{1 + \exp(\theta_{11} X_{1t})} \\ f_{2t} &= \frac{\exp(\theta_{12} X_{2t})}{1 + \exp(\theta_{12} X_{2t})}, \end{aligned} \tag{4.11}$$

with X_{1t} and X_{2t} scalar explanatory variables underpinning the two forecasts, although KK combination is a computationally attractive method of combining forecasts whilst ensuring $f_t \in (0, 1)$ more generally.

4.2.2 Forecast encompassing

The concept of forecast encompassing relates to whether or not one forecast encapsulates all the useful predictive information contained in a second forecast. Formally, using a squared error loss function as above, f_{1t} is said to encompass f_{2t} if, in a linear combination of the two forecasts, f_{2t} optimally receives zero weight, so that combining f_{1t} with f_{2t} does not lead to a reduction in the MSFE. Thus, using the simplest Bates and Granger (1969) form of linear combination, f_{1t} encompasses f_{2t} if the optimal value of λ in (4.1) is zero. This concept was originally proposed by Nelson (1972) and Granger and Newbold (1973), with f_{1t} referred to as being conditionally efficient with respect to f_{2t}; the terminology has subsequently been modified by Chong and Hendry (1986) to that of forecast encompassing, adopting the language of the model encompassing literature (see, *inter alia*, Mizon, 1984; Mizon and Richard, 1986).

Chong and Hendry (1986) focus on the fact that, if f_{1t} encompasses f_{2t}, the forecast errors of the encompassing forecast, e_{1t}, should be uncorrelated with the encompassed forecast f_{2t}. This obtains since e_{1t} should be uncorrelated with information available at the time of the forecast, while, on the other hand, correlation between e_{1t} and f_{2t} would imply that the accuracy of f_{1t} could be improved by linear combination with f_{2t}. This approach results in an alternative definition of forecast encompassing, namely that f_{1t} encompasses f_{2t} if the optimal value of λ is zero in a regression:

$$e_{1t} = \lambda f_{2t} + \varepsilon_t.$$

The two definitions of forecast encompassing presented thus far implicitly assume that the forecasts are unbiased and efficient. To account for potential forecast bias and inefficiency, alternative forecast encompassing specifications can also be derived by defining encompassing as f_{2t} receiving zero optimal weight in a more general forecast combination such as (4.7) or (4.8). Both approaches have been proposed in the literature, with Fair and Shiller (1989, 1990) using (4.8), allowing for the forecasts to be both biased and inefficient, and Andrews, Minford and Riley (1996) advocating use of (4.7), an in-between case allowing for forecast bias while retaining the assumption that the combination weights sum to one.

The alternative forecast encompassing definitions can be summarized and given a regression interpretation as follows. Beginning with the most general formulation, the Fair and Shiller (1989) definition of f_{1t} encompassing f_{2t} equates to $\beta_2 = 0$ in the regression:

$$\text{FE(1):} \qquad y_t = \alpha + \beta_1 f_{1t} + \beta_2 f_{2t} + \varepsilon_t.$$

Relative to this specification, the Nelson (1972) and Granger and Newbold (1973) approach imposes the restrictions $\alpha = 0$ and $\beta_1 + \beta_2 = 1$, with encompassing defined by $\lambda = 0$ in the regression:

$$\text{FE(2):} \qquad e_{1t} = \lambda(e_{1t} - e_{2t}) + \varepsilon_t.$$

The Chong and Hendry (1986) definition can be obtained by assuming f_{1t} in FE(1) to be efficient, i.e., imposing $\alpha = 0$ and $\beta_1 = 1$, with encompassing then defined by $\lambda = 0$ in the regression:

$$\text{FE(3):} \qquad e_{1t} = \lambda f_{2t} + \varepsilon_t.$$

The FE(2) and FE(3) cases can also be modified to allow for forecast bias by relaxing the $\alpha = 0$ assumption, yielding the Andrews, Minford and Riley (1996) regression:

$$\text{FE(2}'\text{):} \qquad e_{1t} = \alpha + \lambda(e_{1t} - e_{2t}) + \varepsilon_t,$$

and a modified Chong–Hendry regression:

$$\text{FE(3}'\text{):} \qquad e_{1t} = \alpha + \lambda f_{2t} + \varepsilon_t.$$

In the remainder of this chapter, we focus on the more commonly used definitions FE(1), FE(2) and FE(3).

It is clear that if the restrictions imposed by FE(2) and FE(3) are not satisfied, the three definitions of encompassing are not equivalent, and the forecast f_{1t} may encompass f_{2t} according to one definition, but not another. FE(1) is the most general approach of the three, and allows an analysis of the forecast encompassing hypothesis without the additional requirements that the individual forecasts are unbiased and efficient. Note that if the optimal value of β_2 in FE(1) is zero, it does not follow that the optimal forecast is simply f_{1t}: the correct inference is that a *linear function of* f_{1t}, i.e., $\alpha + \beta_1 f_{1t}$, cannot be improved (in terms of MSFE) through combination with f_{2t}. If the restrictions underlying FE(2) and FE(3) do hold, tests based on these approaches should be more powerful.

When the actuals and forecasts are integrated time series processes, FE(1) should be implemented using actual and predicted changes rather than the levels of the series, as otherwise the test statistics will not have their standard distributions. When the data (and forecasts) are integrated, the FE(3) approach can be problematic, as noted by Ericsson (1992). Because a forecast f_{1t} would be expected to be cointegrated with y_t, the resulting forecast error e_{1t} is integrated of order zero. The regression FE(3) is then unbalanced in the sense that the dependent and explanatory variables have differing orders of integration, and Phillips (1995) shows that the resulting forecast encompassing tests have an asymptotic size of one.

Tests of the null hypothesis of forecast encompassing can be conducted using any of the above definitions. In terms of the more general FE(1) definition, the null and alternative can be expressed as:

$$\begin{aligned} H_0: &\quad \beta_2 = 0 \quad (f_{1t} \text{ encompasses } f_{2t}) \\ H_1: &\quad \beta_2 > 0 \quad (f_{1t} \text{ does not encompass } f_{2t}). \end{aligned}$$

The alternative hypothesis is often chosen to be one-sided, to rule out the possibility of negative combination weights. Note, however, that negative weights can arise: from (4.3) it is apparent that the weight on f_{2t} in the Bates–Granger combination will be negative if $\sigma_2\rho > \sigma_1$ (and the weight on f_{1t} will exceed unity). For

FE(2) and FE(3), the null and alternative hypotheses take the same form as above but with the parameter λ replacing β_2.

The most straightforward approach to testing would be to simply estimate the relevant regression, FE(1), FE(2) or FE(3), by OLS, and then perform a standard t-test of the null that $\beta_2 = 0$ or $\lambda = 0$. However, as Harvey, Leybourne and Newbold (1998) show in the context of the FE(2) regression, such an approach is not robust to properties of the forecast errors that one might expect to encounter in practice. First, an implicit assumption of the regression error ε_t being identically and independently distributed (i.i.d.) is not plausible for forecasts at horizons greater than one, since even optimal forecasts in this setting would be expected to have errors that follow a moving-average process of order $h-1$. Second, in some applications it is likely that the forecast errors are non-normally distributed (for example, Harvey and Newbold, 2003, find substantial evidence of non-normality in US macroeconomic forecast errors). Non-normality in the errors induces conditional heteroskedasticity in the regression FE(2), resulting in oversized tests if conventional t-tests are applied.

Harvey, Leybourne and Newbold (1998) consider two ways of obtaining asymptotically correctly-sized tests in these situations. One is to continue with a regression-based t-test, but using standard errors that are robust to heteroskedasticity and autocorrelation. Specifically, assuming the forecast errors are at most lag $(h-1)$ dependent (in line with forecast optimality), they propose the use of a rectangular lag window for long-run variance estimation, as in Diebold and Mariano (1995). This approach yields the test statistic:

$$R_1 = \frac{\hat{\lambda}}{\sqrt{\dfrac{\sum_{j=-(h-1)}^{h-1} \sum_{t=|j|+1}^{n} (e_{1t} - e_{2t})\hat{\varepsilon}_t (e_{1,t-|j|} - e_{2,t-|j|})\hat{\varepsilon}_{t-|j|}}{\left[\sum_{t=1}^{n} (e_{1t} - e_{2t})^2\right]^2}}},$$

where $\hat{\lambda}$ is the least squares estimate of λ in the FE(2) regression. Alternatively, one could impose the information that $\lambda = 0$ under the null, replacing $\hat{\varepsilon}_t$ with e_{1t} in the variance estimator:

$$R_2 = \frac{\hat{\lambda}}{\sqrt{\dfrac{\sum_{j=-(h-1)}^{h-1} \sum_{t=|j|+1}^{n} (e_{1t} - e_{2t})e_{1t}(e_{1,t-|j|} - e_{2,t-|j|})e_{1,t-|j|}}{\left[\sum_{t=1}^{n} (e_{1t} - e_{2t})^2\right]^2}}}.$$

Under standard assumptions about the forecast errors, both R_1 and R_2 are asymptotically standard normally distributed.

The second approach proposed by Harvey, Leybourne and Newbold (1998) observes that the null hypothesis under the FE(2) specification requires:

$$E[e_{1t}(e_{1t} - e_{2t})] = 0.$$

This motivates testing for forecast encompassing via a test for whether the series $d_t = e_{1t}(e_{1t} - e_{2t})$ has zero mean, along the lines of Diebold and Mariano (1995),

who presented such an approach for testing the null of equal forecast accuracy. Under standard assumptions:

$$\sqrt{n}[\bar{d} - E(d_t)] \Rightarrow N(0, S), \tag{4.12}$$

where S denotes the long-run variance of d_t, giving rise to the statistic:

$$DM = \frac{n\bar{d}}{\sqrt{\sum_{j=-(h-1)}^{h-1} \sum_{t=|j|+1}^{n} (d_t - \bar{d})(d_{t-|j|} - \bar{d})}}, \tag{4.13}$$

where $\bar{d} = n^{-1} \sum_{t=1}^{n} d_t$ and the implied estimator of S uses a rectangular lag window as above. This statistic has an asymptotic standard normal distribution under the null of forecast encompassing, and is robust to the aforementioned forecast error properties of autocorrelation and non-normality. Harvey, Leybourne and Newbold (1998) propose a small modification of this test which has improved finite sample properties, drawing on work by Harvey, Leybourne and Newbold (1997). The modified statistic is:

$$MDM = n^{-1/2}[n + 1 - 2h + n^{-1}h(h-1)]^{1/2} DM, \tag{4.14}$$

and the recommendation is to use critical values from the t_{n-1} distribution rather than those from the limiting standard normal. Simulation results in Harvey, Leybourne and Newbold (1998) show that *MDM* has better finite-sample size properties than the regression-based variants R_1 and R_2, although some loss in size-adjusted power relative to R_1 is observed for small samples.

In addition to forecast errors being autocorrelated (for $h > 1$) and possibly non-normally distributed, it may also be the case that the errors exhibit autoregressive conditional heteroskedasticity (ARCH – see, e.g., Engle, 1982), with the squared forecast errors following a dependent sequence. Intuitively, this describes the situation where, if a variable proves difficult to forecast in one period, it is likely to prove difficult to forecast in the next period as well. In such circumstances, and again in the context of FE(2), Harvey, Leybourne and Newbold (1999) show that the forecast encompassing tests suffer asymptotic size distortions, rejecting the forecast encompassing null too frequently. They also propose a simple modification which largely overcomes the size problem; this involves computing *MDM* as above, but replacing h in (4.13) and (4.14) with $\lfloor 0.5n^{1/3} \rfloor + h$, where $\lfloor . \rfloor$ denotes integer part. This modification should be employed whenever ARCH in the forecast errors is suspected, or is detected through prior testing.

Although Harvey, Leybourne and Newbold (1998) propose the *MDM* test (4.14) in the context of FE(2), the test can also be applied using the forecast encompassing specifications FE(1) and FE(3), the only difference being the specification of d_t. For FE(1), application of the Frisch–Waugh theorem shows that β_2 is identical to that in the regression $\eta_{1t} = \beta_2 \eta_{2t} + \nu_t$, where η_{1t} and η_{2t} denote the errors from regressions of y_t and f_{2t}, respectively, on a constant and f_{1t}. This allows us to write the null hypothesis as:

$$E(\eta_{1t}\eta_{2t}) = 0,$$

with the corresponding specification for d_t being $d_t = \eta_{1t}\eta_{2t}$; in practice, η_{1t} and η_{2t} can be replaced with their residual counterparts $\hat{\eta}_{1t}$ and $\hat{\eta}_{2t}$, respectively. For FE(3), testing can proceed by setting $d_t = e_{1t}f_{2t}$.[1] Variants of R_1 and R_2 can also be constructed for FE(1) and FE(3) in a straightforward manner; see, for example, Newbold and Harvey (2002) for FE(1).

Tests for forecast encompassing can also be devised for the ANN combination. This would require the computationally more burdensome estimation of $\theta = \left(\alpha, \beta_1, \ldots \beta_k, \gamma_1, \ldots \gamma_p, \delta_1, \ldots \delta_p\right)$ by NLS, rather than choosing the γ_i as random draws from a $U(-1, 1)$ distribution: i.e., minimizing $Q_n(\theta) = \sum_{t=1}^{n}\left[y_t - f_t(\theta)\right]^2$ to give $\hat{\theta}_n$. We can then use the results that, under general conditions, $\hat{\theta}_n$ converges to θ^*, where:

$$\theta^* = \arg\min_{\theta} E\left[y_t - f_t(\theta)\right]^2,$$

and that $\sqrt{n}\left(\hat{\theta} - \theta^*\right) \Rightarrow N\left(0, \Omega_\theta\right)$, where Ω_θ can be consistently estimated, to conduct inference. The null hypothesis that f_{1t} encompasses f_{2t} based on the ANN combination can be constructed as a test of the joint significance of all the parameters related to f_{2t}, i.e., $\beta_2 = \gamma_{21} = \ldots = \gamma_{2p} = 0$: see White (1989), Kuan and White (1994) and the discussion by Franses and van Dijk (2000, pp. 230–2) for details.

4.3 Model-based forecasts

The analysis and forecast encompassing tests considered in the previous section treat the forecasts as given. However, in many practical applications forecasts are obtained using estimated regression models, and the impact of estimation uncertainty on the encompassing tests then needs to be examined if we wish to assess the predictive ability of the underlying models. West and McCracken (1998) and West (2001) study the impact of estimation uncertainty for the forecast encompassing specifications FE(3) and FE(2) respectively, drawing on the work of West (1996), although the general results are equally applicable to FE(1). Suppose, by way of a simple example, that the forecasts f_{1t} and f_{2t} are generated using the non-nested regression models:

$$\begin{aligned} \text{Model 1:} \quad & y_t = \theta_1 X_{1t} + e_{1t} \\ \text{Model 2:} \quad & y_t = \theta_2 X_{2t} + e_{2t}, \end{aligned}$$

where the scalar regressors X_{1t} and X_{2t} are assumed to be stationary and well behaved, and where $E(e_{1t}X_{1t}) = E(e_{2t}X_{2t}) = 0$. Given estimates of the model parameters ($\hat{\theta}_{1t}$ and $\hat{\theta}_{2t}$) using data prior to time t, the corresponding forecasts can then be constructed as:

$$\begin{aligned} \hat{f}_{1t} &= \hat{\theta}_{1t} X_{1t} \\ \hat{f}_{2t} &= \hat{\theta}_{2t} X_{2t}. \end{aligned}$$

As in the previous section, assume that a record of n past forecasts and actuals are available for evaluation, denoting the corresponding forecast errors by $\hat{e}_{1t}$ and $\hat{e}_{2t}$. The n forecasts can be derived using model parameter estimates obtained in one of three main ways. First, a *fixed* estimation scheme involves a one-off estimation of $\hat{\theta}_{1t}$ and $\hat{\theta}_{2t}$ using data from, say, $t = 1, \ldots, R$, and then using that same set of estimates to produce n forecasts from $t = R + h$ to $R + n + h - 1$. Second, a *recursive* estimation scheme might be adopted, where the sample used for estimation uses all available information at each point, increasing by one observation per period, i.e., the models are first estimated over $t = 1, \ldots, R$ to produce forecasts for $t = R + h$, then the model parameters are re-estimated over $t = 1, \ldots, R + 1$ to give forecasts for $t = R + 1 + h$, etc. Finally, a *rolling* scheme uses a moving window of R observations to estimate the models, so that recent data is included, but more distant observations discarded, i.e., the initial estimation sample is again $t = 1, \ldots, R$ for forecasts of the period $t = R + h$, then $t = 2, \ldots, R + 1$ for use in forecasts for $t = R + 1 + h$, etc.

The encompassing tests of the previous section must now be constructed using $\hat{d}_t$, defined as d_t for the appropriate forecast encompassing specification FE(1), FE(2) or FE(3), but based on the quantities $\hat{f}_{1t}$, $\hat{f}_{2t}$, $\hat{e}_{1t}$ and $\hat{e}_{2t}$, which embody the estimated parameters $\hat{\theta}_{1t}$ and $\hat{\theta}_{2t}$. The results of West and McCracken (1998) and West (2001) show that the additional uncertainty implicit in $\hat{d}_t$ affects the asymptotic variance of $\bar{\hat{d}}$. We now have:

$$\sqrt{n}[\bar{\hat{d}} - E(d_t)] \Rightarrow N(0, \Omega), \tag{4.15}$$

where $\bar{\hat{d}} = n^{-1} \sum_{t=R+h}^{R+n+h-1} \hat{d}_t$ and:

$$\Omega = S + \delta_{dg}(DBS'_{dg} + S_{dg}B'D') + \delta_{gg}DBS_{gg}B'D', \tag{4.16}$$

with S denoting the long run variance of d_t as before, and:

$$\begin{aligned}
D &= E\left[\begin{array}{cc} \partial d_t/\partial\theta_1 & \partial d_t/\partial\theta_2 \end{array} \right] \\
B &= \left[\begin{array}{cc} [E(X_{1t}^2)]^{-1} & 0 \\ 0 & [E(X_{2t}^2)]^{-1} \end{array} \right] \\
S_{gg} &= \textstyle\sum_{j=-\infty}^{\infty} E(g_t g'_{t-j}), \qquad g_t = \left[\begin{array}{c} e_{1t}X_{1t} \\ e_{2t}X_{2t} \end{array} \right] \\
S_{dg} &= \textstyle\sum_{j=-\infty}^{\infty} E\{[d_t - E(d_t)]g'_{t-j}\},
\end{aligned}$$

and where the parameters δ_{dg} and δ_{gg} are given in the following table:

Estimation scheme	δ_{dg}	δ_{gg}
Fixed	0	π
Recursive	$1-\pi^{-1}\ln(1+\pi)$	$2\left[1-\pi^{-1}\ln(1+\pi)\right]$
Rolling, $\pi \leq 1$	$\pi/2$	$\pi-\pi^2/3$
Rolling, $\pi > 1$	$1-(2\pi)^{-1}$	$1-(3\pi)^{-1}$

with $\pi = \lim_{R,n\to\infty}(n/R), 0 \leq \pi < \infty$. Note that $BS_{gg}B'$ in the last term of (4.16) defines the asymptotic ($R \to \infty$) variance-covariance matrix of the estimator of the parameter vector $\theta = [\theta_1, \theta_2]'$, denoted V_θ. The above results can also be generalized beyond the example considered of scalar linear regression models estimated by least squares, provided the models continue to be non-nested. For results pertaining to multiple regressors in a linear framework, and also more general models and estimation techniques, see West and McCracken (1998) and West (2001). Essentially, (4.15) and (4.16) continue to hold, but involve more general representations for the constituent components of Ω.

Comparing (4.12) and (4.15)–(4.16), it can be seen that the uncertainty involved through estimation of the model parameters gives rise to additional terms in the asymptotic variance of $\bar{\hat{d}}$. To see how this arises, consider the FE(2) *MDM* test for the simple example above, assuming the forecasts have been obtained via the fixed estimation scheme, so that $\hat{\theta}_{it} = \hat{\theta}_i = \sum_{t=1}^{R} y_t X_{it} / \sum_{t=1}^{R} X_{it}^2$, $t = R+h, \ldots, R+n+h-1$, $i = 1, 2$. In this case, the expression (4.16) simplifies to $\Omega = S + \pi D V_\theta D'$ with $D = [E(e_{2t}X_{1t}), E(e_{1t}X_{2t})]$. Now the forecast errors can be written as $\hat{e}_{it} = e_{it} - (\hat{\theta}_i - \theta_i)X_{it}$, $i = 1, 2$, resulting in the decomposition:

$$\bar{\hat{d}} = \bar{d} + n^{-1}\sum_{t=R+h}^{R+n+h-1}\Big[(\hat{\theta}_1-\theta_1)e_{2t}X_{1t} + (\hat{\theta}_2-\theta_2)e_{1t}X_{2t} + (\hat{\theta}_1-\theta_1)^2X_{1t}^2 - (\hat{\theta}_1-\theta_1)(\hat{\theta}_2-\theta_2)X_{1t}X_{2t} - 2(\hat{\theta}_1-\theta_1)e_{1t}X_{1t}\Big].$$

It then follows that:

$$\begin{aligned} V\left[\sqrt{n}[\bar{\hat{d}} - E(d_t)]\right] &= V\left[\sqrt{n}[\bar{d} - E(d_t)]\right] + nE\Big\{n^{-2}\Big[(\hat{\theta}_1-\theta_1)^2\Big(\sum_{t=R+h}^{R+n+h-1} e_{2t}X_{1t}\Big)^2 \\ &\quad + (\hat{\theta}_2-\theta_2)^2\Big(\sum_{t=R+h}^{R+n+h-1} e_{1t}X_{2t}\Big)^2 \\ &\quad + 2(\hat{\theta}_1-\theta_1)(\hat{\theta}_2-\theta_2)\sum_{t=R+h}^{R+n+h-1} e_{2t}X_{1t}\sum_{t=R+h}^{R+n+h-1} e_{1t}X_{2t}\Big]\Big\} + o_p(1) \\ &= V\left[\sqrt{n}[\bar{d} - E(d_t)]\right] + (n/R)E\Big\{[R^{1/2}(\hat{\theta}_1-\theta_1)]^2\Big(n^{-1}\sum_{t=R+h}^{R+n+h-1} e_{2t}X_{1t}\Big)^2 \\ &\quad + [R^{1/2}(\hat{\theta}_2-\theta_2)]^2\Big(n^{-1}\sum_{t=R+h}^{R+n+h-1} e_{1t}X_{2t}\Big)^2 \end{aligned}$$

$$+2R^{1/2}(\hat{\theta}_1-\theta_1)R^{1/2}(\hat{\theta}_2-\theta_2)(n^{-1}\textstyle\sum_{t=R+h}^{R+n+h-1} e_{2t}X_{1t})(n^{-1}\sum_{t=R+h}^{R+n+h-1} e_{1t}X_{2t})\Big\}$$

$$+ o_p(1)$$

$$\Rightarrow S + \pi\{V_{\theta,11}[E(e_{2t}X_{1t})]^2 + V_{\theta,22}[E(e_{1t}X_{2t})]^2 + 2V_{\theta,12}E(e_{2t}X_{1t})E(e_{1t}X_{2t})\}$$

$$= S + \pi D V_\theta D',$$

where $V_{\theta,ij}$ denotes the (i,j) element of V_θ.

If forecast encompassing tests are conducted without taking account of the additional terms present in Ω, i.e., by simply using $\hat{d}_t$ in place of d_t in the tests in the previous section, and using the usual implicit long run variance estimator that only estimates S, then asymptotic size distortions are generally obtained. For example, simulations by West (2001), using the example considered above with $\theta_1 = 1$, $\theta_2 = 0$ and $(e_{1t}, X_{1t}, X_{2t})'$ i.i.d. normal with variance-covariance matrix $diag(1,1,2)$, show that the FE(2) *MDM* test of the previous section, run at the nominal 5% significance level against a two-sided alternative, has empirical size around 25% for large n when $n/R = 2$.

In order to obtain asymptotically correctly-sized tests in general, the variance estimators implicit in the forecast encompassing tests must be modified so as to consistently estimate Ω. Consistent estimation of Ω can be obtained by estimating the constituent quantities S, S_{dg}, S_{gg}, B and D using their natural sample counterparts, and using n/R in place of π for determining δ_{dg} and δ_{gg}. To illustrate, consider again the FE(2) *MDM* test for the simple example above, assuming the forecasts have been obtained via the fixed estimation scheme. A further simplification of Ω is possible, since under the encompassing null hypothesis, e_{1t} cannot be predicted by model 2, so $E(e_{1t}X_{2t}) = 0$, yielding $D = [E(e_{2t}X_{1t}), 0]$ and:

$$\Omega = S + \pi V_{\theta,11}[E(e_{2t}X_{1t})]^2.$$

A consistent estimator is:

$$\hat{\Omega} = \hat{S} + (n/R)\hat{V}_{\theta,11}\left[n^{-1}\sum\nolimits_{t=R+h}^{R+n+h-1}\hat{e}_{2t}X_{1t}\right]^2,$$

where:

$$\hat{S} = [n+1-2h+n^{-1}h(h-1)]^{-1}\sum\nolimits_{j=-(h-1)}^{h-1}\sum\nolimits_{t=|j|+R+h}^{R+n+h-1}(\hat{d}_t-\overline{\hat{d}})(\hat{d}_{t-|j|}-\overline{\hat{d}}),$$

and $\hat{V}_{\theta,11}$ is the heteroskedasticity consistent estimator of the asymptotic variance of $\hat{\theta}_1$:

$$\hat{V}_{\theta,11} = \frac{R\sum_{t=1}^{R}\hat{e}_{1t}^2X_{1t}^2}{\left(\sum_{t=1}^{R}X_{1t}^2\right)^2}.$$

The resulting *MDM* statistic is then given by:

$$MDM = \frac{n^{1/2}\overline{\hat{d}}}{\sqrt{\hat{\Omega}}}.$$

There are, however, a number of special cases where the forecast encompassing tests do not require correction for model parameter estimation uncertainty. First, if $\pi = 0$, then the parameters δ_{dg} and δ_{gg} are zero regardless of the model estimation scheme, ensuring that Ω in (4.16) reduces to S. Thus if the ratio n/R is very small, a case could be made for abstracting from the issue of model estimation uncertainty and proceeding with the unadjusted tests of the previous section. Intuitively, this arises because, if R is very large compared to n, the model parameter estimation uncertainty becomes relatively insignificant compared to the uncertainty that would be present in the testing problem even if the model parameters were known.

A second case where model estimation corrections are not required is when the two models are linear, estimated by least squares, with each involving just a single regressor, as in the example above, and the forecast encompassing approach is FE(1). This case is considered by Clements and Harvey (2006). As noted in the previous section, for the FE(1) *MDM* test, $d_t = \eta_{1t}\eta_{2t}$, with η_{1t} and η_{2t} the errors from regressions of y_t and f_{2t}, respectively, on a constant and f_{1t}. Hence, letting $C(.,.)$ denote a covariance:

$$d_t = \left\{[y_t - E(y_t)] - \frac{C(y_t, f_{1t})}{V(f_{1t})}[f_{1t} - E(f_{1t})]\right\} \times \left\{[f_{2t} - E(f_{2t})] - \frac{C(f_{1t}, f_{2t})}{V(f_{1t})}[f_{1t} - E(f_{1t})]\right\}.$$

For forecasts from linear single regressor models, results such as $E\left(f_{it}\right) = \theta_i E\left(X_{it}\right)$, $i = 1, 2$, are obtained, so that d_t can be written as:

$$d_t = \theta_2 \left\{[y_t - E(y_t)] - \frac{C(y_t, X_{1t})}{V(X_{1t})}[X_{1t} - E(X_{1t})]\right\} \times \left\{[X_{2t} - E(X_{2t})] - \frac{C(X_{1t}, X_{2t})}{V(X_{1t})}[X_{1t} - E(X_{1t})]\right\}.$$

Clearly, $\partial d_t/\partial\theta_1 = 0$, and:

$$E\left(\frac{\partial d_t}{\partial \theta_2}\right) = C(y_t, X_{2t}) - \frac{C(X_{1t}, X_{2t})C(y_t, X_{1t})}{V(X_{1t})}. \tag{4.17}$$

The null hypothesis of $\beta_2 = 0$ in the FE(1) regression implies that:

$$V(f_{1t})C(y_t, f_{2t}) - C(f_{1t}, f_{2t})C(y_t, f_{1t}) = 0.$$

Substituting for f_{1t} and f_{2t} in this expression, and dividing both sides by $\theta_1^2\theta_2$ (noting that $\theta_1 \neq 0$, $\theta_2 \neq 0$), the right-hand side of (4.17) equals zero. So $D = (0, 0)$ under the null, and estimation uncertainty is irrelevant asymptotically for FE(1), contrasting with the findings using the *MDM* variants of the FE(2) and FE(3) tests.

Finally, West and McCracken (1998) show that while tests based on the FE(3) specification do require adjustment for estimation uncertainty, an alternative to directly estimating Ω exists when the models are linear. Consider augmenting

the FE(3) regression with the regressors from Model 1, i.e., in the above example, replacing the FE(3) regression with:

$$\hat{e}_{1t} = \lambda \hat{f}_{2t} + \gamma X_{1t} + \varepsilon_t.$$

West and McCracken (1998) show that tests of $\lambda = 0$ from this augmented regression only require standard autocorrelation and heteroskedasticity robust variance estimators, such as those of the previous section, and do not need estimators that explicitly account for the model parameter estimation uncertainty. In terms of an *MDM*-type testing approach, this augmented version of FE(3) can be executed by computing (4.14) with $\hat{d}_t = \hat{u}_{1t}\hat{u}_{2t}$ in place of d_t, where $\hat{u}_{1t}$ and $\hat{u}_{2t}$ denote the residuals from regressions of $\hat{e}_{1t}$ and $\hat{f}_{2t}$, respectively, on X_{1t}.

4.4 Nested model comparisons

The results of the previous section apply in the case where the rival forecasting models are non-nested. However, it is also common in forecast evaluation exercises for the forecasts under consideration to be obtained from models that are, in fact, nested. The primary situation where this arises is when forecast encompassing tests are employed to help determine whether a particular variable is useful for prediction, by testing whether a forecast based on a model including that variable as a regressor is encompassed by a forecast from the same model with that variable excluded. In such situations, the forecasts are asymptotically equivalent under the encompassing null hypothesis, and this affects the usual asymptotic results derived under a non-nested model assumption.

Clark and McCracken (2001) examine the asymptotic properties of FE(2)-based forecast encompassing tests for the special case of one-step-ahead forecasts ($h = 1$), when the models are nested, linear and estimated by OLS. Consider the following nested models:

$$\text{Model 1: } y_t = X_{1t}'\theta_{11} + e_{1t}$$
$$\text{Model 2: } y_t = X_{1t}'\theta_{21} + X_{2t}'\theta_{22} + e_{2t},$$

where the vectors X_{1t} and X_{2t} contain k_1 and k_2 regressors, respectively. The corresponding forecasts are denoted by:

$$\hat{f}_{1t} = X_{1t}'\hat{\theta}_{11t}$$
$$\hat{f}_{2t} = X_{1t}'\hat{\theta}_{21t} + X_{2t}'\hat{\theta}_{22t},$$

where the parameter vectors are first estimated from the above models, using data prior to time t. Under the null hypothesis that f_{1t} encompasses f_{2t}, Model 2 contains k_2 redundant variables (those in X_{2t}), and the population forecasts f_{1t} and f_{2t} are identical. Under the conditions outlined by Clark and McCracken (2001), which include conditionally homoskedastic forecast errors, the asymptotic null distribution of the FE(2) *MDM* statistic (4.14) (with $\hat{d}_t$ replacing d_t), for the general

case $0 < \pi < \infty$ (with $\pi = \lim_{R,n\to\infty}(n/R)$ as before), is given by:

$$MDM \Rightarrow \frac{\Gamma_1}{\sqrt{\Gamma_2}}, \tag{4.18}$$

where the terms Γ_1 and Γ_2 depend on the estimation scheme as follows:

Estimation scheme	Γ_1	Γ_2
Fixed	$\lambda^{-1}[W(1) - W(\lambda)]'W(\lambda)$	$\pi\lambda^{-1}W(\lambda)'W(\lambda)$
Recursive	$\int_\lambda^1 r^{-1}W(r)'dW(r)$	$\int_\lambda^1 r^{-2}W(r)'W(r)dr$
Rolling	$\lambda^{-1}\int_\lambda^1 [W(r) - W(r-\lambda)]'dW(r)$	$\lambda^{-2}\int_\lambda^1 [W(r) - W(r-\lambda)]'$ $[W(r) - W(r-\lambda)]dr$

with $\lambda = (1+\pi)^{-1}$ and $W(r)$ a $(k_2 \times 1)$ vector standard Brownian motion. In the case of the fixed estimation scheme, $(\Gamma_2)^{-1/2}\Gamma_1 \sim N(0,1)$, so that standard critical values can be employed. However, for the recursive and rolling estimation schemes, the forecast encompassing statistic no longer has a standard limit distribution under the null; critical values for these non-standard distributions are provided for a range of values of k_2 and π by Clark and McCracken (2000, 2001).

The above results assume the presence of model estimation uncertainty, with $0 < \pi < \infty$. If, on the other hand, $\pi = 0$, Clark and McCracken (2001) show that the *MDM* statistic is again standard normally distributed in the limit under the null hypothesis. Thus, if the ratio n/R is very small, standard normal critical values may be employed.

In the more general case where $h > 1$ and conditionally heteroskedastic forecast errors are permitted, the above results no longer hold in general. Clark and McCracken (2005) analyze this situation for predictions from nested linear models, where the forecasts are obtained using direct multi-step methods (see, e.g., Bhansali, 2002; Marcellino, Stock and Watson, 2006), as opposed to forecasts obtained by iterated one-step methods. They find that, for $0 < \pi < \infty$, FE(2) *MDM*-type test statistics do not have pivotal asymptotic null distributions, instead depending on nuisance parameters that vary with the second moments of the forecast errors, the model regressors, and the orthogonality conditions implicit in the OLS model estimations.

Two exceptions exist where FE(2) *MDM*-type forecast encompassing tests do possess pivotal limit distributions under the null for $h > 1$. First, if $k_2 = 1$, then the nuisance parameters vanish and the limit distribution of the test statistics reduces to that for $h = 1$, as given by (4.18) above. Second, if $\pi = 0$, the test statistics are standard normally distributed. Aside from these exceptions, however, no nuisance parameter-free asymptotic distributions exist from which critical values can be obtained. In such cases, critical values must instead be generated by simulation or bootstrap methods. Clark and McCracken (2005) outline a method for simulating the asymptotic critical values using estimates of the nuisance parameters, and also an algorithm for obtaining critical values via a parametric bootstrap;

simulation evidence suggests that the latter approach yields considerably better finite sample size control.

Finally, Clark and McCracken (2001, 2005) also propose a new FE(2)-based encompassing test for use with nested linear model forecasts, which is shown to be more powerful than the corresponding *MDM*-type tests. The test statistic is given by:

$$ENC\text{-}F = \frac{n\bar{\hat{d}}}{n^{-1}\sum_{t=R+h}^{R+n+h-1}\hat{e}_{2t}^2}.$$

When $h = 1$ and the forecast errors are conditionally homoskedastic, the statistic has the following limit distribution for $0 < \pi < \infty$ under the null:

$$ENC\text{-}F \Rightarrow \Gamma_1,$$

and critical values from this distribution are provided by Clark and McCracken (2000, 2001) for the fixed, recursive and rolling estimation schemes. When $h > 1$, the *ENC-F* statistic does not have a pivotal asymptotic distribution, even when $k_2 = 1$; in this more general case of multi-step prediction, therefore, critical values must be obtained by bootstrapping. When $\pi = 0$, *ENC-F* is degenerate, and needs to be rescaled by $(R/n)^{1/2}$ to obtain a limit distribution under the null.

4.5 Conditional tests of forecast encompassing

Hitherto, we have considered tests of forecast encompassing that are based on the notion of unconditional expected loss. Giacomini and White (2006) present a general framework for out-of-sample predictive ability testing which is characterized by the formulation of tests (such as tests for forecast encompassing) based on conditional expected loss. Tests of forecast encompassing based on unconditional expected loss indicate whether f_{1t} encompasses f_{2t} on average, i.e., over the whole sample, whereas a conditional evaluation would indicate that f_{1t} encompasses f_{2t} if it were not possible to predict whether the combination of f_{1t} and f_{2t} would outperform f_{1t} based on information known at $t - 1$. The approach of Giacomini and White (2006) also differs from the standard approach to testing for predictive ability in that it compares forecasting *methods* rather than forecasting *models*. Following the seminal contribution of West (1996), the underlying aim is to compare the forecast performance of the models *in population*. Although forecasts are derived from models with estimated parameters, hypotheses concerning predictive ability are framed in terms of forecasts based on the population values of the model parameters, necessitating an allowance for the impact of estimation uncertainty, as discussed in section 4.3. Instead, the approach of Giacomini and White (2006) compares the forecast performance of the methods, where the method comprises the method of estimation and the number of observations to include in the estimation window, in addition to the specification of the model. Estimation uncertainty is thus a key feature of the forecasting method and affects forecast performance.

An implication of evaluating methods rather than models is that it may be optimal to combine forecasts from the data-generating process with those from other models. This situation is ruled out when models are compared. Clements and Hendry (1998, Ch. 10) provide the following illustration based on an AR(1) process, $y_t = \psi y_{t-1} + v_t$, where $v_t \sim$ i.i.d. $N(0, \sigma_v^2)$ and $|\psi| < 1$. Then the h-step-ahead conditional MSFE, assuming an in-sample size of R observations, is:

$$E[\hat{e}_{R+h}^2 \mid y_R] = \frac{\sigma_v^2\left(1-\psi^{2h}\right)}{\left(1-\psi^2\right)} + E[\left(\psi^h - \hat{\psi}^h\right)^2]y_R^2, \tag{4.19}$$

where $\hat{\psi}$ is the OLS estimator of the unknown parameter ψ. The first term is the contribution of future disturbances, and the second is due to parameter uncertainty. Using the asymptotic formula in Baillie (1979, equation 1.6, p. 676):

$$E\left[\hat{e}_{R+h}^2 \mid y_R\right] = \frac{\sigma_v^2\left(1-\psi^{2h}\right)}{\left(1-\psi^2\right)} + h^2\psi^{2(h-1)}R^{-1}\left(1-\psi^2\right)y_R^2. \tag{4.20}$$

Chong and Hendry (1986) note that $h^2\psi^{2(h-1)}$ in the second term of (4.20) has a maximum at $h = -1/\ln\psi$, and so is not monotonic. It is straightforward to show that (4.20) will exceed the unconditional variance of the process ($\sigma_y^2 = E\left(y_t^2\right) = \sigma_v^2\left(1-\psi^2\right)^{-1}$) when:

$$\frac{y_R^2}{\sigma_y^2} > \frac{R\psi^2}{h^2\left(1-\psi^2\right)},$$

where the unconditional variance can be viewed as the expected squared forecast error of a forecast of zero (the unconditional mean), $\bar{y} = 0$. This establishes that the data-generating forecast can be beaten in terms of (squared-error loss) accuracy when there is estimation uncertainty. Moreover, consider the combined forecast:

$$\tilde{y}_{R+h} = \beta\bar{y} + (1-\beta)\hat{y}_{R+h} = (1-\beta)\hat{y}_{R+h}, \tag{4.21}$$

where $0 \leq \beta \leq 1$, with h-step-ahead forecast error:

$$\tilde{e}_{R+h} = y_{R+h} - \tilde{y}_{R+h} = \beta\bar{e}_{R+h} + (1-\beta)\hat{e}_{R+h}, \tag{4.22}$$

where $\hat{e}_{R+h} \equiv y_{R+h} - \hat{y}_{R+h}$ and $\bar{e}_{R+h} \equiv y_{R+h} - \bar{y} = y_{R+h}$. Minimizing $E\left[\tilde{e}_{R+h}^2 \mid y_R\right]$ with respect to β yields:

$$\beta_h^* = \left(1 + \frac{R\psi^2}{h^2\left(1-\psi^2\right)}\right)^{-1}. \tag{4.23}$$

Clements and Hendry (1998) compare the performance of $\hat{y}_{R+h}$, $\bar{y}$ and $\tilde{y}_{R+h}$ in terms of the unconditional MSFE, and establish that there are gains to forecast combination.

The key differences between Giacomini and White (2006) and the approach of Diebold and Mariano (1995) and West (1996) (DMW) to testing predictive ability

become apparent by contrasting their null hypotheses for a general test of equal forecast accuracy for a general loss function $L(.)$. The DMW null is that:

$$H_0: \quad E\left[L\left(Y_t, f_{1t}\left(\beta_1^*\right)\right) - L\left(Y_t, f_{2t}\left(\beta_2^*\right)\right)\right] = 0,$$

so that L is defined over the random variable Y_t and the one-step forecast based on information up to $t-1$ from Model i with population parameter vector β_i^*, denoted $f_{it}\left(\beta_i^*\right)$. The expectation of the loss differential is unconditional. By contrast, the Giacomini and White (2006) null is:

$$H_0: \quad E\left[L\left(Y_t, f_{1t}\left(\hat{\beta}_1\right)\right) - L\left(Y_t, f_{2t}\left(\hat{\beta}_2\right)\right) \mid \digamma_{t-1}\right] = 0, \tag{4.24}$$

so that loss depends on the estimates, and the expectation is with respect to an information set $\digamma_{t-1}$.

In terms of testing for forecast encompassing with standard squared-error loss (i.e., $L\left(Y_t, f_{it}\left(\beta_i^*\right)\right) = e_{it}^2$, where $e_{it} = Y_t - f_{it}^*$), the DMW null becomes:

$$H_0: \quad E(d_t) = 0,$$

where $d_t = e_{1t}\left(e_{1t} - e_{2t}\right)$ for the null that Model 1 encompasses Model 2 using FE(2). Assuming β_1^* and β_2^* are known, under standard conditions (see Diebold and Mariano, 1995; Harvey, Leybourne and Newbold, 1998; West and McCracken, 1998) we obtain (4.12), namely:

$$\sqrt{n}[\bar{d} - E(d_t)] \Rightarrow N(0, S).$$

When β_1^* and β_2^* are not known and the forecasts are based on $\hat{\beta}_1$ and $\hat{\beta}_2$, the variance of the limiting normal distribution will in general include an additional term for the effect of estimation uncertainty, as described in section 4.3.

To test for forecast encompassing using (4.24), let $\hat{d}_t = \hat{e}_{1t}\left(\hat{e}_{1t} - \hat{e}_{2t}\right)$, where $\hat{e}_{it} = y_t - f_{it}(\hat{\beta}_i)$ to make explicit the use of parameter estimates. Then $E(\hat{d}_t \mid \digamma_{t-1}) = 0$ is equivalent to $E(h_{t-1}\hat{d}_t) = 0$ when $\digamma_{t-1} = \mathcal{F}_{t-1}$ (where $\mathcal{F}_t$ is the information available at time t) and h_{t-1} is a $\mathcal{F}_{t-1}$-measurable function of dimension q. Standard asymptotic normality arguments then give rise to the (one-step) Conditional Forecast Encompassing Test (see Giacomini and White, 2006, Theorem 1, p. 1553):

$$T_n^h = n\bar{Z}_n'\hat{\Omega}_n^{-1}\bar{Z}_n,$$

where $\bar{Z}_n = n^{-1}\sum_{t=1}^n Z_t$, $Z_t = h_{t-1}\hat{d}_t$, and $\hat{\Omega}_n$ is the standard variance estimator, $\hat{\Omega}_n = n^{-1}\sum_{t=1}^n Z_t Z_t'$. Under the null:

$$T_n^h \Rightarrow \chi_q^2,$$

as $n \to \infty$. The sequences of forecasts are based on rolling estimation windows of fixed size to ensure non-vanishing parameter estimation uncertainty as the sample of forecasts (n) goes to infinity. (This aspect is suppressed in the notation for convenience.) The choice of h_{t-1} is crucial, in that the test will have no power if $E(\hat{d}_t \mid \digamma_{t-1}) \neq 0$ for some elements of $\digamma_{t-1}$, but an injudicious choice of h_{t-1}

leads to those elements not being included in h_{t-1} : h_{t-1} should include variables that are thought likely to distinguish between the two forecasting methods: such variables are likely to include indicators of past performance, as well as context-specific variables, such as business cycle indicators if it is thought that the relative performance of the two sets of forecasts may vary systematically with the business cycle. Further details of conditional forecast encompassing tests are provided in the discussion of the application of these methods to quantile forecasts in the following section.

4.5.1 Quantile forecasts

Giacomini and Komunjer (2005) present an application of the general approach of Giacomini and White (2006) to forecasting tests for quantile forecasts. The conditional aspect of their approach can be brought to the fore by considering the tests of correct conditional and unconditional coverage of Christoffersen (1998). According to Christoffersen (1998), a set of quantile forecasts is efficient with respect to an information set (denoted Ω_t) if $E\left(\alpha - 1\left(Y_t - \hat{q}_t < 0\right)|\Omega_{t-1}\right) = 0$, where $\hat{q}_t$ is a forecast of $Q_{t,\alpha}$, the α-quantile of the distribution of Y_t conditional on $\mathcal{F}_{t-1}$, namely $Q_{t,\alpha} \equiv F_t^{-1}(\alpha)$, with F_t the conditional distribution function of Y_t. $1(.)$ is the indicator function that takes the value one when the argument is true and zero otherwise. If we define $I_t \equiv 1\left(Y_t - \hat{q}_t < 0\right)$, then the condition for conditional efficiency can be written more succinctly as $E\left(\alpha - I_t|\Omega_{t-1}\right) = 0$. Testing whether this holds is a test of correct conditional coverage, because it requires both that (i) on average over the sample ($t = 1, \ldots, n$) the probability of an exceedence is not significantly different from α, and (ii) that there is no systematic relationship between these exceedences and any variables in the agent's information set at the time the forecast was made. The first requirement is that of correct *unconditional* coverage, often termed a test for unbiasedness, as it is based on whether the sample proportion of exceedences (say, $\hat{\pi} = n^{-1}\sum_{t=1}^{n} I_t$) is significantly different from the nominal proportion α. The null hypothesis is that $E\left(\alpha - I_t\right) = 0$ versus $E\left(\alpha - I_t\right) \neq 0$, and the standard likelihood ratio test is:

$$LR = -2\left[n_0 \ln\left(\frac{1-\alpha}{1-\hat{\pi}}\right) + n_1 \ln\frac{\alpha}{\hat{\pi}}\right] \overset{asy}{\sim} \chi_1^2,$$

where $n_1 = n\hat{\pi}$ and $n_0 = n - n_1$. Tests for correct unconditional coverage, or bias, can also be found in Granger, White and Kamstra (1989), Baillie and Bollerslev (1992) and McNees (1995).

The second requirement can be tested by restricting the information set to past values of I_t, namely $\Omega_{t-1} = \left\{I_{t-1}, I_{t-2}, \ldots\right\}$. The suggestion of Christoffersen (1998) is to test whether $E\left(\alpha - I_t|\Omega_{t-1}\right) = 0$ by testing whether $\left\{I_t\right\}$ follows a binary first-order Markov chain. If the transition probabilities are defined as:

$$\pi_{ij} = \Pr(I_t = j|I_{t-1} = i),$$

where $i, j = \{0, 1\}$, a lack of a systematic relationship between I_t and Ω_{t-1} (here $\Omega_{t-1} = I_{t-1}$) requires that $\pi_{0j} = \pi_{1j}$, $j = \{0, 1\}$, which gives rise to a simple likelihood ratio test. Note that this test does not consider unbiasedness mentioned

under (i). Granger, White and Kamstra (1989, note c to Table 1, p. 91) suggest using a contingency table approach to test the conditional aspect, based on whether the number of occurrences of (say) zeros followed by zeros is consistent with there being no association between the occurrence of a zero in one period and the occurrence of a zero in the following period. Clements and Taylor (2003) suggest a regression-based approach that facilitates the inclusion of variables besides lagged values of $\{I_t\}$ in the information set.

The tests of Christoffersen (1998) illustrate the distinction between conditional and unconditional tests in the context of the evaluation of a single sequence of forecasts. From a conceptual point of view, the approach of Giacomini and Komunjer (2005) can be viewed as replacing the single quantile forecast $\hat{q}_t$ by a combination of two (or more) quantile forecasts, $\theta'\hat{q}_t$, where $\theta = (\theta_1, \theta_2)'$ and $\hat{q}_t = (\hat{q}_{1t}, \hat{q}_{2t})'$, followed by the development of tests of conditional and unconditional forecast encompassing based on the estimated weights $\hat{\theta}$. Their treatment follows Giacomini and White (2006) (although complications arise due to the discontinuous nature of the moment conditions on which the generalized method of moments (GMM) estimation of θ is based).

The conditional α-quantile of Y_t, Q_t, is the optimal forecast for a "tick" or "check" loss function:

$$L_\alpha(e_t) = (\alpha - 1(e_t < 0))\, e_t,$$

where $e_t = y_t - \hat{q}_t$, so that $L(.)$ is used as the basis for assessing whether combinations of forecasts reduce loss. A straightforward application of the definition of forecast encompassing to quantile forecasts gives the following definition of conditional quantile forecast encompassing based on Giacomini and Komunjer (2005, Definition 1, p. 418): $\hat{q}_{1t}$ encompasses $\hat{q}_{2t}$ at time t if:

$$E_{t-1}\left[L_\alpha\left(Y_t - \hat{q}_{1t}\right)\right] = E_{t-1}\left[L_\alpha\left(Y_t - \left(\theta_{1t}^*\hat{q}_{1t} + \theta_{2t}^*\hat{q}_{2t}\right)\right)\right],$$

where $E_{t-1}(.) \equiv E(. \mid \mathcal{F}_{t-1})$ and where $\theta^* = \left(\theta_1^*, \theta_2^*\right)'$ are the optimal weights in that they minimize tick loss:

$$\left(\theta_1^*, \theta_2^*\right) \equiv \underset{(\theta_1,\theta_2)\in\Theta}{\arg\min} E_{t-1}\left[L_\alpha\left(Y_t - \left(\theta_{1t}\hat{q}_{1t} + \theta_{2t}\hat{q}_{2t}\right)\right)\right].$$

Thus the optimal weights are $\left(\theta_1^*, \theta_2^*\right) = (1, 0)$, so assigning a zero weight to $\hat{q}_{2t}$.

Giacomini and Komunjer (2005, Lemma 1, p. 419) show that θ^* satisfies the first-order condition:

$$E_{t-1}\left[\alpha - 1\left(Y_t - \theta^*\hat{q}_t < 0\right)\right] = 0, \tag{4.25}$$

which is the correct conditional coverage condition of Christoffersen (1998). These moment conditions are used to estimate the optimal weights by GMM and to test for forecast encompassing (that $\hat{q}_{1t}$ encompasses $\hat{q}_{2t}$): $\left(\theta_1^*, \theta_2^*\right) = (1, 0)$. The conditional moment conditions (4.25) are replaced by:

$$E\left[\left(\alpha - 1\left(Y_t - \theta^*\hat{q}_t < 0\right)\right) W_{t-1}^*\right] = 0,$$

where W_t^* is an $\mathcal{F}_t$-measurable function. W_{t-1} plays the same role as h_{t-1} in the Conditional Forecast Encompassing Test of Giacomini and White (2006) and the same issues relate to its selection. The sample moment function is given by:

$$g_n(\theta) = \frac{1}{n}\sum_{t=1}^{n}\left[\alpha - 1\left(y_t - \theta'\hat{\boldsymbol{q}}_t < 0\right)\right]w_{t-1}^*, \tag{4.26}$$

and the GMM estimator of θ^*, denoted by $\hat{\theta}_n$, is the solution of:

$$\min_{(\theta_1,\theta_2)\in\Theta}\left[g_n(\theta)\right]'\hat{S}_n^{-1}\left[g_n(\theta)\right], \tag{4.27}$$

where:

$$\hat{S}_n = \frac{1}{n}\sum_{t=1}^{n}\left[\alpha - 1\left(y_t - \theta_t'\hat{q}_t < 0\right)\right]^2 w_{t-1}^* w_{t-1}^{*\prime}, \tag{4.28}$$

and $\hat{\theta}_n$ is obtained by solving (4.27) and (4.28) iteratively, starting with (4.27) and $\hat{S}_n = \mathrm{I}$. This gives $\hat{\theta}_n\left(\hat{S}_n = \mathrm{I}\right)$, after which we obtain an updated estimate of $\hat{S}_n$ from (4.28), etc.

Giacomini and Komunjer (2005, Propositions 1 and 2, p. 420) establish the consistency and asymptotic normality of $\hat{\theta}_n$. Specifically, under some conditions:

$$\left(\gamma' S^{-1}\gamma\right)^{-1/2}\sqrt{n}\left(\hat{\theta}_n - \theta^*\right) \Rightarrow N(0,1),$$

where $\gamma \equiv -E[f_t(\theta^{*\prime}\mathrm{q}_t)W_{t-1}^*\mathrm{q}_t']$, $S = E[g(\theta^*; Y_t, W_{t-1}^*)g(\theta^*; Y_t, W_{t-1}^*)']$, and f_t is the conditional density of Y_t. Given the asymptotic distribution of $\hat{\theta}_n$, the CQFE (Conditional Quantile Forecast Encompassing) test that $\hat{q}_{1t}$ encompasses $\hat{q}_{2t}$ is given by:

$$ENC_n = n\left(\hat{\theta}_n' - (1,0)\right)\hat{\Omega}_n^{-1}\left(\hat{\theta}_n' - (1,0)\right)',$$

where $\hat{\Omega}_n^{-1}$ is a consistent estimate of $\Omega = \left(\gamma' S^{-1}\gamma\right)^{-1}$. Under the null, $ENC_n \Rightarrow \chi_2^2$ as $n \to \infty$. The estimate for S is given by (4.28), and that for γ is given by Giacomini and Komunjer (2005).

4.6 Loss functions and forecast combination

Ever since the early work on forecast combination of Bates and Granger (1969) and Granger and Ramanathan (1984), combination weights have generally been chosen to minimize a symmetric, squared-error loss function, and the empirical forecast performance of the combination has typically been assessed by squared-error loss. This reflects the widespread use of squared-error loss in the forecast evaluation literature. For example, the "regression method" of Granger and Ramanathan (1984) estimates by OLS an equation such as:

$$y_t = \beta_1 f_{1t} + \beta_2 f_{2t} + e_t,$$

so that the combination weights are selected to minimize $\sum_t e_t^2$, the sum of squares of the forecast error for the combined forecast. Similarly, the "variance-covariance approach" of Bates and Granger (1969) selects the weights to minimize the variance of the forecast error of the combination of forecasts. Nevertheless, a number of papers have allowed for asymmetric loss, and have considered how the properties of optimal forecasts change once we dispense with the assumption of symmetric loss, as well as providing tests of rationality once we allow forecasters to have asymmetric loss functions.[2]

A key paper that investigates forecast combination in the context of asymmetric loss is Elliott and Timmermann (2004). They show that, for general loss functions and forecast error distributions, the optimal combination weights depend on higher-order moments of the forecast error distribution, such as the skew. However, under certain restrictions on the form of the forecast error distribution, they establish an *invariance* result, whereby the optimal combination weights on the individual forecasts are identical to the squared-error loss weights for almost all loss functions and that only the value of the constant term in the combination will differ. The value of the constant is chosen to generate the optimal amount of bias in the combination given the degree of asymmetry of the loss function. Their invariance result holds when the marginal distribution of the forecast errors depends only on the first two moments of the forecast errors, which holds when the joint distribution of the actual and forecasts $(y_t, \mathrm{f}_t)'$ is elliptically symmetric (which includes the multivariate normal and t-distributions: see Elliott and Timmermann, 2004, Proposition 2, p. 53).

Suppose:

$$E\begin{pmatrix} y_t \\ \mathrm{f}_t \end{pmatrix} = \begin{pmatrix} \mu_y \\ \mu \end{pmatrix}, \quad C\begin{pmatrix} y_t \\ \mathrm{f}_t \end{pmatrix} = \begin{pmatrix} \sigma_y^2 & \sigma_{21}' \\ \sigma_{21} & \Sigma_{22} \end{pmatrix},$$

then the forecast combination error is:

$$e_t = y_t - \beta_0 - \beta' \mathrm{f}_t,$$

with moments:

$$\mu_e = \mu_y - \beta_0 - \beta' \mu \tag{4.29}$$

$$\sigma_e^2 = \sigma_y^2 + \beta' \Sigma_{22} \beta - 2\beta' \sigma_{21}. \tag{4.30}$$

The decision maker selects (β_0, β) according to:

$$\min_{\beta_0, \beta} \int L(e_t)\, dF(e_t),$$

i.e., to minimize $E[L(e_t)]$. Under elliptical symmetry we can write $E[L(e_t)] = g\left(\mu_e, \sigma_e^2\right)$. From (4.29) and (4.30), only μ_e depends on β_0. Thus the first-order condition for minimizing $E[L(e_t)]$ with respect to β_0 is:

$$\frac{\partial g\left(\mu_e, \sigma_e^2\right)}{\partial \beta_0} = \frac{\partial g\left(\mu_e, \sigma_e^2\right)}{\partial \mu_e} \frac{\partial \mu_e}{\partial \beta_0} = 0.$$

As $\frac{\partial \mu_e}{\partial \beta_0} = -1$, the optimal value for β_0, β_0^*, solves $\frac{\partial g\left(\mu_e, \sigma_e^2\right)}{\partial \mu_e} = 0$. β_0^* depends on $L(.)$, and is set to generate the optimal amount of bias (μ_e^*) given the form of $L(.)$. For squared-error loss, $L\left(e_t\right) = e_t^2$, $E\left[L\left(e_t\right)\right] = \mu_e^2 + \sigma_e^2$, and $\frac{\partial g\left(\mu_e, \sigma_e^2\right)}{\partial \beta_0} = -2\mu_e$, so that the optimal amount of bias is, of course, zero ($\mu_e^* = 0$).

Consider the first-order condition with respect to β:

$$\frac{\partial g\left(\mu_e, \sigma_e^2\right)}{\partial \beta} = \frac{\partial g\left(\mu_e, \sigma_e^2\right)}{\partial \sigma_e^2} \frac{\partial \sigma_e^2}{\partial \beta} = 0.$$

Provided $\frac{\partial g\left(\mu_e, \sigma_e^2\right)}{\partial \sigma_e^2} \neq 0$, $\frac{\partial g\left(\mu_e, \sigma_e^2\right)}{\partial \beta} = 0$ implies that $\frac{\partial \sigma_e^2}{\partial \beta} = 0$, so from (4.30), $2\Sigma_{22}\beta^* = 2\sigma_{21}$ and $\beta^* = \Sigma_{22}^{-1}\sigma_{21}$ irrespective of the form of $L(.)$, matching the expression for squared-error loss.

As Elliott and Timmermann (2004) remark, if an element of β^* is zero under squared-error loss, then the corresponding forecast will also receive zero weight under any other loss function, assuming that the stated properties of the forecast error distribution hold. In the general case, it will not be possible to set up a general forecast encompassing test that does not depend on the form of the loss function.

4.7 Conclusions

We have discussed the different types of standard linear forecast combination that are commonly applied in the literature and the related tests of forecast encompassing. The tests of forecast encompassing depend upon whether the forecasts are generated by models with unknown parameters and on whether the underlying aim is to compare the forecasts themselves or the models on which they are based. There is also an important distinction to be drawn between conditional and unconditional tests.

More sophisticated forms of combination are reviewed, including nonlinear forms of combination that might be useful when large numbers of forecasts are available, and types of combination that might be preferable when the forecasts are density or probability forecasts. For the most part, forecast accuracy is assessed by the standard squared-error loss, although under certain conditions on the data-generating process forecast encompassing is invariant to the form of the loss function.

Notes

1. For the specification FE(2′) one would use $d_t = (e_{1t} - \bar{e}_1)[(e_{1t} - \bar{e}_1) - (e_{2t} - \bar{e}_2)]$, and for FE(3′), $d_t = (e_{1t} - \bar{e}_1)(f_{2t} - \bar{f}_2)$.
2. These include, *inter alia*, Granger (1969), Zellner (1986), Christoffersen and Diebold (1997), Clements (1997), Elliott, Komunjer and Timmermann (2005), Patton and Timmermann (2007) and Clements (2008).

Recent Developments in Density Forecasting

Stephen G. Hall and James Mitchell

Abstract

With the growing recognition that point forecasts, the traditional focus, are better seen as the central points of ranges of uncertainty, in recent years increased emphasis has been given to density forecasts. This chapter reviews these recent developments, with a focus on the production and use of density forecasts in macroeconomics. Particular attention is paid to the evaluation and combination of density forecasts.

5.1 Introduction

Forecasts of the future values of economic variables are used widely in decision making. For example, in many countries inflation forecasts are now central to the setting of monetary policy since monetary policy works with a lag (e.g., see Svensson, 2005, for a review). But it has become increasingly well understood that it is not a question of this forecast proving to be "right" and that forecast proving to be "wrong." Point forecasts, the traditional focus, are better seen as the central points of ranges of uncertainty. A forecast of, say, 2% must mean that people should not be surprised if actual inflation turns out to be a little larger or smaller than that. Moreover, at a time of heightened economic uncertainty, they should not be very surprised if it turns out to be much larger or smaller. Consequently, to provide a complete description of the uncertainty associated with the point forecast many professional forecasters now publish density forecasts, or more popularly "fan charts." A famous example is the Bank of England's fan chart (see Britton, Fisher and Whitley, 1998). Importantly, as this chapter reviews, just as point forecasts are commonly evaluated using the subsequent outturn, so the reliability of uncertainty forecasts can be evaluated.

More formally, density forecasts of inflation provide an estimate of the probability distribution of its possible future values. In contrast to interval forecasts, which give the probability that the outcome will fall within a stated interval, such as inflation falling within its target range, density forecasts provide a complete description of the uncertainty associated with a forecast; they can thus be seen to provide information on all possible intervals.

In conjunction with the increased use of density forecasts by professional forecasters and central banks, the academic literature has also devoted increased emphasis to density forecasting, with the *Journal of Forecasting* devoting a special issue to it in 2000 and the *Handbook of Economic Forecasting*, published in 2006, containing a chapter surveying methods for predictive density evaluation. This chapter, with a macroeconomic focus, reviews several aspects of these recent developments, breaking them down into four areas which, in turn, are considered in separate sections of the chapter:

1. The importance of density forecasts
2. The production of density forecasts
3. The evaluation of density forecasts
4. The combination of density forecasts.

In so doing we extend the coverage, and update in the light of recent research, previous surveys and textbooks, including Tay and Wallis (2000), Clements (2005), Timmermann (2006) and Wallis (2008). The principal extensions in terms of coverage are the last two sections. In particular we focus on how to choose the weights when combining density forecasts. Reflecting the infancy of this material, considerable applied and theoretical work remains to be done to establish a consensus about how best this should be achieved. Nevertheless, this chapter attempts

to bring together current wisdom and indicates areas where more research would be welcome. Our discussion also draws out, particularly in section 5.3, which has much relevance for how forecasting is conducted in practice by professional forecasters, the distinction between model-based and subjective density forecasts, and we also consider their reconciliation. We do not discuss presentation issues, which we defer to Tay and Wallis (2000) and Wallis (2007).

We confine attention to univariate density forecasts. There is a smaller but growing literature on multivariate density forecasting, some of it drawing on recent applications of copula functions in economics (e.g., Patton, 2006), where the copula characterizes the dependence between the density forecasts. Diebold, Gunther and Tay (1998) and Diebold, Hahn and Tay (1999) show that the principle behind the evaluation of univariate density forecasts, discussed in section 5.4 below, generalizes to the multivariate case (see also Clements and Smith, 2000, 2002). Adolfson, Linde and Villani (2007) use a multivariate scoring rule to compare density forecasts of the Euro-area from vector autoregressive (VAR) and dynamic stochastic general equilibrium (DSGE) models. Barrell, Hall and Hurst (2006) and Mitchell (2007a) consider how bivariate density forecasts for inflation and output growth facilitate the evaluation of policy rules simultaneously with respect to their performance against the inflation target and any output growth target that the policy makers may also have in mind.

5.2 The importance of density forecasts

Periodically, and perhaps especially at times of heightened uncertainty, one hears the argument that it is time to jettison economic forecasts given their unreliability. But, as discussed above, in fact we should not be surprised by the unreliability of point forecasts – indeed, the unreliability of point forecasts is itself a useful indication of uncertainty. In a loose sense, ignoring for now moments higher than the second, what is important is the ability of the point forecast, relative to its variance, to track the outturn. More generally, it is important to provide a quantitative indication of the uncertainty associated with a point forecast, along with the balance of risks (skewness) on the upside and downside and the probability of extreme events (fat tails or kurtosis). This is achieved by publishing a density forecast. Importantly, the density forecast gives any users of the forecast an indication, in advance, of the health risks associated with its use.

Although it is a truism to say that density forecasts cannot capture unknowable uncertainty (Knightian uncertainty) and only capture "risk" (knowable uncertainty), the distinction introduced by Knight (1921), these "risk" assessments can be evaluated *ex post*. Indeed, they should be assessed on a regular and ongoing basis. There is no reason to expect, especially at times of structural change, that the density forecast correctly captures uncertainty. Forecasters' statements about the underlying uncertainty may be, and indeed often are, unreliable. When forecasters expect them to be unreliable the variance of the conditional variance forecast need not equal zero. Therefore evaluation tests, reviewed in section 5.4, have been developed to test, essentially, whether on average over a given sample a forecaster's

assessment of "risk" was correct. When it is correct their "risk" forecast might be said to have captured "true" uncertainty.

These sort of historical evaluations of fan charts, complementing the traditional and widespread practice of evaluating the trackrecord of point forecasts, are beginning to be carried out routinely by forecasters (for an appraisal of UK inflation density forecasts by the Bank of England and/or the National Institute of Economic and Social Research (NIESR), see Clements, 2004; Wallis, 2004; Mitchell, 2005; Elder *et al.*, 2005). The results provide an indication as to whether, albeit historically, a series of fan charts was reliable. Just as measures of point forecast accuracy indicate, to a degree, our confidence in point forecasts, these tests provide an indication of our confidence in fan charts.

5.2.1 Forecasting under general loss functions

What really matters is how forecasts affect decisions. The "better" forecasts are those that deliver "better" decisions. On this basis it is argued that the appropriate way of evaluating forecasts is not to use some arbitrary statistical loss function, but the appropriate economic loss function (see Granger, 1969; Granger and Pesaran, 2000). Only when the forecast user has a symmetric, quadratic loss function, and the constraints (if relevant) are linear, is it correct to focus on the point forecast alone. This is what the textbook's call "certainty equivalence" (for further discussion and a proof, see Ljungqvist and Sargent, 2000, pp. 57–9). In the more general case, the degree of uncertainty matters. Publishing a point forecast alone is not sufficient; users are not indifferent to the degree of uncertainty about the point forecast.[1] They will not then make decisions as if they were certain. Uncertainty is expected to attenuate their response or reaction to the point forecast (see Brainard, 1967). For more recent discussion in the context of policy makers' reactions to real-time output gap estimates, which are known to be unreliable (Orphanides and van Norden, 2002), although this is not surprising (as discussed above: see also Mitchell, 2007b), see Swanson (2004).

The importance of publishing density forecasts then follows from the fact that we tend, in reality, not to know users' loss functions. Central banks do not quantify, explicitly at least, their loss functions, but we should not expect these (unknown to us) functions to be quadratic. For example, we should expect the range of uncertainty to matter to the Federal Reserve since it probably does not care equally about inflation above and below the zero bound. The central bank has then to be what Svensson (2001) calls a *distribution* forecast targeter.

When the forecast user's loss function is asymmetric, such that positive and negative forecasting errors have differing costs, the user's "optimal" forecast need not equal the conditional mean (e.g., Zellner, 1986; see Pesaran and Weale, 2006, for a survey). Working out the optimal forecast can be complex, but if it is assumed that the conditional distribution of $y_t \mid \Omega_{t-h}$ is normal such that $y_t \mid \Omega_{t-h} \sim N(E(y_t \mid \Omega_{t-h}), V(y_t \mid \Omega_{t-h}))$ and the loss function is modeled via the Linex loss function, an analytical solution can be derived. Under these conditions the optimal or minimum loss point forecast, $\widehat{y}_{t|t-h}$, is no longer equal to the conditional mean

but equals:

$$\widehat{y}_{t|t-h} = E(y_t \mid \Omega_{t-h}) + \frac{\phi V(y_t \mid \Omega_{t-h})}{2}, \tag{5.1}$$

where ϕ is the asymmetry parameter in the Linex function. It reflects differing costs to over and under prediction. This means that it can be "rational" for the user to focus on what are effectively biased point (conditional mean) forecasts.

The trend towards forecasters publishing density forecasts is also explained by the obvious advantages they bring when communicating with the public and reminding them that the forecasters themselves expect the point forecasts to be "wrong." Indeed, interest may lie in the dispersion or tails of the density itself; e.g., inflation targets often focus the attention of monetary authorities to the probability of future inflation falling within some predefined target range, while users of growth forecasts may be concerned about the probability of recession. These probability event forecasts can readily be extracted from the density forecast. In addition, ranking forecasting models according to their point forecasting performance alone can be misleading. For example, Clements *et al.* (2003) find that the failure to find empirical support out-of-sample for nonlinear business cycle forecasts may be explained by the traditional focus on point forecasts and their root mean squared error (RMSE). They argue that nonlinear models may do better at forecasting the higher moments that are captured by density forecasts.

5.3 The production of density forecasts

In general, forecasts can be produced in a wide variety of ways, ranging from complete model-based approaches to pure judgmental approaches, sometimes referred to as Delphic forecasts; indeed, almost any combination of model and judgment is possible. In the conventional point forecasting world, it is probably fair to say that almost all forecasts which are made by policy or commercial institutes involve a considerable degree of judgment, although there is, of course, a considerable academic literature on pure model-based forecasts. When we consider density forecasting, a similar range of formal and informal techniques are used, although it is probably fair to say that, given the greater complexity of a density forecast, there should be more reliance on formal model-based information.

There is not a widespread, long history of regular published density forecasts in macroeconomics. One of the longest continuously published series is the Survey of Professional Forecasters (SPF), which is now conducted by the Federal Reserve Bank of Philadelphia and was originally started in 1968 by the American Statistical Association and the National Bureau of Economic Research.

Nevertheless, there is a tradition, which has been maintained to the present day, of publishing (unbalanced) panel data sets of competing point forecasts. For example, in the UK each month since January 1987 Her Majesty's Treasury (HMT) has collected together, in its publication *Forecasts for the UK Economy: A Comparison of Independent Forecasts*, the point forecasts of (as of December 2007) 43 independent City and non-City forecasters. Disagreement among forecasters (as measured by the variance of competing point forecasts at a given point in time) has then

been used as a proxy for true uncertainty. As the SPF also offers a direct measure of uncertainty, since forecasters are asked to report not just their point but density forecasts, it has provided the opportunity, not possible with the HMT dataset, to test the reliability of disagreement as a measure of uncertainty (see Zarnowitz and Lambros, 1987; Bomberger, 1996; Giordani and Söderlind, 2003. Boero, Smith and Wallis, 2008, introduce a new source of survey data for the UK, the Bank of England's Survey of External Forecasters, which also facilitates a comparison of disagreement and uncertainty).

Macroeconomic forecasters have also studied the density of their forecasts over a long period, although they have not typically published, on a regular and ongoing basis, density forecasts as such. The reason for this is, partly, that for a long time it was felt that density forecasts were too sophisticated for the public to understand and partly that, as the models being used made the assumption that the parameters and the error terms had constant covariance structures, the overall density function would not vary from one period to another except with respect to its conditional mean. There was therefore relatively little interest in publishing the same error bands over and over again. However, it is certainly true that modelers and forecasters in the 1970s and 1980s were calculating the uncertainty surrounding their forecasts and, occasionally at least, publishing it. For example, the London Business School, one of the UK's leading forecasters at the time, began regularly publishing the average absolute errors for its forecasts in October 1983. Some early work in this area includes Schink (1971), Bianchi and Calzolari (1980) and Fair (1980). Fair (1984) surveyed a range of stochastic simulation techniques which were being used to calculate the density functions for large nonlinear forecasting models. Hall (1986), and later Blake (1996), reported studies of the density of the NIESR's forecasts, again using extensive stochastic simulations.

These later model-based studies contrast strongly with the SPF, which was purely judgmentally based. This introduces an important theme into this section, which is the issue of combining judgment with formal model-based analysis. Another and related theme is the production of density forecasts where the density itself changes over time. It is only when the whole density changes in a significant way through time that it is worth going to the lengths of publishing a regular full density forecast.

5.3.1 Sources of uncertainty

A forecast is usually subject to a range of types of uncertainty, which we can begin to categorize by considering the following simple decomposition.[2] Let Y be the actual outcome of an event and let $\widehat{Y}$ be the forecast of that event. Then we may decompose the forecast error into a number of components:

$$Y - \widehat{Y} = (Y - Y^1) + (Y^1 - Y^2) + (Y^2 - Y^3) + (Y^3 - Y^4) + (Y^4 - \widehat{Y}), \qquad (5.2)$$

where $(Y - Y^1)$ is the contribution to the total error coming from the model's error term, $(Y^1 - Y^2)$ is the contribution coming from the uncertain parameters, $(Y^2 - Y^3)$ is the contribution coming from misspecified functional form, $(Y^3 - Y^4)$

is the contribution coming from incorrect exogenous assumptions, and $(Y^4 - \widehat{Y})$ is the contribution to the complete forecast error coming from the judgment imposed on the forecast from outside the model. This is a useful way of categorizing the total error composition; however, numerically the order in which this decomposition is carried out can affect the numerical evaluation of these components (see Hall and Henry, 1988). It is also worth noting that the variances which lie behind these components and which make up the complete density of the forecast may be either time varying or constant over time, and there will generally be non-zero covariances between these components.

Part of the usefulness of this decomposition is to emphasize the range of sources of uncertainty. Virtually no formal model-based analysis can deal with all of these and so we may justify the use of judgment, which will be discussed below, at least partly on the grounds of this failure on the part of the formal analysis.

5.3.2 Model-based densities

If we now turn to density forecasts produced by a range of models, a natural starting place is a conventional VAR, as this may be thought to capture the basic properties of most standard forecasting models, including large macroeconomic forecasting models. Indeed, the linearized solution of DSGE models, the workhorse of modern macroeconomics (see Woodford, 2003) and from which density forecasts may readily be constructed using simulation methods, can, under certain conditions, be approximated by a (restricted) finite-order VAR (e.g., see Pesaran and Smith, 2006; Ravenna, 2007).

Thus, consider a VAR of the form:

$$Y_t = B(L)Y_{t-1} + \varepsilon_t, \tag{5.3}$$

$(t = 1, \ldots, T)$, where Y_t is a vector of N variables, $B(L)$ is a suitably dimensioned matrix lag polynomial of estimated parameters with fixed covariance matrix and ε_t is an $N \times 1$ vector of residuals with constant covariance matrix. Given the constant covariance assumption for both the parameters and residuals, the density of a forecast of Y_{t+h} $(h = 1, \ldots, H)$ will, in general, vary only with the initial values Y_{t-1}. If the errors in the VAR process are normally distributed then the density function of the VAR forecast h steps ahead is also normally distributed with a covariance structure which can be approximated analytically. Lutkepohl (1991, p. 87) provides an approximate analytical expression for the conditional variance equal to the approximate mean squared error of the forecast with parameter uncertainty. Allowance can also be made for the uncertain parameters of the VAR or non-normality by using either Monte Carlo methods or bootstrap techniques (see Garratt *et al.*, 2006, Ch. 7). For a Bayesian approach, see Zellner (1971, pp. 233–6). In most practical settings, the value of Y_{t-1} will not vary sufficiently to produce large variations in the shape of the density of Y_{t+h}, and so for most practical purposes we can assume that the density is constant across time except for the mean of the distribution. Hence there is little interest in regularly publishing full details of the density forecast from this type of model, as the only element of the density which would change substantially through time is the mean.

Given this obvious limitation of the standard model, when a researcher is interested in producing a regular model-based density forecast there is an obvious need to base it on a model which has a richer structure that allows some interesting time variation in the shape of the density. The earliest and most obvious model to be developed which allowed for this possibility is the ARCH process of Engle (1982), and the associated family of GARCH models which has grown from it. A basic GARCH(1,1) model has the following general form:

$$Y_t = B(L)Y_{t-1} + \varepsilon_t \tag{5.4}$$

$$\varepsilon_t = \omega_t h_t;\ \omega_t \sim N(0,1) \tag{5.5}$$

$$h_t^2 = \alpha_0 + \alpha_1 h_{t-1}^2 + \alpha^2 \varepsilon_{t-1}^2. \tag{5.6}$$

Given the time variation in the variance of the error term, the complete density forecast for Y_{t+h} will also exhibit time variation. A wide range of variants of this basic model have grown up (for an extensive survey, see Bollerslev, Engle and Nelson, 1994), which allow not only for time variation in the variance but also for asymmetry and non-normality. The GARCH family of models has had an enormous impact on econometric modeling and forecasting, especially in the area of finance, but for the purposes being considered here it does have a number of limitations. The first and most obvious is that there are practical difficulties in modeling large systems of equations with GARCH-like structures. While there are a few extensions of the GARCH approach to systems (e.g., Engle and Kroner, 1995), these extensions are not very practical for large systems (beyond five or six variables). The only approaches within the GARCH framework which may be extended to substantial systems are the Orthogonal GARCH model and the Dynamic Conditional Correlation model of Engle (2002), and even these are not easily applied in the context of forecasting a large system of equations. The GARCH structure also imposes a parametric form on the way the density of the forecast variable evolves which may not always be reasonable.

As a result of these limitations, a number of studies have emerged recently which bring together two strands of the literature which both allow fairly general time variation in forecasting models. The first of these strands introduces VAR models which allow time variation in the coefficients; this literature includes Canova (1993), Sims (1993), Stock and Watson (1996) and Cogley and Sargent (2001). The second strand allows for stochastic volatility in the error process of multivariate systems; this includes work by Harvey, Ruiz and Shephard (1994), Jacquier, Polson and Rossi (1995), Kim, Shephard and Chib (1998) and Chib, Nardari and Shephard (2006). Allowing both time variation in the parameters and an error term with stochastic volatility potentially allows considerable variation in the density forecast. Macroeconomists have found this helpful when seeking to explain the "Great Moderation," namely the apparent decline in the volatility of both inflation and output growth in the US since the mid 1980s (see Blanchard and Simon, 2001; Stock and Watson, 2002).

A good example of this approach to generating density forecasts from a complex model is Cogley, Morosov and Sargent (2005), who develop a forecasting Bayesian

VAR (BVAR) model, which incorporates both drifting coefficients and stochastic volatility in the errors. Earlier work by Sims and Zha (1998) considered the use of Bayesian methods to compute fan charts from VAR models. Geweke and Whiteman (2006) review Bayesian methods for the construction of density forecasts, or *posterior* predictive densities. Adolfson, Linde and Villani (2007), in a forecasting application to the Euro-area, use Bayesian methods to produce density forecasts from both DSGE and VAR models.

Cogley, Morosov and Sargent (2005) construct a second-order VAR for RPIX inflation, the output gap and the nominal three-month treasury bill rate, denoted by the vector Y_t:

$$Y_t = X_t'\theta_t + \varepsilon_t, \tag{5.7}$$

where the vector X_t includes lags of Y_t and a constant, and $\varepsilon_t = R_t^{0.5}\xi_t$ is a vector of measurement innovations, where $\xi_t \sim N(0,1)$ and R_t is a stochastic volatility matrix, discussed below.

This model differs from a standard VAR in two important ways. The error process has a stochastic volatility structure, to be described below, and the parameters of the VAR are time-varying and follow a random walk, which is represented by the following joint prior:

$$f(\theta^T, Q) = f(\theta^T \mid Q)f(Q) = f(Q)\prod_{s=0}^{T-1} f(\theta_{s+1} \mid \theta_s, Q), \tag{5.8}$$

where $\theta^T = [\theta_1', \ldots, \theta_T']'$ represents the history of the drifting parameters, $\theta^{T+1,T+F} = [\theta_{T+1}', \ldots, \theta_{T+F}']'$ their potential future paths, and:

$$f(\theta_{t+1} \mid \theta_t, Q) \sim N(\theta_t, Q). \tag{5.9}$$

Thus the parameters are effectively random walks without drift and with a constant covariance structure.

In addition to this, a prior belief is imposed on the VAR that the roots of the lag polynomial must lie inside the unit circle, to ensure that the VAR is stable. This is done by creating a reflecting barrier using an indicator function:

$$I(\theta^T) = \prod_{s=1}^{T} I(\theta_s), \tag{5.10}$$

where the function $I(\theta_s) = 0$ when the roots of the VAR are stable and $I(\theta_s) = 1$ when they are unstable. This reflecting barrier then modifies the random walk prior so that we then have:

$$p(\theta^T, Q) \propto I(\theta^T)f(\theta^T, Q). \tag{5.11}$$

Hence the conditional prior is:

$$p(\theta^T \mid Q) = \frac{I(\theta^T)f(\theta^T \mid Q)}{\int I(\theta^T)f(\theta^T \mid Q)d\theta^T}. \tag{5.12}$$

Finally the reflecting barrier alters the transition density to give:

$$p(\theta_{t+1} \mid \theta_t, Q) \propto I(\theta_{t+1}) f(\theta_{t+1} \mid \theta_t, Q) \int I(\theta^{t+2,T}) f(\theta^{t+2,T} \mid \theta_{t+1}, Q) d\theta^{t+2,T}. \tag{5.13}$$

So far this defines a VAR with parameters which follow a random walk with the additional constraint that the parameters are not allowed to wander into a region with unstable behavior. In addition to this, Cogley, Morozov and Sargent (2005) further extend the model to include a drifting conditional variance. Following the stochastic volatility literature they define:

$$R_t = B^{-1} H_t B^{-1'}, \tag{5.14}$$

where B is lower triangular with unity along the main diagonal and H is assumed diagonal with univariate stochastic volatilities along the main diagonal which evolve as:

$$\ln h_{it} = \ln h_{it-1} + \sigma_i \eta_{it}, \tag{5.15}$$

where the η_{it} are mutually independent volatility innovations and σ_i is a free parameter.

This model then generates a very rich density function as it involves both changing parameters in the VAR and an error term which follows a time-varying stochastic distribution. In terms of a pure model-based density forecast, this type of Bayesian framework is probably as general as is currently possible. Cogley, Morosov and Sargent (2005) detail how to construct the fan chart by simulating the BVAR posterior predictive density, $p(Y^{T+1,T+F} \mid Y^T)$.

5.3.3 Subjective density forecasts

Most of the density forecasts which are produced regularly by national or international institutions are, however, constructed in a much less formal way. The SPF, mentioned in the introduction to this section, is largely judgmental. Each forecaster arrives at his or her own forecast in completely different ways; some may use models but most certainly do not. The key questions of interest here focus on each individual's view of the likely uncertainty surrounding their forecast for inflation and output growth. These individual forecasts are then presented as a set of histograms which are then averaged, using equal weights (see section 5.5), to give a mean density forecast.

The Bank of England began publishing density forecasts at the beginning of 1993. At the beginning of 1996 the Bank changed its methodology somewhat. Before the last quarter of 1995 the Bank's density forecast was implicitly normal. Since the beginning of 1996 the Bank of England has stated clearly that its density forecasts are non-normal, following a two-piece normal distribution; i.e., each side of the mode has a normal shape but they do not have the same standard deviation – hence each side does not represent half of the distribution. This distribution is arrived at as the subjective assessment by the Bank's Monetary Policy Committee (MPC), based partly on past forecast errors, partly on a range of formal models, and partly on subjective judgments regarding the asymmetry of risk in the forecast.

The NIESR began publishing regular density forecasts in 1996, although it had been publishing a mean absolute error for its forecasts of inflation since the second quarter of 1992. The NIESR, in contrast to the Bank, imposes a normal distribution around their point forecast, with the variance determined on the basis of past forecast errors. The window used to calculate this average error turns out to be quite important – there is uncertainty about the variance used to quantify the degree of uncertainty inherent in the fan chart (see Mitchell, 2005). Until 2002 the NIESR used a sample which started in 1982 to estimate the variance. From 2002 onwards it used a sample which began in 1993. Given the general fall in volatility of most economic series in the UK, this change brought about a considerable fall in the estimated size of the variance of its density forecasts, and hence we can see that the choice of this window can be very important in achieving a good forecast.

Mitchell (2005) has found that a break in the unconditional variance of the NIESR's forecast errors around 1993–94 could have been detected via recursive analysis of these forecast errors towards the end of 1996, rather than in 2002. It is therefore important to monitor historical forecast errors regularly, using statistical tests for structural breaks at an unknown point, to help select a period of history which is informative about the future. Stochastic simulation has been discussed as an alternative to historical errors for measuring the uncertainty associated with the forecast. This might be expected to deliver a better measure of uncertainty if a new policy regime (such as a new target for inflation) is adopted.

All of these forecasts can be viewed as being, basically, subjective in nature as they are not the direct result of a formal model. Even in this case the techniques discussed below to evaluate a forecast formally may still be applied, and we argue that an important stage in constructing even a subjective density forecast is an evaluation of the track record of those forecasts.

5.3.4 Combining model-based and subjective density forecasts

In the point forecasting area there has long been a common practice of combining model-based information and subjective judgment. Very few real forecasts are purely the result of a model and, similarly, most forecasters would use a formal model in one form or another to structure the forecasting procedure. It would seem reasonable, therefore, that when we come to consider density forecasts we would similarly want to consider a formal mixture of model and subjective information. One approach would be simply to form two quite separate forecasts, one subjective and one model-based, and to combine them. We discuss density forecast combinations in detail in section 5.5 below, so we will not discuss this possibility here. An alternative, formal means of combining model-based density forecasts with judgment is to adopt a Bayesian approach, with the non-data information summarized by the "prior" (see Sims and Zha, 1998). Waggoner and Zha (1999) consider how to use Bayesian methods to compute density forecasts for conditional forecasts in VAR models, which allow one to impose conditions on the likely future values of endogenous variables. Del Negro and Schorfheide (2004) use a DSGE model as a prior for a VAR and find this improves point forecasting performance as measured by RMSE. Clark and McCracken (2008) essentially impose a hard informative prior

on the steady-state of the VAR model by detrending, in particular inflation, prior to forecasting. Villani (2005) proposes methods to impose an informative prior on the steady-state, in particular the unconditional means of the model, and hence on the long-run forecasts. The priors push the long-run forecasts towards the chosen steady-state, say trend or target inflation.

We will, however, discuss a recently proposed technique which allows a model's density forecast to be altered at a second step in the light of subjective or "off-model" information. This proposal stems from recent work by Robertson, Tallman and Whiteman (2005), which is based on earlier work by Stutzer (1996) and Kitamura and Stutzer (1997).

We are interested in a density forecast for an M-dimensional vector of variables Y. In general, if we are attempting to derive a model-based density forecast based on a possibly nonlinear model it will not be possible to derive this density analytically. However, given the long history of stochastic simulation analysis referenced above, it is usually possible to approximate this density. Thus, assume we have derived a sample of N draws, denoted $\{Y_i\}$, $(i = 1, \ldots, N)$, and that we also have a set of weights $\{\pi_i\}$, $(i = 1, \ldots, N)$. It is then possible to approximate the model's density function by simply weighting together a transformation of the sample of draws. If we have a random sample from the predictive density, the weights are:

$$\pi_i = 1/N, \forall i. \tag{5.16}$$

The mean of the density forecast is:

$$\overline{Y} = \sum_{i=1}^{N} \pi_i Y_i, \tag{5.17}$$

and so on for any other moments.

This, therefore, provides a means to approximate the density forecast of the model. Now assume that, in addition to the model, we have some extra information which we wish to incorporate into the density forecast. We may think of this as a set of moment conditions which we wish the final density forecast to obey. In a very simple example we might wish to locate the mean of a variable at a particular point or we might wish to impose a certain degree of skewness. Suppose we wished the mean of the vector of variables to take some particular set of values, $\overline{g}$. In general, of course, this will not coincide with $\overline{Y}$ as:

$$\sum_{i=1}^{N} \pi_i Y_i \neq \overline{g}. \tag{5.18}$$

The idea then is to create a new set of weights π_i^* such that this restriction holds exactly. Of course, for N sufficiently large, there will generally be an infinite number of sets of weights which would satisfy this restriction, so the idea is to choose a set of weights which satisfy the restriction while, at the same time, remaining as close as possible to the original weights. This, of course, requires a definition of closeness and Robertson *et al.* (2005) establish that, under a set of regularity conditions, the appropriate measure of closeness is the Kullback–Leibler information criterion

(KLIC), which may be stated as:

$$K(\pi^* : \pi) = \sum_{i=1}^{N} \pi_i^* \log\left(\frac{\pi_i^*}{\pi_i}\right). \tag{5.19}$$

Obviously, if $\pi_i^* = \pi_i$ then the KLIC will be zero, so this is in effect measuring the distance between the two distributions. If π_i is uniform then this is sometimes termed the entropy; if it is non-uniform it is termed the relative entropy.

The idea is simply to choose a set of weights π^* which minimize $K(\pi^* : \pi)$ subject to the following set of restrictions:

$$\pi_i^* \geq 0; \ \sum_{i=1}^{N} \pi_i^* = 1; \ \sum_{i=1}^{N} \pi_i^* g(Y_i) = \overline{g}. \tag{5.20}$$

Once we have solved for the new weights we may then easily calculate the new density forecast simply by weighting together all the original draws with the new weights π^*.

Robertson, Tallman and Whiteman (2005) illustrate this technique by considering a small VAR model for the Federal Funds rate, inflation and the output gap and then imposing a set of prior restrictions on the forecast via a set of moment conditions. These include the prior view that inflation should be at its target rate of 2.5% three years in the future, various assumptions regarding the operation of a Taylor rule, and that the output gap eventually closes. They argue that there is some evidence that the restricted forecasts are an improvement over the standard VAR.

Cogley, Morosov and Sargent (2005) combine this technique with their time-varying parameter BVAR with stochastic volatility, outlined above, to generate forecasts for UK inflation which they contrast with the Bank of England's density forecast. They find that to impose the Bank of England's density forecast on the VAR forecasts requires a considerable change to the weighting vector, sometimes referred to as "twisting" the weights. They warn that the relative entropy (KLIC distance) points to "a severe twisting," which may be interpreted as saying that the Bank's density is a long way from the BVAR model and, on this basis, they recommend "a careful review of the evidence being used to twist the forecast."

5.4 The evaluation of density forecasts

In practice, forecasters make successive forecasts of the same event, so-called "fixed-event" forecasts, as well as series of forecasts of fixed length h, so-called "rolling" forecasts. There exist well established statistical techniques for the *ex post* evaluation of both fixed event and rolling point forecasts. For rolling point forecasts these are often based around the RMSE of the forecast relative to the subsequent outturn. Indeed, publication of RMSE statistics is itself a welcome indication that point forecasts are uncertain; in the absence of knowledge of the true loss function, squared-error loss has become the most commonly used function (see Lee, 2007, for a review of loss functions). The unbiasedness and efficiency of point forecasts are also tested using Mincer and Zarnowitz (1969) tests. For fixed-event point

forecasts, again under quadratic loss (see Clements, 1997, for an extension), the most common evaluation method (see Nordhaus, 1987) is to test whether revisions to successive point forecasts of the same event are independent. Clements and Hendry (1998, Ch. 3) provide a textbook discussion of these tests. Patton and Timmermann (2007) establish tests of point forecast optimality when the loss function is unknown.

In turn, the *ex post* evaluation of rolling density forecasts has begun to attract considerable attention, and there now exist established evaluation methods based on both the probability integral transforms and the logarithmic score, as we review below, although there remains some uncertainty about their implementation in practice and their relative merits (see Gneiting, Balabdaoui and Raftery, 2007).

The genesis of these evaluation tests, as indicated in Diebold *et al*. (1998), was the literature on the evaluation of interval forecasts and probability forecasts. Since these tests can also be applied to density forecasts, as a density forecast can always be reduced to an interval forecast, they also constitute a means of evaluating density forecasts. We therefore start our review of extant evaluation methods, in section 5.4.1, with interval forecasts. Interval evaluation tests also serve as the basis for tests of probability event forecasts. But since there are an infinity of possible interval forecasts implied by a given density forecast, rendering it impracticable to test all but plausible (or at least a finite set of) intervals, we then move our attention to "whole" density evaluation methods. In the ensuing discussion we distinguish between distributional (unconditional) and dependence (conditional) aspects of the evaluation tests (see Giacomini and White, 2004).

In contrast, little attention has been paid, at least explicitly, to the fixed-event aspect of density forecasts. This is despite the availability of the aforementioned tests for the efficiency of fixed-event point forecasts – the testable proposition (for weak efficiency) is that, under quadratic loss, forecast revisions should be uncorrelated with past forecast revisions.

Extending efficiency tests to the density case, say using the KLIC (discussed again in more detail below) to measure revisions to successive densities (as in Lahiri and Liu, 2006), is the subject of ongoing research and, to date, there are no established tests to review. But it does appear that KLIC revisions to successive densities do not convey any information on forecast efficiency since conditional variance forecasts, unlike conditional mean forecasts, are predictable even when the forecaster is assumed efficient (see Mitchell, 2007c). Consistent with the "fan" shape of density forecasts published by the Bank of England and others, conditional variance forecasts decline as we get closer to the event of interest. This "trend" precludes testing the efficiency of density forecasts, as with point forecasts, simply by testing the independence of revisions. But Mitchell (2007c) does note that fixed-event density forecasts can always be evaluated similarly to fixed-event point forecasts by reducing them to an event forecast. As we briefly explain in section 5.4.1, fixed-event probability event forecasts can be evaluated just like fixed-event point forecasts. Variance rationality has been examined by Batchelor and Zarkesh (2000).

5.4.1 Interval forecasts

A "good" interval forecast should, at a minimum, have correct coverage *ex post*; i.e., the outturn should fall in the interval the predicted proportion of times: for example, on 95% of occasions for a 95% confidence interval. But, as argued by Christoffersen (1998), in a time series context a "good" interval forecast should not just have correct *unconditional* coverage, but correct *conditional* coverage, so that in volatile periods the interval is wider than in less volatile periods. This means that occurrences inside the interval should not come in clusters over time. This is analogous to expecting independence of orders greater than or equal to h when evaluating a sequence of rolling optimal h-step-ahead point forecasts or optimal fixed-event point forecasts; e.g., see Clements and Hendry (1998, pp. 56–62).

More formally, define I_t as an indicator variable that takes the value 1 if the outcome falls within the interval forecast at time t, and 0 otherwise. Consider an interval forecast for coverage probability p, $0 \leq p \leq 1$. Then Christoffersen (1998) defines a set of *ex ante* forecasts as having correct *conditional* coverage, or as being "efficient" with respect to the information set (say, Ω_{t-1}), if $\mathsf{E}(I_t \mid \Omega_{t-1}) = p$. If $\Omega_{t-1} = \{I_{t-1}, I_{t-2}, \ldots\}$ then this implies $\{I_t\}$ is independent and identically distributed (i.i.d.) Bernoulli with parameter p.

Christoffersen (1998) then suggests a likelihood ratio (LR) test for correct *conditional* coverage. When $\Omega_{t-1} = \varnothing$, the empty set, the test reduces to an *unconditional* test of the null hypothesis that $\mathsf{E}(I_t) = p$. Wallis (2003) describes an asymptotically equivalent Pearson chi-squared test, with the advantage that, unlike the LR tests, its exact distribution can be derived. Wallis (2003) also extends the tests to density forecasts. The extension is based on reducing the density forecast to a k-interval forecast; Boero, Smith and Wallis (2004) explore, as a function of the size of k, the properties of the chi-squared test in small to moderate sample sizes typical to macroeconomics.

Christoffersen (1998) also suggested, and Clements and Taylor (2003) refined, regression-based tests of interval forecasts. They involve estimating:

$$I_t = \alpha + \beta \Omega_{t-1} + \varepsilon_t, \tag{5.21}$$

where the set of interval forecasts are conditionally efficient when $\alpha = p$ and $\beta = 0$, implying that, as before, $\mathsf{E}(I_t \mid \Omega_{t-1}) = p$. Similarly to Mincer–Zarnowitz regressions, these regression-based tests distinguish between conditional and unconditional objectives. The forecasts have correct unconditional coverage when $\alpha = p$, and are conditionally efficient when the forecast "errors" are uncorrelated with information available at the time the forecast was made, i.e., $\alpha = p$ and $\beta = 0$.

Equation (5.21) also serves as the basis for tests of probability event forecasts; see Clements (2004). Consider $p_{t|t-1}$ to be the probability forecast made one period ahead of an event (such as a breach of the inflation target, a) happening at time t; $p_{t|t-1} = P(y_t \geq a \mid \Omega_{t-1})$. Conditional efficiency, $\mathsf{E}\left[I_t \mid \Omega_{t-1}\right] = p_{t|t-1}$, then

implies $\lambda = 1$, $\alpha = 0$ and $\beta = 0$ in the following variant of (5.21):

$$I_t = \lambda p_{t|t-1} + \alpha + \beta \Omega_{t-1} + \varepsilon_t, \tag{5.22}$$

where the indicator variable I_t is redefined with respect to the event forecasts.

It is also worth noting, given our reference above to the evaluation of fixed-event probability event forecasts, that when probability event forecasts are conditionally efficient, which they are when the density forecast from which they are extracted is "correct" (as defined in section 5.4.2.1), we know from the law of iterated expectations that:

$$\mathsf{E}\left\{\mathsf{E}(I_t \mid \Omega_{t-h}) \mid \Omega_{t-h-1}\right\} = \mathsf{E}(I_t \mid \Omega_{t-h-1}). \tag{5.23}$$

This implies:

$$\mathsf{E}(p_{t|t-h} - p_{t|t-h-1} \mid \Omega_{t-h-1}) = 0, \tag{5.24}$$

which says that the revision to the probability event forecast is orthogonal to information available at $(t - h - 1)$, including lagged revisions to the probability event forecasts. Thus a testable proposition for (weakly) efficient fixed-event density forecasts is that revisions to probability forecasts, extracted from the density forecast, are independent. When there is a clear objective, such as a central bank keeping inflation at less than 2%, it is obvious what a to consider. However, for the density forecast to be well calibrated overall, (5.24) needs to hold for all possible a's. Since an infinity of event forecasts can be extracted from the density forecast, in an application evaluating the fixed-event aspect of the SPF density forecasts, Mitchell (2007c) evaluates both over a large number of arbitrary events and over events of specific interest, such as inflation falling in its "comfort zone" of 1–2%.

5.4.2 Rolling density forecasts

When evaluating the performance of density forecasts as a "whole," economists have tended to rely on using goodness-of-fit tests to establish whether the probability integral transforms of the forecast density with respect to the realizations of the variable are uniform or, via a transformation, normal. In contrast, others have employed scoring rules. Both evaluation criteria have proved popular, since they avoid having to estimate the true but unknown conditional density $f(y_t \mid \Psi_{t-h})$ (where the density of the random variable y_t is defined with respect to the total information set Ψ_{t-h} (where the forecasters' information set $\Omega_{t-h} \subset \Psi_{t-h}$), and only require a time series of realizations $\{y_t\}_{t=1}^{T}$.[3] We review both evaluation criteria below.

Derivatives of both evaluation criteria have also been developed in the papers referred to below when interest lies not in the "whole" density but in specific areas, such as the probability of tail events or economic events of interest, such as a (one period) recession.

5.4.2.1 Goodness-of-fit tests: in theory

Diebold, Gunther and Tay (1998) popularized the idea in economics of statistically evaluating a sample of density forecasts based on the probability integral transforms (pit's) of the realization of the variable with respect to the forecast densities. An alternative approach is based on the integrated squared difference between the density forecast and a nonparametric estimate of $f(y_t \mid \Psi_{t-h})$; see Li and Tkacz (2006). We focus on the former approach since it does not require the strict stationarity of y_t.

Diebold, Gunther and Tay (1998) proved that a sequence of estimated h-step-ahead density forecasts, $\{g(y_t \mid \Omega_{t-h})\}_{t=1}^{T}$, for the realizations of the process $\{y_t\}_{t=1}^{T}$, coincides with the (unknown) true densities $\{f(y_t \mid \Psi_{t-h})\}_{t=1}^{T}$ when the sequence of pit's, $z_{t|t-h}$, are uniform variates, where:[4]

$$z_{t|t-h} = \int_{-\infty}^{y_t} g(u \mid \Omega_{t-h})du = G(y_t \mid \Omega_{t-h}); \ (t = 1, \ldots, T). \tag{5.25}$$

Since the correct density forecast will be preferred by all users, irrespective of their loss function, testing the pit's is attractive as it offers a means of evaluating forecasts without the need to specify a loss function. This is convenient given that it is hard to define an appropriate general (economic) loss function, although it is sometimes possible: Clements (2004) provides an evaluation of the Bank of England's fan charts for inflation based on economic as well as statistical loss.

But just as a "good" interval forecast should be correctly calibrated both unconditionally and conditionally, so should a "good" density forecast. This translates into the requirement that, when $h = 1$, $z_{t|t-h}$ is not just uniform but also independently distributed. In other words, one-step-ahead density forecasts are optimal and capture all aspects of the distribution of y_t only when the $z_{t|t-1}$ are independently and uniformly distributed. When $h > 1$ we should expect serial dependence in $z_{t|t-h}$ even for correctly specified density forecasts. Again this is analogous to expecting dependence (an $MA(h-1)$ process) when evaluating a sequence of optimal rolling h-step-ahead point forecasts. There is not, however, a one-for-one relationship between the point forecast errors and $z_{t|t-h}$.

It is important, as stressed by Mitchell and Wallis (2008), to test density forecasts not just unconditionally, via a distributional test, but conditionally via a test for independence. Otherwise one does find, as in Gneiting, Balabdaoui and Raftery (2007) and motivating their advocation of scoring rules, that uniformity of the pit's is a necessary but not sufficient condition for optimal density forecasts.

5.4.2.2 Goodness-of-fit tests: in practice

Following the lead of Diebold, Gunther and Tay (1998), evaluation tests are commonly based on the difference between the empirical distribution of $z_{t|t-h}$ and the cumulative distribution function of a uniform random variable on [0,1], i.e., the 45° line. In many empirical studies, this has simply involved the application of a Kolmogorov–Smirnov or Anderson–Darling test for uniformity. For one-step-ahead forecasts this is often supplemented with a separate test for the independence of

$z_{t|t-h}$. For empirical examples and references, see Clements and Smith (2000), Clements (2004) and Hall and Mitchell (2004).

By taking the inverse normal cumulative density function (c.d.f.) transformation of $z_{t|t-h}$ to give, say, $z^*_{t|t-h}$, the test for uniformity can be considered to be equivalent to one for normality of $z^*_{t|t-h}$; see Berkowitz (2001). For Gaussian forecast densities with mean given by the point forecast, $z^*_{t|t-h}$ is simply the standardized forecast error (outturn minus point forecast divided by the standard error of the Gaussian density forecast). Testing normality is convenient as normality tests are widely seen to be more powerful than uniformity tests. However, testing is complicated by the fact that the impact of dependence on the tests for uniformity/normality is unknown, as is the impact of non-uniformity/non-normality on tests for dependence.

Consequently, various single and joint tests of uniformity/normality and independence have been employed in empirical studies.[5] These include Kolmogorov–Smirnov, Anderson–Darling and Doornik and Hansen (1994) tests for uniformity/normality, Ljung–Box tests and Lagrange multiplier (LM) tests for independence, and Hong (2002), Thompson (2002) and Berkowitz (2001) LR tests for both uniformity/normality and independence. Using Monte Carlo techniques, Noceti, Smith and Hodges (2003) found the Anderson–Darling test to have more power to detect misspecification than the Kolmogorov–Smirnov test (and related distributional tests). However, they maintained an assumption of a random sample and did not consider the effect dependence may have on the performance of the tests. Many of the popular distributional tests, such as the Kolmogorov–Smirnov and Anderson–Darling tests, are not robust to dependence, their properties having been developed under independence.

Parameter uncertainty and dependence Testing uniformity is complicated by both parameter uncertainty and possible dependence in the $z_{t|t-h}$. For a review and derivation of out-of-sample versions of the tests we consider below, see Corradi and Swanson (2006c).

Parameter uncertainty is a concern when the density forecast is model-based and depends on estimated parameters. This is because when parameters are estimated the Kolmogorov test is no longer asymptotically distribution free, meaning that critical values cannot be tabulated as they are dependent on the null hypothesis and the parameter values. Bai (2003) therefore developed a modified Kolmogorov-type test, based on a martingale transformation, which is asymptotically distribution free. While this test has power against violations of uniformity, it does not necessarily have power against violations of independence in the $z_{t|t-h}$.

This means that these Kolmogorov tests require the density forecast not just to capture the distribution of y_t correctly but to be correctly specified dynamically. Following Corradi and Swanson (2006c), let us illustrate what this means via a simple example. Let the true (conditional) density be $f(y_t \mid \Psi_{t-1}) = N(\alpha_1 y_{t-1} + \alpha_2 y_{t-2}, \sigma_2)$, but the density forecast, while normal, be misspecified in terms of its dynamics: $g(y_t \mid \Omega_{t-1}) = N(\alpha_1^* y_{t-1}, \sigma_1)$, where $\alpha_1^* \neq \alpha_1$. In this case $z_{t|t-1}$ is no longer independent but remains uniform. To test the null hypothesis that the

density forecasts are optimal with dynamic misspecification under both the null and alternative hypotheses therefore requires a test for uniformity that is robust to dependence. Use of the traditional Kolomogorov-type tests, including the Bai test, will lead to invalid inference as the critical values are invalid.

Accordingly, Hong (2002) and Corradi and Swanson (2005a) have developed uniformity tests robust to dependence. The Hong test is based on the generalized cross-spectrum; see also Hong, Li and Zhao (2004). Corradi and Swanson suggest a Kolmogorov-type test. At the expense of an assumption of strict stationarity for $\{y_t\}$ and having to use the block bootstrap, which they prove can be used to construct valid critical values, the advantage of the Corradi and Swanson test relative to Hong's is that it converges at a parametric rather than nonparametric rate. In addition, it directly accounts for parameter estimation uncertainty; Hong assumes parameter estimation error vanishes asymptotically.

Multi-step-ahead density forecasts A distinct form of dependence to that caused by dynamic misspecification can be induced in the pit's when forecasting more than one step ahead ($h > 1$). Even when the density forecasts are correctly conditionally calibrated we should expect dependence of order $(h-1)$ because consecutive observations are subject to common shocks. This complicates further the task of evaluating multi-step-ahead ($h > 1$) density forecasts since one risks confounding *good* dependence, explained by $h > 1$, with *bad* dependence, due to dynamic misspecification. Distributional tests applied to the pit's, which are designed to be robust to dependence, will ideally distinguish between *good* and *bad* dependence. Otherwise, when $h > 1$, one risks declaring incorrect density forecasts "correct," on the basis that the pit's are uniform, with the dependence in the pit's dismissed on the grounds that it is not a symptom of dynamic misspecification but attributable to $h > 1$.

Distributional tests designed to accommodate dependence of order $(h - 1)$, i.e., *good* dependence, have been considered. Most simply, as suggested by Diebold, Gunther and Tay (1998), the pit's have been partitioned into $(h-1)$ blocks for which we expect uniformity and independence when the density forecasts are conditionally well-calibrated. For further discussion see Clements and Smith (2000). Dowd (2007) compares, using simulation experiments, alternative methods of dealing with the dependence and finds that it is best to carry out tests on a bootstrapped resample of the pit's designed to be independent. This remains an active area for research, since applied studies continue to employ different evaluation methods in similar contexts.

Joint tests Another option to overcome the deleterious effects of dependence is to consider a joint test for uniformity and independence of $z_{t|t-h}$ (see Hong, 2002). Berkowitz (2001) also presents a parametric, LR, test for the null of standard normality against autoregressive alternatives. While obviously not robust under the null hypothesis to dynamic misspecification, these joint tests do, at least in principle, have power against violations of both uniformity/normality and independence.

For $h = 1$ Berkowitz (2001) proposes a three degrees-of-freedom LR test of the joint null hypothesis of a zero mean, unit variance and independent $z^*_{t|t-1}$ against

$z^*_{t|t-1}$ following an AR(1) process: $z^*_{t|t-1} = \mu + \rho z^*_{t-1|t-2} + \varepsilon_t$, where $\varepsilon_t \sim N(0, \sigma^2)$. The test statistic LR_B is computed as:

$$LR_B = -2\left[L(0,1,0) - L(\widehat{\mu}, \widehat{\sigma}^2, \widehat{\rho})\right], \tag{5.26}$$

where $L(\widehat{\mu}, \widehat{\sigma}^2, \widehat{\rho})$ is the value of the exact log-likelihood of a Gaussian AR(1) model (e.g., see Hamilton, 1994, p. 119). Under the null $LR_B \sim \chi^2_3$. The test can be readily generalized to higher-order AR models; squared (and higher power) lagged values of $z^*_{t|t-1}$ can also be included in the model in an attempt to pick up nonlinear dependence. The test abstracts from parameter uncertainty, but is expected to perform well in the small samples typical to macroeconomics; in contrast, the nonparametric goodness-of-fit tests discussed above rely on larger samples.

When $h > 1$, recognizing that this LR test is not designed to deal with dependence, Clements (2004) used a two degrees-of-freedom LR test, which drops the test for autocorrelation, to evaluate the Bank of England's year-ahead (h = five quarters) density forecasts. But this test still assumes independence in the construction of the likelihood function; since the likelihood function is misspecified a robust Wald or LM test might be considered instead (see White, 1982). Alternatively, Dowd (2008) suggests that the dependence be mopped up by first fitting an ARMA process to $z^*_{t|t-h}$.

A criticism of these LR tests is the maintained assumption of normality. They only have power to detect non-normality through the first two moments. Consequently, some authors, such as Clements and Smith (2000) and Hall and Mitchell (2004), have supplemented the LR test with a nonparametric normality test, such as the Doornik–Hansen test. But, as Bao, Lee and Saltoglu (2007) explain, one can still construct a Berkowitz-type LR test without maintaining the normality assumption. They let ε_t follow a more general distribution, specifically a semi-nonparametric density, which nests normality. Alternatively, Chen and Fan (2004) generalize Berkowitz (2001) by proposing the use of copula functions to design tests which have power against a wider range of alternative processes. Berkowitz also proposed a censored version of the LR test which focuses on the tails of the forecast density. Diks, Panchenko and van Dijk (2008) show that the censored LR test can be biased when it is used to *compare* alternative density forecasts, rather than just test a given model for goodness-of-fit. Promising new joint tests, using autocontours, have been developed by Gonzalez-Rivera, Senyuz and Yoldas (2007) which are robust to parameter uncertainty.

The KLIC as the loss function Despite the apparent choice over which distributional test to apply to the pit's, which explains the variety used in extant applied work, these evaluation tests can all be related to the KLIC. In particular, following Bao, Lee and Saltoglu (2007), we consider how one of the most popular tests, namely the Berkowitz (2001) LR test, can be directly related to the KLIC. The KLIC can therefore be interpreted as the loss function for density forecast evaluation (see Lee, 2007). As argued by Mitchell and Hall (2005), it offers a unifying framework

for density forecast evaluation, as well as comparison and combination, to which we turn below.

The KLIC offers a measure of distance, or more accurately "divergence," between the "true" but unknown conditional density $f(y_t \mid \Psi_{t-h})$, defined with respect to the total information set Ψ_{t-h}, and the ith conditional density forecast $g(y_t \mid \Omega_{it-h})$, defined with respect to forecaster i's information set Ω_{it-h}:

$$KLIC^i_{t|t-h} = \mathsf{E}\left[\ln\, f(y_t \mid \Psi_{t-h}) - \ln\, g(y_t \mid \Omega_{it-h})\right] = \int f(y_t \mid \Psi_{t-h}) \ln\left\{\frac{f(y_t \mid \Psi_{t-h})}{g(y_t \mid \Omega_{it-h})}\right\} dy_t. \tag{5.27}$$

$KLIC^i_{t|t-h} = 0$ if and only if $g(y_t \mid \Omega_{it-h}) = f(y_t \mid \Psi_{t-h})$. But, as explained, since $f(y_t \mid \Psi_{t-h})$ is unknown even *ex post*, typically density forecasts are evaluated by employing a goodness-of-fit test on the pit's $z_{it|t-h} = \int_{-\infty}^{y_t} g(u \mid \Omega_{it-h})du$. These amount to a test for whether $KLIC^i_{t|t-h} = 0$.

Estimates of $KLIC^i_{t|t-h}$ can be obtained when we follow Bao, Lee and Saltoglu (2007), invoke Proposition 2 of Berkowitz (2001) and note the following equivalence:

$$d^i_{t|t-h} = \ln\, f(y_t \mid \Psi_{t-h}) - \ln g(y_t \mid \Omega_{it-h}) = \ln q(z^*_{it|t-h}) - \ln \phi(z^*_{it|t-h}) = \ln h(z_{it|t-h}), \tag{5.28}$$

where $z^*_{it|t-h} = \Phi^{-1} z_{it|t-h}$, $q(.)$ is the unknown density of $z^*_{it|t-h}$, which needs to be specified, $\phi(.)$ is the standard normal density and Φ is the c.d.f. of the standard normal. Equation (5.28) offers a direct link between the Berkowitz test and the KLIC. For the nonparametric uniformity tests we see that, when $h(z_{it|t-h}) = 1$, as it does under the null of correct conditional calibration, $d^i_{t|t-h} = 0$.

Under some regularity conditions, $\mathsf{E}\left[KLIC^i_{t|t-h}\right]$ can be consistently estimated by sample ($t = 1, \ldots, T$) information:

$$\overline{KLIC}^i_{t-h} = \frac{1}{T}\sum\nolimits_{t=1}^{T} d^i_{t|t-h}, \tag{5.29}$$

where, following Berkowitz (2001), for $h = 1$, we could assume:

$$q(z^*_{it|t-1}) = \phi\left[\left(z^*_{it|t-1} - \mu - \rho z^*_{it-1|t-2}\right)/\sigma\right]/\sigma. \tag{5.30}$$

Noting that the LR test as traditionally written equals:

$$LR^i_B = 2\sum\nolimits_{t=1}^{T}\left[\ln q(z^*_{it|t-1}) - \ln \phi(z^*_{it|t-1})\right], \tag{5.31}$$

reveals that $\overline{KLIC}^i_{t-1} = LR^i_B/2T$.

More general specifications for $q(.)$, allowing ε_t to follow a more general distribution than the Gaussian, could also be specified. When $h > 1$ we should expect dependence, due to overlapping observations, and we might then

consider the two degrees-of-freedom LR test referred to above, where $q(z^*_{it|t-h}) = \phi\left[\left(z^*_{it|t-h} - \mu\right)/\sigma\right]/\sigma$.

5.4.2.3 *Scoring rules*

In contrast to evaluation based on the pit's there is a tradition, particularly within meteorology, of employing scoring rules (see Gneiting and Raftery, 2007, for a review, and Hall and Mitchell 2007; Amisano and Giacomini, 2007; Adolfson, Linde and Villani, 2007, for applications in economics). Scoring rules are (specific) loss functions that assign a numerical score based on the density forecast and the subsequent realization of the variable. They evaluate relative, but not absolute, density forecast performance. Gneiting, Balabdaoui and Raftery (2007) provide a related discussion of the *sharpness* of density forecasts, which refers to the concentration of the density forecast, and argue that, subject to correct calibration, the sharper the better.

Following the aforementioned applied papers, we restrict attention to the logarithmic scoring rule: $S(g(y_t \mid \Omega_{it-h}), y_t) = \ln g(y_t \mid \Omega_{it-h})$, where the density forecast is evaluated at the realisation of the random variable. The logarithmic scoring rule is intuitively appealing as it gives a high score to a density forecast that provides a high probability to the value y_t that materializes. It also conveniently relates to the KLIC; see (5.27). When the predictive density $g(y_t \mid \Omega_{it-h})$ is normal with mean m_{it} and variance v_{it} (defined below):

$$S(g(y_t \mid \Omega_{it-h}), y_t) = -0.5 \ln 2\pi - 0.5 \ln v_{it} - 0.5 \frac{(y_t - m_{it})^2}{v_{it}}, \tag{5.32}$$

indicating that the logarithmic score depends on the conditional forecasts for both the mean and variance. Competing density forecasts can be ranked according to the size of $S(g(y_t \mid \Omega_{it-h}), y_t)$, with higher values indicating better performance. $S(g(y_t \mid \Omega_{it-h}), y_t)$ cannot be used to test the null hypothesis H_0: $\overline{KLIC}^i_{t-h} = 0$, as this can be achieved only if the practitioner specifies $f(.)$, or $q(.)$ or $h(.)$; see (5.28).

5.4.2.4 *Comparing competing density forecasts*

The KLIC, and also $S(g(y_t \mid \Omega_{it-h}), y_t)$ given its relationship with the KLIC, can be used to compare competing density forecasts; Bao, Lee and Saltoglu (2007) developed a test for equal predictive performance. It formalizes previous attempts that visually compared alternative density forecasts according to their relative distance to, say, the uniform distribution; e.g., see Clements and Smith (2000). Bao, Lee and Saltoglu (2007) test is a direct generalization of tests of equal point forecast accuracy popularized by Diehold and Mariano (1995) (DM) and extended by West (1996) and White (2000). These tests assume some, usually a quadratic, loss function.

A test for equal density forecast accuracy of two competing (non-nested) density forecasts $g(y_t \mid \Omega_{1t-h})$ and $g(y_t \mid \Omega_{2t-h})$, both of which may be misspecified, is

then constructed based on $\left\{d_{t|t-h}\right\}_{t=1}^{T}$, where:

$$d_{t|t-h} = \left[\ln f(y_t \mid \Psi_{t-h}) - \ln g(y_t \mid \Omega_{1t-h})\right] - \left[\ln f(y_t \mid \Psi_{t-h}) - \ln g(y_t \mid \Omega_{2t-h})\right], \tag{5.33}$$

$$= \ln g(y_t \mid \Omega_{2t-h}) - \ln g(y_t \mid \Omega_{1t-h}), \tag{5.34}$$

$$= \left[\ln q(z^*_{1t|t-h}) - \ln \phi(z^*_{1t|t-h})\right] - \left[\ln q(z^*_{2t|t-h}) - \ln \phi(z^*_{2t|t-h})\right]. \tag{5.35}$$

The null hypothesis of equal accuracy is then:

$$H_0 : \mathsf{E}(d_{t|t-h}) = 0 \Rightarrow \overline{KLIC}^1_{t-h} - \overline{KLIC}^2_{t-h} = 0. \tag{5.36}$$

The sample mean $\overline{d}$ is defined as:

$$\overline{d} = \frac{1}{T}\sum_{t=1}^{T}\left[\left[\ln q(z^*_{1t|t-h}) - \ln \phi(z^*_{1t|t-h})\right] - \left[\ln q(z^*_{2t|t-h}) - \ln \phi(z^*_{2t|t-h})\right]\right]. \tag{5.37}$$

A test can be constructed since we know that $\overline{d}$, under appropriate assumptions, has the limiting distribution:

$$\sqrt{T}(\overline{d} - \mathsf{E}(d_{t|t-h})) \xrightarrow{d} \mathsf{N}(0, \widehat{v}), \tag{5.38}$$

where Bao, Lee and Saltoglu (2007), following West (1996), discuss estimators $\widehat{v}$ for the long-run asymptotic variance of $d_{t|t-h}$ allowing for parameter uncertainty, e.g., when the forecasts are model-based and the models are estimated using an expanding, not rolling (fixed length), window (see Giacomini and White, 2006). In the absence of parameter uncertainty, the test (5.38) reduces to a DM-type test: $\overline{d}/\sqrt{\frac{S_d}{T}} \xrightarrow{d} \mathsf{N}(0,1)$, where $S_d = \gamma_0 + 2\sum_{j=1}^{\infty}\gamma_j$ and $\gamma_j = \mathsf{E}(d_{t|t-h}d_{t-j|t-j-h})$. As suggested by White (2000), the test of equal predictive accuracy (5.36) can readily be extended to multiple (greater than two) models.

To avoid having to postulate an unknown density $q(.)$, it is more convenient to couch the test in terms of (5.34) rather than (5.35).[6] In this case we see clearly that the test is equivalent to that proposed by Amisano and Giacomini (2007).

Amisano and Giacomini (2007), independently of Bao, Lee and Saltoglu (2007), proposed tests that can be used to compare the accuracy of density forecasts where evaluation is based on logarithmic scores, e.g., $\ln g(y_t \mid \Omega_{1t-h})$, rather than the pit's. These tests can be superficially related to the traditional Bayesian approach to comparing models using Bayes factors (e.g., see Koop, 2003). When there are no parameters to be estimated, the logarithmic Bayes factor is equal to the difference of the two models' logarithmic scores seen in (5.34) (see Gneiting and Raftery, 2007).

Related approaches of comparing density forecasts statistically have been proposed by Sarno and Valente (2004) and Corradi and Swanson (2006b). Rather than using the KLIC measure of "distance," these rely on the integrated squared difference between the forecast density and the true density (Sarno and Valente) and

the mean square error between the c.d.f. of the density forecast and the true c.d.f., integrated out over different quantiles of the c.d.f. (Corradi and Swanson). Rather than relying on the pit's or the logarithmic score, in both cases they estimate the true density or c.d.f. empirically. y_t is then required to be strictly stationary, an assumption often not supported for economic time-series.

(5.36) is an *unconditional* test for equal forecast accuracy (see Giacomini and White, 2006 (GW)). GW have developed more general *conditional* tests. These test which forecast will be more accurate at a future date, rather than, as with the unconditional tests, testing which forecast was more accurate "on average." One could, for example, then recursively select at time t the best forecasting method for $t+1$. Conditional tests can be straightforwardly implemented in our framework. The null hypothesis of equal conditional forecast accuracy (for one-step-ahead forecasts) amounts to testing $\mathsf{E}(d_{t|t-1} \mid h^*_{t-1}) = \mathsf{E}(h^*_{t-1} d_{t|t-1}) = 0$ $(t = 2, 3, \ldots)$, where h^*_t is a vector of "test functions" which we set equal to $h^*_{t-1} = (1, d_{t-1|t-2})'$. The GW test statistic GW_T can be computed as the Wald statistic:

$$GW_T = T\left(T^{-1}\sum_{t=2}^{T} h^*_{t-1} d_{t|t-1}\right)' \widehat{\Sigma}_T^{-1} \left(T^{-1}\sum_{t=2}^{T} h^*_{t-1} d_{t|t-1}\right), \qquad (5.39)$$

where $\widehat{\Sigma}_T$ is a consistent estimator for the asymptotic variance of $h^*_{t-1} d_{t|t-1}$ and $GW_T \xrightarrow{d} \chi^2_2$. GW note that a robust *HAC* estimator for this variance could be employed, as with DM-type tests, but they also explain that the sample variance is a consistent estimator when one exploits the fact that the null hypothesis implies $\left\{h^*_{t-1}, d_{t|t-1}\right\}_{t=2}^{T}$ is a martingale difference sequence. GW argue that this has the advantage of allowing the data $\{y_t\}$ to be heterogeneous and characterized by arbitrary structural breaks at unknown points. Their test is also valid for nested models.

5.5 The combination of density forecasts

Rather than select a single "best" forecast it can be felicitous to combine competing forecasts. This follows from appreciation of the fact that, although one model may be "better" than the others, we may not select it with probability one; we may not be sure that it is the best forecast. Therefore, if we considered this single forecast alone, we would be overstating its precision. We may better approximate the truth, and account for the uncertainty in model selection, by combining forecasts. Forecast combination also provides a means of reconciling subjective and model-based densities as discussed above (see also Osterholm, 2006).

Indeed, it is well recognized both theoretically and empirically that combining competing individual point forecasts of the same event can deliver more accurate forecasts, in the sense of a lower RMSE (see Bates and Granger, 1969; Stock and Watson, 2004; Timmermann, 2006). The success of combination follows from the fact that individual forecasts may be based on misspecified models, poor estimation or non-stationarities. Moreover, recent work (e.g., Hendry and Clements,

2004) has begun to explore further why point forecast combination works through analytical and Monte Carlo investigation. But, given that measures of uncertainty surrounding a point forecast enhance its usefulness, the natural next step is to consider density forecast combination. While Clements (2006) and Granger, White and Kamstra (1989) have considered, respectively, the combination of event and quantile forecasts, that inevitably involve a loss of information compared with consideration of the "whole" density, the combination of density forecasts has been relatively neglected. In fact, Clements (2003, p. 2) identified this as "an area waiting investigation."

5.5.1 Combination methods

While methods for combining point forecasts are well established and much exploited, less direct attention has been given in econometrics to the combination of density forecasts. This is also a concern in practice since many professional forecasters, particularly central banks, consult more than one forecast. Central bankers often look at what they call a "suite of models." These competing forecasts are produced using both structural macro (usually large-scale but increasingly DSGE) models and atheoretical models, as well as variants in-between. In addition, central bankers routinely add off-model information ("judgment") to model-based forecasts to produce predictive densities. The issue then again arises as to how they should internally reconcile or combine competing density forecasts of the same event to arrive at a single density which is then used to communicate policy.

However, the expert combination literature, more commonly seen in management science and risk analysis journals, has considered density forecast combination, although not evaluation as discussed in section 5.4. This literature adopts a Bayesian approach whereby competing densities are combined by a "decision maker" who views them as data that are used to update a prior distribution (for reviews see Genest and Zidek, 1986; Clemen and Winkler, 1999). There is also, as we discuss in section 5.5.4.1, a related Bayesian literature in econometrics, but only recently has this turned to the combination and evaluation of combined density forecasts. Its use for the combination of subjectively-formed density forecasts is also little discussed.

Within the expert combination literature Clemen and Winkler (1999) distinguish behavioral and mathematical approaches to combination. The behavioral approach seeks to combine experts' opinions by letting the experts interact in some manner to reach a collective opinion. This approach is not considered further since one can imagine many situations in economic forecasting, e.g., when forecasts are model-based, when it is inappropriate. By contrast, mathematical approaches combine the information across experts by using some rule or model. Work has focused on combination rules that satisfy certain properties or axioms. Two common axiomatic approaches are the "linear opinion pool" (Morris, 1974, 1977; Winkler, 1981; Lindley, 1983; Genest and McConway, 1990) and the "logarithmic opinion pool."

The "linear opinion pool" takes a weighted linear combination of the forecasters' probabilities. The combined density is then defined as the finite mixture:

$$p(y_t \mid \Omega_{t-h}) = \sum_{i=1}^{N} w_i g(y_t \mid \Omega_{it-h}), \tag{5.40}$$

where $g(y_t \mid \Omega_{it-h})$ are the h-step-ahead density forecasts of model i ($i = 1, \ldots, N$) of a random variable y_t at time t ($t = 1, \ldots, T$) conditional on the information set Ω_{it-h}, and $\Omega_{t-h} = \cup_{i=1}^{N} \{\Omega_{it-h}\}$. The set of non-negative weights, w_i, sum to unity. The restriction that each weight is positive might be relaxed (for discussion and references, see Genest and Zidek, 1986). In the finite mixture distribution the weights, the mixing proportions, are positive by construction (see Everitt and Hand, 1981). In (5.40) the weights are assumed time-invariant, $w_{it} = w_i$, since below we consider their estimation using sample averages ($t = 1, \ldots, T$). But in general, e.g., when computed on an out-of-sample (recursive) basis, they can be time-varying. (5.40) satisfies certain properties such as the "unanimity" property (if all forecasters agree on a probability then the combined probability agrees also). For further discussion, and consideration of other properties, see Genest and Zidek (1986) and Clemen and Winkler (1999).

The logarithmic opinion pool is defined as:

$$p(y_t \mid \Omega_{t-h}) = k \prod_{i=1}^{N} g(y_t \mid \Omega_{it-h})^{w_i}, \tag{5.41}$$

where k is a normalizing constant. When $w_i = (1/N)$, $p(y_t \mid \Omega_{t-h})$ is proportional to the geometric mean of the experts' distributions. In (5.41) $p(y_t \mid \Omega_{t-h})$ is, in fact, that density forecast "closest," in a KLIC sense, to each of the N competing density forecasts (see Heskes, 1998).

5.5.2 The linear opinion pool

We follow Mitchell and Hall (2005), Wallis (2005), Timmermann (2006, p. 177) and Hall and Mitchell (2007) and focus on density forecast combination via the linear opinion pool. Indeed, (5.40) offers a well understood and much exploited means of combining density forecasts. The SPF, previously the ASA-NBER survey, has essentially used it since 1968 to publish a combined density forecast of inflation, amongst other things, from the individual-level density forecasts which are supplied to it.

Inspection of (5.40) reveals that taking a weighted linear combination of the forecasters' densities can generate a combined density with characteristics quite distinct from those of the forecaster, although this will not be the case for the combination of natural-conjugate densities (Winkler, 1968). For example, if all the forecasters' densities are normal, but with different means and variances, then the combined density will be mixture normal. Mixture normal distributions can have heavier tails than normal distributions, and can therefore potentially accommodate skewness and kurtosis. Combining individual normal density forecasts may mitigate misspecification of the individual densities. As $N \to \infty$ the mixture distribution

is essentially nonparametric and can accommodate any possible distribution. For finite N the mixture distribution still offers a very flexible modeling approach.

Further characteristics of the combined density $p(y_t \mid \Omega_{t-h})$ can be drawn out by defining m_{it} and v_{it} as the mean and variance of forecast i's distribution at time t:

$$m_{it} = \int_{-\infty}^{\infty} y_t g(y_t \mid \Omega_{it-h}) dy_t \text{ and } v_{it} = \int_{-\infty}^{\infty} (y_t - m_{it})^2 g(y_t \mid \Omega_{it-h}) dy_t; (i = 1, \ldots, N).$$

Then the mean and variance of (5.40) are given by:[7]

$$\mathsf{E}\left[p(y_t \mid \Omega_{t-h})\right] = \sum_{i=1}^{N} w_i m_{it}, \tag{5.42}$$

$$\mathsf{Var}\left[p(y_t \mid \Omega_{t-h})\right] = \sum_{i=1}^{N} w_i v_{it} + \sum_{i=1}^{N} w_i \left\{m_{it} - m_t^*\right\}^2. \tag{5.43}$$

(5.43) indicates that the variance of the combined distribution equals average individual uncertainty ("within" model variance) plus disagreement ("between" model variance).[8] This result stands in contrast to that obtained when combining point forecasts, where combination using "optimal" (variance or RMSE minimizing) weights means the RMSE of the combined forecast must be equal to or less than that of the smallest individual forecast (see Bates and Granger, 1969, and, for related discussion in a regression context, Granger and Ramanathan, 1984). Density forecast combination will in general increase the combined variance. However, this increase in uncertainty need not be deleterious; when evaluated the combined density forecast may perform better than the individual density forecasts. Hall and Mitchell (2004) distinguish between combining competing forecasts of various moments of the forecast density and directly combining the individual densities themselves, as with the finite mixture density.

Focusing on the predictive accuracy of the combination, rather than the individual components, the key practical issue is to determine w_i.[9] We consider two methods in sections 5.5.3 and 5.5.4.

5.5.3 Equal weights

Most simply, equal weights, $w_i = 1/N$, have been advocated (see Hendry and Clements, 2004; Smith and Wallis, 2008). Indeed, equal weights are used by the SPF when publishing their combined density forecasts. Also based on equal weights, there are derivative combination methods which use some *ad hoc* rule, such as trimming or thick-modeling (Granger and Jeon, 2004), to eliminate the k% worst performing forecasts and then take an equal weighted average of the remaining forecasts.

As experience of combining point forecasts has taught us, irrespective of its performance in practice, use of equal weights is only one of many options. For example, one popular alternative to equal weights in the point forecast literature,

the so-called regression approach, is to tune the weights to reflect the historical performance of the competing forecasts (e.g., see Granger and Ramanathan, 1984). Choosing the weights via OLS estimation of the realizations of the variable on the competing point forecasts is "optimal," given quadratic loss; the optimal weighted combination of the point forecasts is the most "accurate" point forecast, in the sense of minimum RMSE. In the following section we consider extensions to density forecasts that, essentially, involve choosing the weights to maximize the in-sample or out-of-sample (predictive) "fit" of (5.40).

5.5.4 KLIC minimizing weights

How we measure the accuracy of forecasts is central to how we might choose to combine them. Similar to how RMSE (least squares) has been the historical basis for much analysis of point forecasts, Mitchell and Hall (2005) and Hall and Mitchell (2007) suggest that the KLIC can serve as the basis for density forecast combination, as well as evaluation and combination. The KLIC offers a unifying framework in which to consider choosing the combination weights.

The KLIC *distance* between the true density $f(y_t \mid \Psi_{t-h})$ and the combined density forecast $p(y_t \mid \Omega_{t-h})$ $(t = 1, \ldots, T)$ is defined as:

$$\begin{aligned} KLIC_{t|t-h} &= \int f(y_t \mid \Psi_{t-h}) \ln \left\{ \frac{f(y_t \mid \Psi_{t-h})}{p(y_t \mid \Omega_{t-h})} \right\} dy_t \\ &= \mathsf{E}\left[\ln f(y_t \mid \Psi_{t-h}) - \ln p(y_t \mid \Omega_{t-h}) \right]. \end{aligned} \tag{5.44}$$

The smaller this distance, the closer the density forecast to the true density. $KLIC_{t|t-h} = 0$ if and only if $f(y_t \mid \Psi_{t-h}) = p(y_t \mid \Omega_{t-h})$, which is an "average form" of the rational expectations hypothesis (see Pesaran and Weale, 2006, p. 722).

Given this loss function, Hall and Mitchell (2007) define the "optimal" combined density forecast as:

$$p^*(y_t \mid \Omega_{t-h}) = \sum_{i=1}^{N} w_i^* g(y_t \mid \Omega_{it-h}), \tag{5.45}$$

where the optimal weight vector $\mathbf{w}^* = (w_1^*, .., w_N^*)$ minimizes the KLIC distance between the combined and true density, (5.44). This minimization is achieved as follows:

$$\mathbf{w}^* = \arg\max_{\mathbf{w}} \frac{1}{T} \sum_{t=1}^{T} \ln p(y_t \mid \Omega_{t-h}), \tag{5.46}$$

where $\frac{1}{T}\sum_{t=1}^{T} \ln p(y_t \mid \Omega_{t-h})$ is the average logarithmic score of the combined density forecast over the sample $t = 1, \ldots, T$; for related discussion in terms of quasi-maximum likelihood estimation, see White (1982). For an analytical discussion of "optimal" pooling using (5.46), see Geweke and Amisano (2008). Minimizing the KLIC distance by maximizing the logarithmic score is convenient as it avoids having to postulate and estimate $f(y_t \mid \Psi_{t-h})$, which is unknown. At the expense of having to make an assumption about the form of $q(.)$, Hall and Mitchell (2007) do consider how, for those goodness-of-fit tests directly related to

the KLIC, such as the Berkowitz (2001) LR test, the KLIC can also be minimized by searching for those weights that minimize LR_B. For other goodness-of-fit tests the relevant test statistic can again be minimized, but since the direct link with the KLIC is lost, the weights that deliver this minimum cannot be interpreted as KLIC minimizing. This is because KLIC minimization using tests based on the pits is only as good as the underlying goodness-of-fit test.

This methodology for combining density forecasts is designed to try and mimic the optimal combination of point forecasts. It is motivated by the desire to obtain the most "accurate" density forecast, in a statistical sense, as measured by the KLIC.

The KLIC minimizing weights, $\mathbf{w}^*$, are the maximum likelihood (ML) estimates of the weights in (5.40). These ML estimates, requiring iteration via the EM algorithm, are given as (see Hamilton, 1994, p. 688):

$$w_i^* = \frac{1}{T} \sum_{t=1}^{T} \frac{g(y_t \mid \Omega_{it-h}) w_i}{p(y_t \mid \Omega_{t-h})}, \tag{5.47}$$

where w_i is the probability at the previous iteration that the data are generated by the ith density. This ML interpretation may be helpful to move from inspection of combination weights to tests of their statistical significance by accounting for their uncertainty using the inverse of the Hessian matrix. This might facilitate tests for "conditional efficiency" (*encompassing*) of forecast i relative to its competitors, tests which have yet to be applied to density forecasts, although a definition introduced by Clemen, Murphy and Winkler (1995) has been discussed by Timmermann (2006, p. 176).

5.5.4.1 *Bayesian Model Averaging (BMA)*

From a Bayesian perspective, the KLIC minimizing weights, (5.46), based on the logarithmic score, have some superficial similarities with a BMA approach. Geweke and Amisano (2008) explain the differences. Hoeting *et al.* (1999), Koop (2003, Ch. 11) and Geweke and Whiteman (2006) provide recent general discussions of BMA methods.

BMA offers a conceptually elegant means of dealing with model uncertainty. BMA is an application of Bayes' theorem; model uncertainty is incorporated into the theorem by treating the set of models S as an additional parameter and then integrating over S, where $S \equiv \{S_i, i = 1, \ldots, N\}$ and the models S_i are defined as continuous density functions $g(y_t \mid \Omega_{it-h})$ for the variable of interest y_t. BMA, especially approximate, methods are also feasible, unlike iterative methods such as (5.46), even for large N.

Specifically, $p(y_t \mid \Omega_{t-h})$ can be interpreted as the posterior density of y_t given "data" Ω_{t-h} and written like (5.40) as:

$$p^{\text{BMA}}(y_t \mid \Omega_{t-h}) = \sum_{i=1}^{N} w_i^{\text{BMA}} g(y_t \mid \Omega_{it-h}), \tag{5.48}$$

where $g(y_t \mid \Omega_{it-h}) = \Pr(y_t \mid S_i, \Omega_{t-h})$, and the weights w_i^{BMA} are the model's posterior probabilities. As shown by Draper (1995) and Hoeting *et al.* (1999), these

weights are given as:

$$w_i^{\text{BMA}} = \Pr(S_i \mid \Omega_{t-h}) = \frac{\Pr(\Omega_{t-h} \mid S_i)\Pr(S_i)}{\sum_{i=1}^{N} \Pr(\Omega_{t-h} \mid S_i)\Pr(S_i)}, \tag{5.49}$$

where all probabilities are implicitly conditional on the set of all models S under consideration.

The posterior probabilities, w_i^{BMA}, provide a natural means of ranking the N models, which relates to the discussion above about the comparison of alternative density forecasts. w_i^{BMA} indicate the probability that model i is the best model in a KLIC sense (see, e.g., Fernandez-Villaverde and Rubio-Ramirez, 2004).

Equal weights combination (see section 5.5.3) attaches equal (prior) weight to each model with no updating of the weights based on the "data."

A relationship between (5.47) and (5.49) is apparent when (i) $\Pr(S_i) = w_i$, and (ii) $\Pr(\Omega_{t-1} \mid S_i) = g(y_{t-1} \mid \Omega_{it-2})$, so that in both the "no parameters" and univariate case the log density of Ω_{t-1}, conditional on model i, equals the logarithmic score.[10] More generally, $\Pr(\Omega_{t-1} \mid S_i)$ is specified only up to unknown parameters (in forecasting model i) and the logarithmic *integrated* likelihood can now be viewed as the relevant scoring rule. Further, as discussed by Andersson and Karlsson (2007), when combining forecasts from different multivariate models, in-sample measures of fit based on the marginal likelihood for the system differ from measures of forecasting performance based on the logarithmic score for the variable of interest. Geweke and Amisano (2008) discuss how the properties of w_i^{BMA} differ from those of w_i^*, considering the case when the "true" model is not in the set of N models under consideration. Unlike w_i^{BMA}, w_i^* do not then necessarily tend to zero or one asymptotically.

In practice, when the density forecasts are model-based, approximate Bayesian methods based on information criteria are often used to proxy w_i^{BMA} (see Garratt *et al.*, 2003; Garratt *et al.,* 2006, Ch. 7; Kapetanios, Labhard and Price, 2008). These methods measure the fit of the models, corrected in line with their parsimony, such that:

$$w_i^{\text{BMA}} = \frac{\exp(\Delta_i)}{\sum_{i=1}^{N} \exp(\Delta_i)} \ (i = 1, \ldots, N), \tag{5.50}$$

where $\Delta_i = IC_i - \max(IC_j)$ and $IC_i = \sum_{t=h+1}^{T} \ln g(y_t \mid \Omega_{it-h}) - K_i$ is the information criterion for model i, such that $\sum_{t=h+1}^{T} \ln g(y_t \mid \Omega_{it-h})$ is the maximized value of the log-likelihood (or logarithmic score) and K_i is a penalty term for over-parameterization. Therefore $\Delta_i = 0$ for the best density and is positive for the other density forecasts; the larger Δ_i the less plausible is density i as the best density. Popular choices are to set K_i equal to the number of freely estimated parameters in model i (k_i), so that IC_i equals the Akaike criterion, or to set $K_i = (k_i/2)\ln(T)$, so that IC_i equals the Schwarz Bayesian information criterion. The Schwarz weights are asymptotically optimal when the true model lies in the set of N models under consideration; otherwise the Akaike weights are likely to perform better. w_i^{BMA} in (5.50) can be interpreted as the probability that the model is the best approximation

to the truth given the data (posterior probabilities) when attaching equal (prior) weight to each model, which a Bayesian would term non-informative priors (see Burnham and Anderson, 2002). Minimizing the Akaike criterion is approximately equivalent to minimizing the expected Kullback–Leibler distance between the true density and the estimated density; again see Burnham and Anderson (2002, Ch. 2, Ch. 6).

The combined density forecast $p^{\text{BMA}}(y_t \mid \Omega_{t-h})$ also has established optimality properties given the set of models under consideration (see Madigan and Raftery, 1994; Raftery and Zheng, 2003). The central estimate from $p^{\text{BMA}}(y_t \mid \Omega_{t-h})$ minimizes mean squared error, the prediction intervals are well calibrated and $p^{\text{BMA}}(y_t \mid \Omega_{t-h})$ maximizes the logarithmic score given $\Pr(S_i)$. On this basis the combined density cannot provide worse forecasts (in-sample, $t = 1, \ldots, T$), as evaluated by the average logarithmic score, than the best individual forecast. This follows from:

$$KLIC_{it} = \mathsf{E}\left[\ln f(y_t \mid \Psi_{t-h}) - \ln g(y_t \mid \Omega_{it-h})\right] \geq 0 \tag{5.51}$$

$$\Rightarrow \mathsf{E}(\ln p^{\text{BMA}}(y_t \mid \Omega_{t-h})) \geq \mathrm{E}(\ln g(y_t \mid \Omega_{it-h})) \Leftrightarrow KLIC_t \leq KLIC^{i}_{t|t-h}, \tag{5.52}$$

($i = 1, \ldots, N$; $t = 1, \ldots, T$). However, BMA implicitly assumes that all the models under consideration are stable. When they are not, perhaps if there are structural breaks, and when the set of models under consideration is not exhaustive (and, therefore, does not include the *true* model), non-Bayesian weights, like equal weights or w_i^*, might be more appropriate and, e.g., deliver a higher log score (see Geweke and Amisano, 2008). In the presence of unknown structural breaks, Pesaran and Timmermann (2007) proved that it can be helpful to average not just over different models, but over different estimation windows for a given model; Assenmacher-Wesche and Pesaran (2008) found equal weights performed best (i.e., delivered the lowest RMSE) in an application to the Swiss economy.

In contrast to methods designed to combine point forecasts (cf. Bates and Granger, 1969), the weights w_i^* or w_i^{BMA} do not allow explicitly for correlation between forecasts. One possibility for future research is to consider the use of copula functions to account for the dependence between the density forecasts (see Jouini and Clemen, 1996; Mitchell, 2007a).

5.5.4.2 Out-of-sample measures of fit

To protect against in-sample overfitting, predictive, rather than in-sample (likelihood-based), measures of fit have also been proposed as the basis for forecast combination (see Eklund and Karlsson, 2007; Kapetanios, Labhard and Price, 2006; Andersson and Karlsson, 2007), although these papers do not consider forecast density evaluation. However, in a specific sense, the marginal likelihood can be interpreted as a measure of out-of-sample predictive performance, as well as a measure of in-sample fit. This is because the marginal likelihood can be written, as seen, as the product of one-step-ahead predictive densities; also see Geweke and Whiteman (2006, pp. 15–17). However, it cannot be decomposed directly into the product of h-step-ahead density forecasts. Moreover, to interpret the marginal

likelihood as an out-of-sample measure of fit relies on the prior being informative (see Eklund and Karlsson, 2007). When an uninformative prior is used, as is common (see Fernandez, Ley and Steel 2001), the marginal likelihood reduces to an in-sample measure of fit. The relationship between in-sample (system) fit and the expected forecasting performance of the variable of interest is also lost in multivariate forecasting models, prompting Andersson and Karlsson (2007) to suggest use of the predictive likelihood for forecast combination since the univariate predictive density of interest can be readily simulated.

These out-of-sample measures of fit involve splitting the available sample ($t = 1, \ldots, T$) in two and measuring the fit of the models according to how well recursively computed h-step ahead forecasts perform, according to the marginal likelihood or logarithmic score, over a hold-out (or predictive) period ($t = t_0, \ldots, T$). Importantly, this means the measure of fit varies according to h. Empirically, the size of the hold-out period also matters. Theoretically, as the size of the hold-out period increases we should expect the weights w_i^{BMA} based on the predictive likelihood to select the correct model consistently (Eklund and Karlsson, 2007). But there is a trade-off when selecting the size of the hold-out period. A small value means the weights adapt quickly to change; but a larger value means the weights are better estimated. Pesaran and Timmermann (2007) have established the optimal trade-off between bias and forecast error variance in regression models subject to one or more structural breaks. Similarly when density forecasting, since economic time-series are known to exhibit structural breaks (Stock and Watson, 1996), unless the true model is in the set of models under consideration we might expect the ranking of the N models to vary over time. This might make it advantageous to consider selecting the size of the hold-out period using the data.

Out-of-sample measures of fit, based on the logarithmic score, can serve as the basis for density forecast combination whether the forecasts are model-based or subjectively formed (see Hall and Mitchell, 2007; Jore, Mitchell and Vahey, 2008). All that is required is the history of the density forecasts. Alternatively, Mitchell and Hall (2005) advocate density forecast combination using what they call 'KLIC' weights, which use the pit's rather than the logarithmic score, measured over a hold-out period, to measure fit. This involves using each model's $\overline{KLIC}_{t-h}^{i}$ value (see (5.29)) computed recursively over the out-of-sample window, to determine $-\Delta_i = \overline{KLIC}_{t-h}^{i} - \min(\overline{KLIC}_{t-h}^{i})$ in (5.50).

5.5.4.3 Empirical applications combining and evaluating density forecasts

Despite considerable experience combining point forecasts, and an extensive BMA literature, there has been little applied macroeconomic work devoted explicitly to density forecast combination and evaluation. For example, in his review of the available empirical literature on forecast combination, Timmermann (2006) focuses on point forecasts. Therefore, a consensus about if and when density forecast combination "works" in macroeconomics has yet to emerge. Nevertheless, a tentative start has been made (see Mitchell and Hall, 2005; Hall and Mitchell, 2007; Jore, Mitchell and Vahey, 2008). An early suggestion is that there can be substantial

gains in forecast accuracy when some variant of KLIC minimizing or BMA, rather than equal, weights are used. This contrasts with the conventional wisdom about point (conditional mean) forecasts, where equal weights are generally preferred. However, for other samples and sets of models, Gerard and Nimark (2008) and Kascha and Ravazzolo (2008) have found that equal weight density combinations can remain hard to beat.

Hall and Mitchell (2007) combine, based on their out-of-sample fit, the one-year-ahead density forecasts of UK inflation published in real time by the Bank of England and the NIESR; they search for the set of weights that maximize the logarithmic score, cf. (5.46). When this is undertaken over the full sample period the combined density forecast is found not to beat the best individual density forecast, the Bank's forecast. The KLIC minimizing weights are unity on the Bank and zero on the NIESR, i.e., there is no combination. This is consistent with the view that combination with an inferior forecast need not help. But, similar to when variance minimizing weights are used to combine point forecasts, combination does not make matters worse (as judged by the logarithmic score, and for point forecasts as judged by the RMSE) when the weights are selected using full-sample information (i.e., in-sample). But when the weights are chosen recursively (i.e., out-of-sample) this need not be the case. Hall and Mitchell (2007) find that an equal weighted combination produces a less accurate density forecast.

Again combining the Bank's and the NIESR's inflation densities, Mitchell and Hall (2005) consider the merits of an alternative means of deriving the combination weights. This involves using $-\Delta_i = \overline{KLIC}^i_{t-h} - \min(\overline{KLIC}^i_{t-h})$ in (5.50), with $\overline{KLIC}^i_{t-h}$ estimated from LR^i_B with two degrees-of-freedom. Mitchell and Hall (2005) then find, even in-sample, that the weighted combination performs worse than the Bank's density, as measured by both the logarithmic score and the LR^i_B test statistic. This can be attributed to the danger, discussed in Hall and Mitchell (2007), that the true density for $z^*_{it|t-h}$, essential to estimation of $\overline{KLIC}^i_{t-h}$, need not be nested by the chosen specification for $q(.)$. Parameter uncertainties in small samples, due to the estimation of, in this case, μ and σ, may also be playing a role. Reconciling and comparing the efficacy of the alternative methods of estimating w^*_i and $w_i{}^{\text{BMA}}$ remains the subject of ongoing research.

The starting point for Jore, Mitchell and Vahey (2008) is the application of Clark and McCracken (2008) to real-time US data. Clark and McCracken (2008) argue that combining real-time point forecasts from VAR models of output, prices and interest rates improves point forecast accuracy in the presence of uncertain model instabilities. Using the same real-time dataset, Jore, Mitchell and Vahey (2008) generalize their approach to consider forecast density combinations and evaluations. Whereas Clark and McCracken (2008) show that the point forecast errors from particular equal-weight pairwise averages are typically comparable to or better than benchmark univariate time series models, Jore, Mitchell and Vahey (2008) show that neither approach produces accurate real-time forecast densities for recent US data. But substantially improved predictive density accuracy is obtained when the competing density forecasts are combined on the basis of the fit of the individual

VAR model forecast densities, as measured by the logarithmic score, over the hold-out period. This weighted combination gives greater weight to models that allow for the shifts in volatilities associated with the Great Moderation. This result again contrasts with that typically found with point forecasts, where equal weighted averages are hard to beat.

5.6 Conclusion

The past decade has seen a considerable increase in the production and use of density forecasts in macroeconomics. This reflects both changes in the dynamics of the macroeconomy, with important shifts in both the level and volatility of many macroeconomic variables making it important to forecast the overall density function rather than just the conditional mean, and the development of econometric models that allow for time variation in the conditional variance, as well as the conditional mean. With this increased use of density forecasts, important new econometric challenges have arisen as macroeconomists seek recourse to a toolbox comparable to that routinely used both to produce and use point (conditional mean) forecasts. This chapter has reviewed recent additions to this toolbox, focusing on the practicality rather than rigour of the methods.

This first involved surveying some methods for the production of density forecasts. We also considered combining model-based and subjective information, by *twisting* the model-based densities to reflect prior (perhaps subjectively formed) information. We should imagine that the techniques considered could be of particular use to professional forecasters, like many central banks, who use both model-based information and judgment when forming their density forecasts. Second, we provided a practical discussion of methods for the *ex post* evaluation of density forecasts. This involved discussion of both rolling and fixed-event density forecasts. Numerous tests for both absolute and relative density forecasting performance, using both the probability integral transforms and scoring rules, were discussed, and their relationship to the Kullback–Leibler information criterion considered. But we stressed the need for further work to establish a consensus on the appropriate test(s), especially in the small-samples typical of macroeconomics and when forecasting more than one step ahead. Finally, again reflecting a common situation for many macroeconomists who forecast from a suite of models, we reviewed methods for the combination of density forecasts to overcome the uncertainty in model selection. Particular focus was given to how to choose the combination weights. In contrast to the conventional wisdom about point forecasts, where equal weights are generally preferred, recent applied work has found that the predictive accuracy of combined density forecasts improves when a greater weight is given to models that allow for the shifts in volatility which have been observed in many economies over the last 20 years.

The authors have benefited from numerous discussions with Shaun Vahey and Ken Wallis and thank John Geweke and Terry Mills for useful comments.

Notes

1. However, Granger and Machina (2006) show that, under conditions on the second derivative of the loss function, there is always some point forecast which leads to the same loss as if the decision maker had minimized loss given the density forecast.
2. See Clements and Hendry (1998, Ch. 7) for a complete taxonomy of forecast errors. See also Garratt *et al*. (2006, Ch. 7).
3. We fail to distinguish between random variables and their realizations to avoid introducing yet more notation; but the meaning should be clear from the context. When it is not, we clarify.
4. Diebold, Gunther and Tay (1998) show that the principle generalizes to the case when y_t is multivariate rather than univariate.
5. Alternatively, graphical means of exploratory data analysis are often used to examine the quality of density forecasts (see Diebold, Gunther and Tay, 1998; Diebold, Tay and Wallis, 1999).
6. This also means we do not have to worry about any additional uncertainty introduced because estimation of the loss differential series $d_{t|t-h}$ itself requires parameters (e.g., μ, ρ and σ) to be estimated.
7. Related expressions decomposing the aggregate density (5.40), based on the "law of conditional variances," are seen in Giordani and Söderlind (2003). This law states that for the random variables y_t and i : $V(y_t) = E[V(y_t|i)] + V[E(y_t|i)]$. For criticism see Wallis (2005).
8. For further discussion of the relationship, if any, between dispersion/disagreement and individual uncertainty see Bomberger (1996).
9. The individual forecasts of $g(y_t|\Omega_{it-h})$ are treated as given. Alternatively, one might estimate a finite mixture where the moments of the $g(\cdot)$ are estimated simultaneously with w_i; see Raffery *et al*. (2005) and Geweke and Amisano (2008).
10. The marginal likelihood is the product of the one-step-ahead densities: $\Pr(\Omega_T \mid S_i) = \prod_{t=1}^{T} g(y_t \mid \Omega_{it-1})$.

Investigating Economic Trends and Cycles

D.S.G. Pollock

Abstract

Methods are described for extracting the trend from an economic data sequence and for isolating the cycles that surround it. The latter often consist of a business cycle of variable duration and a perennial seasonal cycle.

There is no evident point in the frequency spectrum where the trend ends and the business cycle begins. Therefore, unless it can be represented by a simple analytic function, such as an exponential growth path, there is bound to be a degree of arbitrariness in the definition of the trend.

The business cycle, however defined, is liable to have an upper limit to its frequency range that falls short of the Nyquist frequency, which is the maximum observable frequency in sampled data. This must be taken into account in fitting an ARMA model to the detrended data.

6.1 Introduction

It has been traditional in economics to decompose time series – more accurately described as temporal sequences – into a variety of components, some or all of which may be present in a particular instance. The essential decomposition is a multiplicative one of the form:

$$Y(t) = T(t) \times C(t) \times S(t) \times E(t), \tag{6.1}$$

where:

$T(t)$ is the global trend,

$C(t)$ is a secular cycle, or business cycle,

$S(t)$ is the seasonal variation and

$E(t)$ is an irregular component.

Occasionally, other cycles of relatively long durations are included. Amongst these are the mysterious Kondratieff cycle, reflecting the ebb and flow of human fortunes over half a century, the Shumpeterian cycle, reflecting currents and tides of technological innovation, and the demographic cycle, reflecting the fluctuations in the procreative urges of human beings.

The factors $C(t)$, $S(t)$ and $E(t)$ in equation (6.1) serve to modulate the trend $T(t)$ by inducing fluctuations in its trajectory. They take the generic form of $X(t) = 1 + \xi(t)$, where $\xi(t)$ is a process that fluctuates about a mean of zero.

Typically, $Y(t)$ and $T(t)$ are strictly positive and, therefore, the modulating factors, which are usually deemed to act independently of each other, must also be bounded away from zero. This condition will be satisfied whenever the generic factor can be expressed in an exponential form:

$$X(t) = 1 + \xi(t) = 1 + \sum_{j=1}^{\infty} \frac{\{x(t)\}^j}{j!} = \exp\{x(t)\}. \tag{6.2}$$

In that case, it is appropriate to take logarithms of the expression (6.1) and to work with an alternative additive decomposition instead of the multiplicative one. This is:

$$y(t) = \tau(t) + c(t) + s(t) + \varepsilon(t), \tag{6.3}$$

where $y(t) = \ln Y(t)$, $\tau(t) = \ln T(t)$, $c(t) = \ln C(t)$, $s(t) = \ln S(t)$ and $\varepsilon(t) = \ln E(t)$. An additional assumption, which might be plausible, is that the components $c(t)$, $s(t)$, and $\varepsilon(t)$ have amplitudes that remain roughly constant over time.

In the absence of extraneous information that correlates them with other variables, it is impossible to distinguish the components of (6.3) perfectly, one from another, unless they occupy separate frequency bands. If their bands do overlap, then any separation of the components will be tentative and doubtful. Thus, a sequence that is deemed to represent one of the components will comprise, to some extent, elements that rightfully belong to the other components.

However, as we shall see, the components of an econometric data sequence often reside within bands of frequencies that are separated by wide dead spaces where there are no spectral elements of any significance. The possibility of definitely separating the components is greater than analysts are likely to perceive unless they work in the frequency domain.

The exception concerns the separation of the business cycle from the trend. These components are liable to be merged within a single spectral structure, and there is no uniquely appropriate way of separating them. Their separation depends upon adopting whatever convention best suits the purposes of the analysis. No such difficulties will affect the simple schematic model of the business cycle that we shall consider in the next section.

6.2 A schematic model of the business cycle

In order to extract the modulating components from the data, it is also necessary to remove the trend component from $Y(t)$. To understand what is at issue in detrending the data, it is helpful to look at a simple schematic model comprising an exponential growth trajectory $T(t) = \beta \exp\{rt\}$, with $r > 0$, that is modulated by a exponentiated cosine function $C(t) = \exp\{\gamma \cos(\omega t)\}$ to create a model for the trajectory of aggregate income:

$$Y(t) = \beta \exp\{rt + \gamma \cos(\omega t)\}. \tag{6.4}$$

The resulting business cycles, which are depicted in Figure 6.1, have an asymmetric appearance. Their contractions are of lesser duration than their expansions and they become shorter as the growth rate r increases.

Eventually, when the rate exceeds a certain value, the periods of contraction will disappear and, in place of the local minima, there will be only points of inflection. In fact, the condition for the existence of local minima is that $\omega\gamma > r$, which is to say the product of the amplitude of the cycles and their angular velocity must exceed the growth rate of the trend.

Next, we take logarithms of the data to obtain a model, represented in Figure 6.2, that has additive trend and cyclical components. This gives:

$$\ln\{Y(t)\} = y(t) = \mu + rt + \gamma \cos(\omega t), \tag{6.5}$$

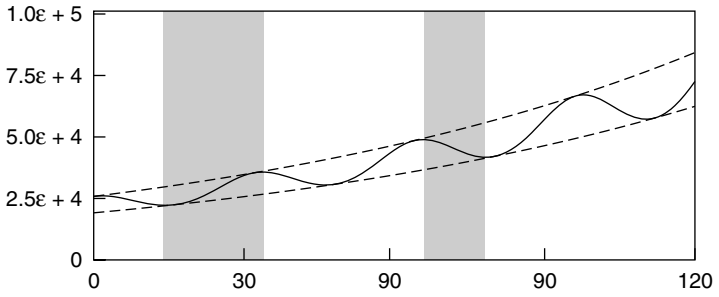

Figure 6.1 The function $Y(t) = \beta \exp\{rt + \gamma \cos(\omega t)\}$ as a model of the business cycle. Observe that, when $r > 0$, the duration of an expansion exceeds the duration of a contraction

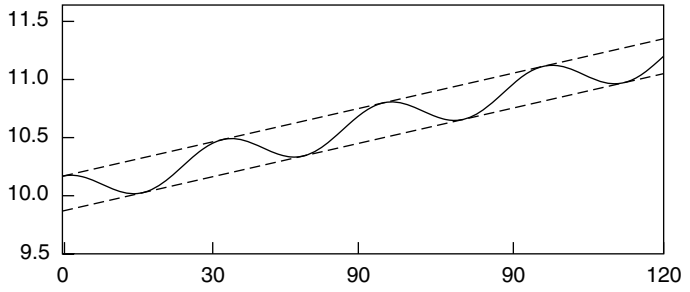

Figure 6.2 The function $\ln\{Y(t)\} = \ln\{\beta\} + rt + \gamma \cos(\omega t)$ representing the logarithmic business cycle data. The durations of the expansions and the contractions are not affected by the transformation

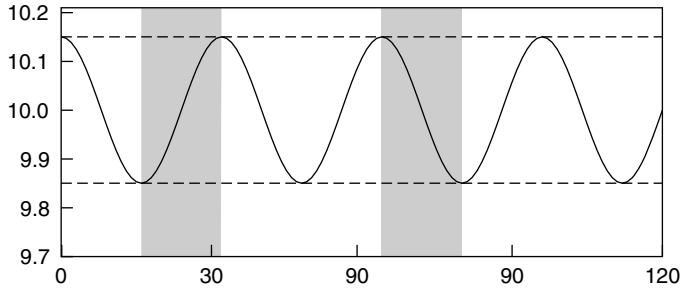

Figure 6.3 The function $\mu + \gamma \cos(\omega t)$ representing the detrended business cycle. The durations of the expansions and the contractions are equal

where $\mu = \ln\{\beta\}$. Since logs effect a monotonic transformation, there is no displacement of the local maxima and minima. However, the amplitude of the fluctuations around the trend, which has become linear in the logs, is now constant.

The final step is to create a stationary function by eliminating the trend. There are two equivalent ways of doing this in the context of the schematic model.

On the one hand, the linear trend $\xi(t) = \mu + rt$ can be subtracted from $y(t)$ to create the pure business cycle $\gamma\cos(\omega t)$. Alternatively, the function $y(t)$ can be differentiated to give $dy(t)/dt = r - \gamma\omega\sin(\omega t)$. When the latter is adjusted by subtracting the growth rate r, by dividing by ω and by displacing its phase by $-\pi/2$ radians – which entails replacing the argument t by $t - \pi/2$ – we obtain the function $\gamma\cos(\omega t)$ again. Through the process of detrending, the phases of expansion and contraction acquire equal durations, and the asymmetry of the business cycle vanishes, as is shown by Figure 6.3.

There is an enduring division of opinion, in the literature of economics, on whether we should be looking at the turning points and phase durations of the original data or at those of the detrended data. The task of finding the turning points is often a concern of analysts who wish to make international comparisons of the timing of the business cycle. There is a belief, which bears investigating, that these cycles are becoming increasingly synchronized amongst member countries of the European Union.

However, since the business cycle is a low-frequency component of the data, it is difficult to find the turning points with great accuracy. In fact, the pinnacles and pits that are declared to be the turning points often seem to be the products of whatever high-frequency components happen to remain in the data after it has been subjected to a process of seasonal adjustment.

If the objective is to compare the turning points of the cycles, then the trends should be eliminated from the data. The countries that are to be compared are liable to be growing at differing rates. From the trended data, it will appear that those with higher rates of growth have shorter recessions with delayed onsets, and this can be misleading.

The various indices of an expanding economy will also grow at diverse rates. Unless they are reduced to a common basis by eliminating their trends, their fluctuations cannot be compared easily. Amongst such indices will be the percentage rate of unemployment, which constitutes a trend-stationary sequence. It would be difficult to collate the turning points in this index with those within a rapidly growing series of aggregate income, which might not exhibit any absolute reductions in its level. A trenchant opinion to the contrary, which opposes the practice of detrending the data for the purposes of describing the business cycle, has been offered by Harding and Pagan (2002).

6.3 The methods of Fourier analysis

A means of extracting the cyclical components from a data sequence is to regress it on a set of trigonometrical functions. The relevant procedures have been described within the context of the statistical analysis of time series by numerous authors, including Bloomfield (1975), Fuller (1976) and Priestley (1989).

In the Fourier decomposition of a finite sequence $\{x_t; t = 0, 1, \ldots, T-1\}$, the T data points are expressed as a weighted sum of an equal number of trigonometrical functions of frequencies that are equally spaced in the interval $[0, \pi]$.

We define $[T/2]$ to be the integer part to $T/2$, which will be $n = T/2$, if T is even, or $(T-1)/2$, if T is odd. Then:

$$\begin{aligned} x_t &= \sum_{j=0}^{[T/2]} \left\{ \alpha_j \cos(\omega_j t) + \beta_j \sin(\omega_j t) \right\} \\ &= \sum_{j=0}^{[T/2]} \rho_j \cos(\omega_j t - \theta_j). \end{aligned} \tag{6.6}$$

Here, $\rho_j^2 = \alpha_j^2 + \beta_j^2$ and $\theta_j = \tan^{-1}(\beta_j/\alpha_j)$, whilst $\alpha_j = \rho_j \cos(\theta_j)$ and $\beta_j = \rho_j \sin(\theta_j)$. The equality of (6.6) follows in view of the trigonometrical identity:

$$\cos(A - B) = \cos(A)\cos(B) + \sin(A)\sin(B). \tag{6.7}$$

The frequency $\omega_j = 2\pi j/T$ is a multiple of the fundamental frequency $\omega_1 = 2\pi/T$. The latter belongs to a sine and a cosine function that complete a single cycle in the time spanned by the data. The zero frequency ω_0 is associated with the constant function $\cos(\omega_0 t) = \cos(0) = 1$, whereas $\sin(\omega_0 t) = \sin(0) = 0$.

If $T = 2n$ is an even number, then the highest frequency is $\omega_n = \pi$; and, within (6.6), there are $\cos(\omega_n t) = \cos(\pi t) = (-1)^t$ and $\sin(\omega_n t) = \sin(\pi t) = 0$. If T is an odd number, then the highest frequency is $\pi(T-1)/T$, and there is both a sine and a cosine function at this frequency. Counting the number of non-zero functions in both cases shows that they are equal in number to the data points. Therefore, there is a one-to-one correspondence between the data points and the coefficients of the non-zero functions in the Fourier expression of (6.6).

In equation (6.6), the temporal index $t \in \{0, 1, \ldots, T-1\}$ assumes integer values. However, by allowing $t \in [0, T)$ to vary continuously, one can generate a continuous function that interpolates the T data points. This method of generating the continuous function from sampled values may be described as Fourier interpolation. It is notable that the interpolated function is analytic in the sense that it possesses derivatives of all orders.

Although the process generating the data may contain components of frequencies higher than the Nyquist frequency, these will not be detected when it is sampled regularly at unit intervals of time. In fact, the effects on the process of components of frequencies in excess of the Nyquist value will be confounded with those of frequencies that fall below it.

To demonstrate this, consider the case where the process contains a component that is a pure cosine wave of unit amplitude and zero phase and of a frequency ω that lies in the interval $\pi < \omega < 2\pi$. Let $\omega^* = 2\pi - \omega$. Then:

$$\begin{aligned} \cos(\omega t) &= \cos\left\{(2\pi - \omega^*)t\right\} \\ &= \cos(2\pi)\cos(\omega^* t) + \sin(2\pi)\sin(\omega^* t) \\ &= \cos(\omega^* t), \end{aligned} \tag{6.8}$$

which indicates that ω and ω^* are observationally indistinguishable. Here, $\omega^* < \pi$ is described as the alias of $\omega > \pi$.

Since the trigonometrical functions are mutually orthogonal, the Fourier coefficients can be obtained via a set of T simple inner-product formulae, which are in the form of ordinary univariate least squares regressions, with the values of the sine and cosine functions at the points $t = 0, 1, \ldots, T-1$ as the regressors.

Let $c_j = [c_{0,j}, \ldots, c_{T-1,j}]'$ and $s_j = [s_{0,j}, \ldots, s_{T-1,j}]'$ represent vectors of T values of the generic functions $\cos(\omega_j t)$ and $\sin(\omega_j t)$ respectively, and let $x = [x_0, \ldots, x_{T-1}]'$ be the vector of the sample data and $\iota = [1, \ldots, 1]'$ a vector of units. The "regression" formulae for the Fourier coefficients are:

$$\alpha_0 = (\iota'\iota)^{-1}\iota' x = \frac{1}{T}\sum_t x_t = \bar{x}, \tag{6.9}$$

$$\alpha_j = (c_j'c_j)^{-1}c_j' x = \frac{2}{T}\sum_t x_t \cos(\omega_j t), \tag{6.10}$$

$$\beta_j = (s_j's_j)^{-1}s_j' x = \frac{2}{T}\sum_t x_t \sin(\omega_j t), \tag{6.11}$$

$$\alpha_n = (c_n'c_n)^{-1}c_n' x = \frac{1}{T}\sum_t (-1)^t x_t. \tag{6.12}$$

However, in calculating the coefficients, it is more efficient to use the family of specialised algorithms known as fast Fourier transforms, which deliver complex-valued spectral ordinates from which the Fourier coefficients are obtained directly. (See, for example, Pollock 1999.)

The power of a sequence is the time average of its energy. It is synonymous with the mean square deviation which, in statistical terms, is its variance. The power of the sequence $x_j(t) = \rho_j \cos(\omega_j t)$ is $\rho_j^2/2$. This result can be obtained in view of the identity $\cos^2(\omega_j t) = \{1 + \cos(2\omega_j t)\}/2$, for the average of $\cos(2\omega_j t)$ over an integral number of cycles is zero. The assemblage of values $\rho_j^2/2; j = 1, 2, \ldots, [T/2]$ constitutes the power spectrum of $x(t)$, which becomes the periodogram when scaled by a factor T. Their sum equals the variance of the sequence. If $T = 2n$ is even, then:

$$\frac{1}{T}\sum_{t=0}^{T-1}(x_t - \bar{x})^2 = \frac{1}{2}\sum_{j=1}^{n-1}\rho_j^2 + \alpha_n^2. \tag{6.13}$$

Otherwise, if T is odd, then the summation runs up to $(T-1)/2$, and the term α_n^2 is missing.

The indefinite sequence $x(t) = \{x_t; t = 0, \pm 1, \pm 2, \ldots\}$, expressed in the manner of (6.6), is periodic with a period T equal to the length of the sample. It is described as the periodic extension of the sample, and it may be obtained be replicating sample elements over all preceding and succeeding intervals of T points. An alternative way of forming the periodic sequence is by wrapping the sample around a circle of circumference T. Then, the periodic sequence is generated by traveling perpetually around the circle.

6.3.1 Approximations, resampling and Fourier interpolation

By letting $t = 0, \ldots, T-1$ in equation (6.6), the data sequence $\{x_t; t = 0, \ldots, T-1\}$ is generated exactly. An approximation to the sequence may be generated by taking a partial sum comprising the terms of (6.6) that are associated with the Fourier frequencies $\omega_0, \ldots, \omega_d$, where $d < [T/2]$. It is straightforward to demonstrate that this is the best approximation, in the least squares sense, amongst all of the so-called trigonometrical polynomials of degree d that comprise the sinusoidal functions in question.

The result concerning the best approximation extends to the continuous functions that are derived by allowing t to vary continuously in the interval $[0, T)$. That is to say, the continuous function derived from the partial Fourier sum comprising frequencies no higher than $\omega_d = 2\pi d/T$ is the minimum mean square approximation to the continuous function derived from (6.6) by letting t vary continuously.

We may exclude the sine function of frequency ω_d from the Fourier sum. Then the continuous approximation is given by:

$$\begin{aligned} z(t) &= \sum_{j=0}^{d} \left\{ \alpha_j \cos\left(\frac{2\pi jt}{T}\right) \right\} + \sum_{j=1}^{d-1} \left\{ \beta_j \sin\left(\frac{2\pi jt}{T}\right) \right\} \\ &= \sum_{j=0}^{d} \left\{ \alpha_j \cos\left(\frac{2\pi j\tau}{N}\right) \right\} + \sum_{j=1}^{d-1} \left\{ \beta_j \sin\left(\frac{2\pi j\tau}{N}\right) \right\}, \end{aligned} \tag{6.14}$$

where $\tau = tN/T$ with $N = 2d$, which is the total number of the Fourier coefficients. Here, τ varies continuously in $[0, N)$, whereas t varies continuously in $[0, T)$. On the right-hand side, there is a new set of Fourier frequencies $\{2\pi j/N; j = 0, 1, \ldots, d\}$.

The N coefficients $\{\alpha_0, \alpha_1, \beta_1, \ldots, \alpha_{d-1}, \beta_{d-1}, \alpha_d\}$ bear a one-to-one correspondence with the set of N ordinates $\{z_\tau = z(\tau T/N); \tau = 0, \ldots, N-1\}$ sampled at intervals of $\pi/\omega_d = T/N$ from $z(t)$. The consequence is that $z(t)$ is fully represented by the resampled data $z_\tau; \tau = 0, \ldots, N-1$, from which it may be derived by Fourier interpolation.

The result concerning the optimality of the approximation is a weak one; for it is possible that the preponderance of the variance of the data will be explained by sinusoids at frequencies that lie outside the range $[\omega_0, \ldots, \omega_d]$. The matter can be judged with reference to the periodogram of the data sequence, which constitutes a frequency-specific analysis of variance.

Example Figure 6.4 represents the logarithms of the data on quarterly real household expenditure in the UK for the period 1956–2005, through which a linear function had been interpolated so as to pass through the midst of the data points of the first and the final years.

This interpolation is designed to minimize any disjunction that might otherwise occur where the ends of the data sequence meet when it is mapped onto the

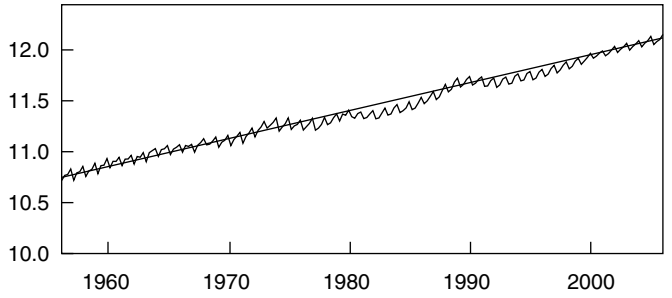

Figure 6.4 The quarterly sequence of the logarithms of household expenditure in the UK for the years 1956–2005, together with an interpolated linear trend

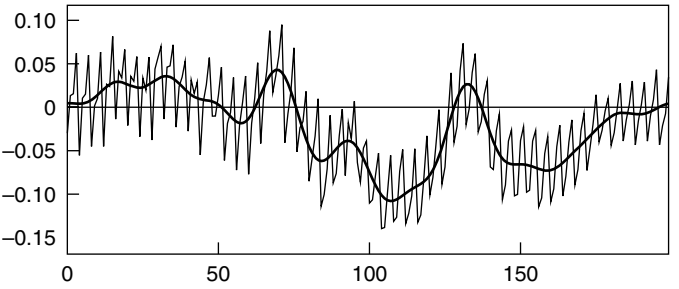

Figure 6.5 The residual deviations of the logarithmic expenditure data from the linear trend of Figure 6.4. The interpolated line, which represents the business cycle, has been synthesized from the Fourier ordinates in the frequency interval $[0, \pi/8]$

circumference of a circle. A trend line fitted by ordinary least squares regression would have a lesser gradient, which would raise the final years above the line. This would be a reflection of the relative prosperity of the times.

The residual deviations of the expenditure data from the trend line of Figure 6.4 are represented in Figure 6.5, and their periodogram is shown in Figure 6.6. Within this periodogram, the spectral structure extending from zero frequency up to $\pi/8$ belongs to the business cycle. The prominent spikes located at the frequency $\pi/2$ and at the limiting Nyquist frequency of π are the property of the seasonal fluctuations. Elsewhere in the periodogram, there are wide dead spaces, which are punctuated by the spectral traces of minor elements of noise.

The slowly varying continuous function interpolated through the deviations of Figure 6.5 has been created by combining a set of sine and cosine functions of increasing frequencies in the manner of (6.14), with the frequencies extending no further than $\omega_d = \pi/8$, and by letting t vary continuously in the interval $[0, T)$. This is a representation of the business cycle as it affects household expenditure. Observe that, since it is analytic, the turning points of this function can be determined via its first derivative.

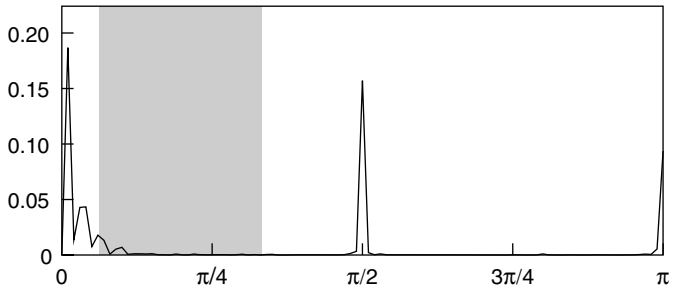

Figure 6.6 The periodogram of the residual sequence of Figure 6.5. A band, with a lower bound of $\pi/16$ radians and an upper bound of $\pi/3$ radians, is masking the periodogram

6.3.2 Complex exponentials

In dealing with the mathematics of the Fourier transform, it is common to use complex exponential functions in place of sines and cosines. This makes the expressions more concise. According to Euler's equations, these are:

$$\cos(\omega_j t) = \frac{1}{2}(e^{\mathrm{i}\omega_j t} + e^{-\mathrm{i}\omega_j t}) \quad \text{and} \quad \sin(\omega_j t) = \frac{-\mathrm{i}}{2}(e^{\mathrm{i}\omega_j t} - e^{-\mathrm{i}\omega_j t}), \tag{6.15}$$

where $\mathrm{i} = \sqrt{-1}$. Therefore, equation (6.6) can be expressed as:

$$x_t = \alpha_0 + \sum_{j=1}^{[T/2]} \frac{\alpha_j + \mathrm{i}\beta_j}{2} e^{-\mathrm{i}\omega_j t} + \sum_{j=1}^{[T/2]} \frac{\alpha_j - \mathrm{i}\beta_j}{2} e^{\mathrm{i}\omega_j t}, \tag{6.16}$$

which can be written concisely as:

$$x_t = \sum_{j=0}^{T-1} \xi_j e^{\mathrm{i}\omega_j t}, \tag{6.17}$$

where:

$$\xi_0 = \alpha_0, \quad \xi_j = \frac{\alpha_j - \mathrm{i}\beta_j}{2} \quad \text{and} \quad \xi_{T-j} = \xi_j^* = \frac{\alpha_j + \mathrm{i}\beta_j}{2}. \tag{6.18}$$

Equation (6.17) may be described as the inverse Fourier transform. The direct transform is the mapping from the data sequence within the time domain to the sequence of Fourier ordinates in the frequency domain. The relationship between the discrete periodic function and its Fourier transform can be summarized by writing:

$$x_t = \sum_{j=0}^{T-1} \xi_j e^{\mathrm{i}\omega_j t} \quad \longleftrightarrow \quad \xi_j = \frac{1}{T} \sum_{t=0}^{T-1} x_t e^{-\mathrm{i}\omega_j t} dt. \tag{6.19}$$

For matrix representations of these transforms, one may define:

$$\begin{aligned} U &= T^{-1/2}[\exp\{-\mathrm{i}2\pi tj/T\}; t, j = 0, \ldots, T-1], \\ \bar{U} &= T^{-1/2}[\exp\{\mathrm{i}2\pi tj/T\}; t, j = 0, \ldots, T-1], \end{aligned} \tag{6.20}$$

which are unitary complex matrices such that $U\bar{U} = \bar{U}U = I_T$. Then:

$$x = T^{1/2}\bar{U}\xi \quad \longleftrightarrow \quad \xi = T^{-1/2}Ux, \tag{6.21}$$

where $x = [x_0, x_1, \ldots x_{T-1}]'$ and $\xi = [\xi_0, \xi_1, \ldots \xi_{T-1}]'$ are the vectors of the data and of their Fourier ordinates respectively.

6.4 Spectral representations of a stationary process

The various equations of the Fourier analysis of a finite data sequence can also be used to describe the processes that generate the data. Thus, within the equation:

$$\begin{aligned} y_t &= \sum_{j=0}^{n} \Big\{ \alpha_j \cos(\omega_j t) + \beta_j \sin(\omega_j t) \Big\} \\ &= \zeta_0 + \sum_{j=1}^{n} \Big\{ \zeta_j e^{\mathrm{i}\omega_j t} + \zeta_j^* e^{-\mathrm{i}\omega_j t} \Big\}, \end{aligned} \tag{6.22}$$

the quantities α_j, β_j can be taken to represent independent real-valued random variables, and the quantities:

$$\zeta_j = \frac{\alpha_j - \mathrm{i}\beta_j}{2} \qquad \text{and} \qquad \zeta_j^* = \frac{\alpha_j + \mathrm{i}\beta_j}{2} \tag{6.23}$$

can be regarded as complex-valued random variables.

The autocovariance of the elements y_t and y_s is given by:

$$\begin{aligned} E(y_t y_s) = \sum_{j=0}^{n}\sum_{k=0}^{n} E\Big[&\zeta_j \zeta_k e^{\mathrm{i}(\omega_j t + \omega_k s)} + \zeta_j \zeta_k^* e^{\mathrm{i}(\omega_j t - \omega_k s)} \\ &+ \zeta_j^* \zeta_k e^{\mathrm{i}(\omega_k s - \omega_j t)} + \zeta_j^* \zeta_k^* e^{-\mathrm{i}(\omega_j t + \omega_k s)} \Big]. \end{aligned} \tag{6.24}$$

The condition of stationarity requires that the covariance should be a function only of the temporal separation $|t - s|$ of y_t and y_s. For this, it is necessary that:

$$E(\zeta_j \zeta_k) = E(\zeta_j^* \zeta_k^*) = E(\zeta_j^* \zeta_k) = E(\zeta_j \zeta_k^*) = 0, \tag{6.25}$$

whenever $j \neq k$. Also, the conditions:

$$E(\zeta_j^2) = 0 \quad \text{and} \quad E(\zeta_j^{*2}) = 0, \tag{6.26}$$

must hold for all j. For (6.25) and (6.26) to hold, it is sufficient that:

$$E(\alpha_j \beta_k) = 0 \quad \text{for all} \quad j, k, \tag{6.27}$$

and that:

$$E(\alpha_j \alpha_k) = E(\beta_j \beta_k) = \begin{cases} 0, & \text{if } j \neq k; \\ \sigma_j^2, & \text{if } j = k. \end{cases} \tag{6.28}$$

An implication of the equality of the variances of α_j and β_j is that the phase angle θ_j is uniformly distributed in the interval $[-\pi, \pi]$.

Under these conditions, the autocovariance of the process at lag $\tau = t - s$ will be given by:

$$\gamma_\tau = \sum_{j=0}^{n} \sigma_j^2 \cos \omega_j \tau. \tag{6.29}$$

The variance of the process is just:

$$\gamma_0 = \sum_{j=0}^{n} \sigma_j^2, \tag{6.30}$$

which is the sum of the variances of the n individual periodic components. This is analogous to equation (6.13).

The stochastic model of equation (6.22) may be extended to encompass processes defined over the entire set of positive and negative integers as well as processes that are continuous in time. First, we may consider extending the length T of the sample indefinitely. As T and n increase, the Fourier coefficients become more numerous and more densely packed in the interval $[0, \pi]$. Also, given that the variance of the process is bounded, the variance of the individual coefficients must decrease.

To accommodate these changes, we may write $\alpha_j = dA(\omega_j)$ and $\beta_j = dB(\omega_j)$, where $A(\omega)$, $B(\omega)$ are cumulative step functions with discontinuities at the points $\{\omega_j; j = 0, \ldots, n\}$. In the limit, the summation in (6.22) is replaced by an integral, and the expression becomes:

$$\begin{aligned} y(t) &= \int_0^\pi \{\cos(\omega t) dA(\omega) + \sin(\omega t) dB)\omega)\} \\ &= \int_{-\pi}^{\pi} e^{\mathrm{i}\omega t} dZ(\omega), \end{aligned} \tag{6.31}$$

where:

$$\begin{aligned} dZ(\omega) &= \frac{1}{2}\{dA(\omega) - \mathrm{i} dB(\omega)\} \quad \text{and} \\ dZ(-\omega) &= dZ^*(\omega) = \frac{1}{2}\{dA(\omega) + \mathrm{i} dB(\omega)\}. \end{aligned} \tag{6.32}$$

Also, $y(t) = \{y_t; t = 0, \pm 1, \pm 2, \ldots\}$ stands for a doubly-infinite data sequence.

The assumptions regarding $dA(\omega)$ and $dB(\omega)$ are analogous to those regarding the random variables α_j and β_j, which are their prototypes. It is assumed that $A(\omega)$ and $B(\omega)$ represent a pair of stochastic processes of zero mean, which are indexed on the continuous parameter ω. Thus:

$$E\{dA(\omega)\} = E\{dB(\omega)\} = 0. \tag{6.33}$$

It is also assumed that the two processes are mutually uncorrelated and that non overlapping increments within each process are uncorrelated. Thus:

$$\begin{aligned} E\{dA(\omega)dB(\lambda)\} &= 0 \quad \text{for all} \quad \omega, \lambda, \\ E\{dA(\omega)dA(\lambda)\} &= 0 \quad \text{if} \quad \omega \neq \lambda, \\ E\{dB(\omega)dB(\lambda)\} &= 0 \quad \text{if} \quad \omega \neq \lambda. \end{aligned} \tag{6.34}$$

The variance of the increments is given by:

$$V\{dA(\omega)\} = V\{dB(\omega)\} = 2dF(\omega). \tag{6.35}$$

The function $F(\omega)$, which is defined provisionally over the interval $[0, \pi]$, is described as the spectral distribution function. The properties of variances imply that it is a non decreasing function of ω. In the case where the process $y(t)$ is purely random, $F(\omega)$ is a continuous differentiable function. Its derivative $f(\omega)$, which is nonnegative, is described as the spectral density function.

The domain of the functions $A(\omega)$, $B(\omega)$ may be extended from $[0, \pi]$ to $[-\pi, \pi]$ by regarding $A(\omega)$ as an even function such that $A(-\omega) = A(\omega)$ and by regarding $B(\omega)$ as an odd function such that $B(-\omega) = -B(\omega)$. Then, $dZ^*(\omega) = dZ(-\omega)$, in accordance with (6.32). From the conditions of (6.34), it follows that:

$$\begin{aligned} E\{dZ(\omega)dZ^*(\lambda)\} &= E\{dZ(\omega)dZ(-\lambda)\} = 0 \quad \text{if} \quad \omega \neq \lambda, \\ E\{dZ(\omega)dZ^*(\omega)\} &= E\{dZ(\omega)dZ(-\omega)\} = dF(\omega), \end{aligned} \tag{6.36}$$

where the domain of $F(\omega)$ is now the interval $[-\pi, \pi]$.

The sequence of the autocovariances of the process $y(t)$ may be expressed in terms of the spectrum of the process. From (6.36), it follows that the autocovariance of $y(t)$ at lag $\tau = t - s$ is given by:

$$\begin{aligned} \gamma_\tau = C(y_t, y_s) &= E\left\{ \int_\omega e^{i\omega t} dZ(\omega) \int_\lambda e^{i\lambda s} dZ(\lambda) \right\} \\ &= \int_\omega \int_\lambda e^{i\omega t} e^{i\lambda s} E\{dZ(\omega)dZ(\lambda)\} \\ &= \int_\omega e^{i\omega\tau} E\{dZ(\omega)dZ^*(\omega)\} \\ &= \int_{-\pi}^{\pi} e^{i\omega\tau} dF(\omega). \end{aligned} \tag{6.37}$$

In the case of a continuous spectral distribution function, we may write $dF(\omega) = f(\omega)d\omega$ in the final expression, where $f(\omega)$ is the spectral density function. If $f(\omega) = \sigma^2/2\pi$, then there is $\gamma_0 = \sigma^2$ and $\gamma_\tau = 0$ for all $\tau \neq 0$, which are the characteristics of a white-noise process comprising a sequence of independently and identically distributed random variables. Thus, a white-noise process has a uniform spectral density function.

The second way of extending the model is to allow the rate of sampling to increase indefinitely. In the limit, the sampled sequence becomes a continuum. Equation (6.31) will serve to represent a continuous process on the understanding that t is now a continuous variable. However, if the discrete-time process has been subject to aliasing, then the range of the frequency integral will increase as the rate of sampling increases.

Under any circumstances, it seems reasonable to postulate an upper limit to the range of the frequencies comprised by a stochastic process. However, within the conventional theory of continuous stochastic processes, it is common to consider an unbounded range of frequencies. In that case, we obtain a spectral representation of a stochastic process of the form:

$$y(t) = \int_{-\infty}^{\infty} e^{i\omega t} dZ(\omega). \tag{6.38}$$

This representation is capable, nevertheless, of subsuming a process that is limited in frequency. If the bandwidth of $Z(\omega)$ is indeed unbounded, then (6.38) becomes the spectral representation of a process comprising a continuous succession of infinitesimal impacts, which generates a trajectory that is everywhere continuous but nowhere differentiable.

Example Figure 6.7 shows the spectral density function of an autoregressive moving average ARMA(2, 2) process $y(t)$, described by the equation $\alpha(z)y(z) = \mu(z)\varepsilon(z)$, where $\alpha(z)$ and $\mu(z)$ are quadratic polynomials and $y(z)$ and $\varepsilon(z)$ are, respectively, the z-transforms of the data sequence $y(t) = \{y_t; t = 0, \pm 1, \pm 2, \ldots\}$ and of a white-noise sequence $\varepsilon(t) = \{\varepsilon_t; t = 0, \pm 1, \pm 2, \ldots\}$ of independently and identically distributed random variables.

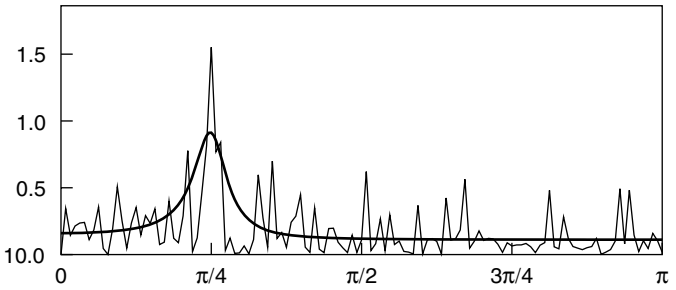

Figure 6.7 The periodogram of 256 points of a pseudo-random ARMA(2, 2) process overlaid by the spectral density function of the process

The ARMA(2, 2) process has been formed by the additive combination of a second-order autoregressive AR(2) process and an independent white-noise process. The autoregressive polynomial is $\alpha(z) = 1 + 2\rho\cos(\theta)z + \rho^2 z^2$, which has conjugate complex roots of which the polar forms are $\rho\exp\{\pm i\theta\}$. In the example, the modulus of the roots is $\rho = 0.9$ and their argument is $\theta = \pi/4$ radians.

The spectral density function attains a non-zero minimum at $\omega = \pi$. However, it is possible to decompose the ARMA(2, 2) process into an ARMA(2, 1) process and a white-noise component that has the maximum variance compatible with such a decomposition. This is a so-called canonical decomposition of the ARMA process. The moving-average polynomial of the resulting ARMA(2, 1) process is $1 + z$, which has a zero at $\omega = \pi$. By maximizing the variance of the white-noise component, an ARMA component is derived that is as smooth and as regular as possible.

Canonical decompositions are entailed in a method for extracting unobserved components from data sequences described by autoregressive integrated moving average (ARIMA) models, which will be discussed in section 6.6.3.

Figure 6.7 also shows a periodogram that has been calculated from a sample of 256 points generated by the ARMA(2, 2) process. Its volatility contrasts markedly with the smoothness of the spectrum. The periodogram has half as many ordinates as the data sequence and it inherits this volatility directly from the data. A nonparametric estimate of the spectrum may be obtained by smoothing the ordinates of the periodogram with an appropriately chosen moving average, or by subjecting the empirical autocovariances to an equivalent weighting operation before transforming them to the frequency domain.

6.4.1 The frequency-domain analysis of filtering

It is a straightforward matter to derive the spectrum of a process $y(t)$ formed by mapping the process $x(t)$ through a linear filter. If:

$$x(t) = \int_{\omega} e^{i\omega t} dZ_x(\omega), \tag{6.39}$$

then the filtered process is:

$$\begin{aligned} y(t) &= \sum_j \psi_j x(t-j) \\ &= \sum_j \psi_j \left\{ \int_{\omega} e^{i\omega(t-j)} dZ_x(\omega) \right\} \\ &= \int_{\omega} e^{i\omega t} \left(\sum_j \psi_j e^{-i\omega j} \right) dZ_x(\omega). \end{aligned} \tag{6.40}$$

On writing $\sum \psi_j e^{-i\omega j} = \psi(\omega)$, which is the frequency response function of the filter, this becomes:

$$\begin{aligned} y(t) &= \int_{\omega} e^{i\omega t} \psi(\omega) dZ_x(\omega) \\ &= \int_{\omega} e^{i\omega t} dZ_y(\omega). \end{aligned} \tag{6.41}$$

If the process $x(t)$ has a spectral density function $f_x(\omega)$, which will allow one to write $dF(\omega) = f(\omega)d\omega$ in equation (6.36), then the spectral density function $f_y(\omega)$ of the filtered process $y(t)$ will be given by:

$$\begin{aligned} f_y(\omega)d\omega &= E\{dZ_y(\omega)dZ_y^*(\omega)\} \\ &= \psi(\omega)\psi^*(\omega)E\{dZ_x(\omega)dZ_x^*(\omega)\} \\ &= |\psi(\omega)|^2 f_x(\omega)d\omega. \end{aligned} \tag{6.42}$$

The complex-valued frequency-response function $\psi(\omega)$, which characterizes the linear filter, can be written in polar form as:

$$\psi(\omega) = |\psi(\omega)|e^{-i\theta(\omega)}, \tag{6.43}$$

The function $|\psi(\omega)|$, which is described as the gain of the filter, indicates the extent to which the amplitude of the cyclical components of which $x(t)$ is composed are altered in the process of filtering.

When $x(t) = \varepsilon(t)$ is a white-noise sequence of independently and identically distributed random variables of variance σ^2, equation (6.42) gives rise to the expression $f_y(\omega) = \sigma^2|\psi(\omega)|^2 = \sigma^2\psi(\omega)\psi^*(\omega)$, which is the spectral density function of $y(t)$. Then, it is helpful to use the notation of the z-transform whereby $\psi(\omega)$ is written as $\psi(z) = \sum_j \psi_j z^j; z = e^{-i\omega}$. If we allow z to be an arbitrary complex number, then we can define the autocovariance generating function $\gamma(z) = \sum_\tau \gamma_\tau z^\tau$ wherein $\gamma_\tau = E(y_t y_{t-\tau})$. This takes the form of:

$$\gamma(z) = \sigma^2\psi(z)\psi(z^{-1}). \tag{6.44}$$

Example Figure 6.8 depicts the squared gain of the difference operator $\nabla(z) = 1 - z$, which is the curve labeled D. The squared gain of $\nabla(z)$ is obtained by setting $z = \exp\{-i\omega\}$ within $|\nabla(z)|^2 = (1 - z)(1 - z^{-1})$ to give $D(\omega) = 2 - 2\cos(\omega)$, whence $W(\omega) = D^{-1}(\omega)$ can be obtained, which is the squared gain of the summation operator. The product of $D(\omega)$ and $W(\omega)$ is the constant function $N(\omega) = 1$, which also represents the spectral density function or power spectrum of a white-noise process with a variance of $\sigma^2 = 2\pi$. Likewise, $W(\omega)$ represents the pseudo-spectrum of a first-order random walk.

This is not a well-defined spectral density function, since the random walk does not constitute a stationary process of a sort that can be defined over a doubly-infinite set of time indices. The unbounded nature of $W(\omega)$ as $\omega \to 0$ is testimony

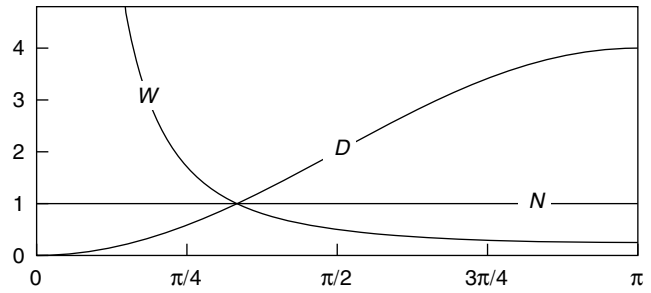

Figure 6.8 The squared gain of the difference operator, labeled D, and that of the summation operator, labeled W

to the fact that the variance of the random walk process is proportional to the time that has elapsed since its start-up. The variance will be unbounded if the start-up is in the indefinite past.

6.5 Stochastic accumulation

In the schematic model of the economy, we have envisaged business cycle fluctuations that are purely sinusoidal, and we have considered a trend that follows an exponential growth path. In a realistic depiction of an economy, both of these functions are liable to be more flexible and more variable through time.

Whereas, in some eras, a linear function, interpolated by least squares regression through the logarithms of the data, will serve as a benchmark about which to measure the cyclical economic activities, the latter usually require to be modeled by a stochastic process. It is arguable that the trend should also be modeled by a stochastic function.

A further feature of the schematic model, which is at odds with the available data, is the continuous nature of its functions. Whereas the processes that generate the data can be thought of as operating in continuous time, the sampled data are sequences of values that are indexed by dates at equal intervals. These data are liable to be modeled via discrete-time stochastic processes. Therefore, some attention needs be paid to the relationship between the discrete data and the underlying continuous process.

The theory of continuous-time stochastic models has been summarized by Bergstrom (1984, 1988), who researched the subject over a 40-year period, beginning in the mid 1960s. His posthumous contributions are to be found in Bergstrom and Nowman (2007), where the contributions of other authors are also referenced.

A linear stochastic process must have a *primum mobile* or forcing function, which is liable to be a stationary process. For the usual discrete-time processes, this is a white-noise sequence of independently and identically distributed random variables. In the theory of continuous stochastic processes, the forcing function consists, almost invariably, of the increments of a Wiener process, which is a process that has an infinite bandwidth in the frequency domain. Already, in

section 6.3, we have encountered a process with a limited bandwidth. Later, in section 6.9, we shall consider some further implications of a limited bandwidth.

The Wiener process $Z(t)$ is defined by the following conditions:

(a) $Z(0)$ is finite,
(b) $E\{Z(t)\} = 0$, for all t,
(c) $Z(t)$ is normally distributed,
(d) $dZ(s), dZ(t)$ for all $t \neq s$ are independent stationary increments,
(e) $V\{Z(t+h) - Z(t)\} = \sigma^2 h$ for $h > 0$.

The increments $dZ(s), dZ(t)$ are impulses that have a uniform power spectrum distributed over an infinite range of frequencies corresponding to the entire real line. Sampling $Z(t)$ at regular intervals to form a discrete-time white-noise process $\varepsilon(t) = Z(t+1) - Z(t)$ entails a process of aliasing, whereby the spectral power of the cumulated increments gives rise to a uniform spectrum of finite power over the frequency interval $[-\pi, \pi]$.

In general:

$$Z(t) = Z(a) + \int_a^t dZ(\tau), \tag{6.45}$$

where $Z(a)$ is a finite starting value at time a. However, if $Z(t)$ were differentiable, as some forcing functions may be, then we should have $dZ(t) = \{dZ(t)/dt\}dt$.

The simplest of stochastic differential equations is the first-order equation, which takes the form:

$$\frac{dx(t)}{dt} - \lambda x(t) = dZ(t) \quad \text{or} \quad (D - \lambda)x(t) = dZ(t). \tag{6.46}$$

Multiplying throughout by the factor $\exp\{-\lambda t\}$ gives:

$$e^{-\lambda t}Dx(t) - \lambda e^{-\lambda t}x(t) = D\{x(t)e^{-\lambda t}\} = e^{-\lambda t}dZ(t), \tag{6.47}$$

where the first equality follows from the product rule of differentiation. Integrating $D\{x(t)e^{-\lambda t}\} = e^{-\lambda t}dZ(t)$ gives:

$$x(t)e^{-\lambda t} = \int_{-\infty}^t e^{-\lambda \tau}dZ(\tau), \tag{6.48}$$

or:

$$x(t) = e^{\lambda t}\int_{-\infty}^t e^{-\lambda \tau}dZ(\tau) = \int_{-\infty}^t e^{\lambda(t-\tau)}dZ(\tau). \tag{6.49}$$

If we write $x(t) = (D - \lambda)^{-1}dZ(t)$, then we get the result that:

$$x(t) = \frac{1}{D - \lambda}dZ(t) = \int_{-\infty}^t e^{\lambda(t-\tau)}dZ(\tau), \tag{6.50}$$

from which it is manifest that the necessary and sufficient condition for stability is that $\lambda < 0$. That is to say, the root of the equation $D - \lambda = 0$, which indicates the rate of decay of the increments, must be less than zero.

The general solution of a differential equation should normally comprise a particular solution, which represents the effects of the initial conditions. However, given that their effects decay as time elapses and given that, in this case, the integral has no lower limit, no account needs to be taken of initial conditions.

When the process is observed at the integer time points $\{t = 0, \pm 1, \pm 2, \ldots\}$, it is appropriate to express it as:

$$\begin{aligned} x(t) &= e^{\lambda} \int_{-\infty}^{t-1} e^{\lambda(t-1-\tau)} dZ(\tau) + \int_{t-1}^{t} e^{\lambda(t-\tau)} dZ(\tau) \\ &= e^{\lambda} x(t-1) + \int_{t-1}^{t} e^{\lambda(t-\tau)} dZ(\tau). \end{aligned} \tag{6.51}$$

This gives rise to a discrete-time equation of the form:

$$x(t) = \phi x(t-1) + \varepsilon(t), \quad \text{or} \quad (1 - \phi L)x(t) = \varepsilon(t), \tag{6.52}$$

where:

$$\phi = e^{\lambda} \quad \text{and} \quad \varepsilon(t) = \int_{t-1}^{t} e^{\lambda(t-\tau)} dZ(\tau), \tag{6.53}$$

and where L is the lag operator, which has the effect that $Lx(t) = x(t-1)$.

The second-order equation may be expressed as follows:

$$(D^2 + \varphi_1 D + \varphi_2)x(t) = (D - \lambda_1)(D - \lambda_2)x(t) = dZ(t). \tag{6.54}$$

Using a partial-fraction expansion, this can be cast in the form of:

$$\begin{aligned} x(t) &= \frac{1}{\lambda_1 - \lambda_2} \left\{ \frac{1}{D - \lambda_1} - \frac{1}{D - \lambda_2} \right\} dZ(t) \\ &= \int_{-\infty}^{t} \left\{ \frac{e^{\lambda_1(t-\tau)} - e^{\lambda_2(t-\tau)}}{\lambda_1 - \lambda_2} \right\} dZ(\tau). \end{aligned} \tag{6.55}$$

Here, the final equality depends upon the result under (6.50). If the roots λ_1, λ_2 have real values, then the condition of stability is that $\lambda_1, \lambda_2 < 0$. If the roots are conjugate complex numbers, then the condition for stability is that they must lie in the left half of the complex plane. In that case, the trajectory of $x(t)$ will have a damped quasi-sinusoidal motion of a sort that is characteristic of the business cycle.

Equation (6.55) gives rise to a second-order difference equation. In the manner that equation (6.50) leads to equation (6.52), we get:

$$\begin{aligned} x(t) &= \frac{1}{\lambda_1 - \lambda_2} \left\{ \frac{\varepsilon_1(t)}{1 - \kappa_1 L} + \frac{\varepsilon_2(t)}{1 - \kappa_2 L} \right\} \\ &= \frac{\theta_0 + \theta_1 L}{1 + \phi_1 L + \phi_2 L} \varepsilon(t). \end{aligned} \tag{6.56}$$

Here, $(\lambda_1-\lambda_2)(1-\kappa_1 L)(1-\kappa_2 L) = 1+\phi_1 L+\phi_2 L$, and we have defined $(\theta_0+\theta_1 L)\varepsilon(t) = (1-\phi_2 L)\varepsilon_1(t) + (1-\phi_1 L)\varepsilon_2(t)$, which is a first-order moving-average process. Equation (6.56) depicts an ARMA(2, 1) process in discrete time. The correspondence between the second-order differential equation and the ARMA(2, 1) process has been discussed by Phadke and Wu (1974) and Pandit and Wu (1975).

Autoregressive models of other orders may be derived in the same manner as the second-order model by putting polynomial functions of D of the appropriate degrees in place of the quadratic function. The models can also be elaborated by applying a moving-average operator or weighting function $\rho(\tau)$ to the stochastic forcing function $dZ(t)$. This gives a forcing function in the form of:

$$\eta(t) = \int_0^q \rho(\tau) dZ(t-\tau) = \int_{t-q}^t \rho(t-\tau) dZ(\tau). \tag{6.57}$$

The consequence of this elaboration for the corresponding discrete-time ARMA model is that its moving-average parameters are no longer constrained to be functions of the autoregressive parameters alone.

In modeling a stochastic trend, it is common to adopt a first- or second-order process in which the roots are set to zeros. In that case, the stochastic increments are accumulated without decay. Therefore, it is crucial to specify the initial conditions of the process. We shall denote the process that is the m-fold integral of the incremental process $dZ(t)$ by $Z^{(m)}(t)$. Then, $Z^{(1)}(t)$ can stand for the Wiener process $Z(t)$, defined previously.

If the process has begun in the indefinite past, then there will be zero probability that its current value will be found within a finite distance from the origin. Therefore, we must impose the condition that, at any time that is at a finite distance both from the origin and from the current time, the process $Z^{(1)}(t)$ assumes a finite value. This allows us to write:

$$Z^{(1)}(t) = Z^{(1)}(t-h) + \int_{t-h}^t dZ^{(1)}(\tau), \tag{6.58}$$

where h is an arbitrary finite step in time and $a = t - h$ is a fixed point in time.

On this basis, the value of the integrated process at time t is:

$$\begin{aligned} Z^{(2)}(t) &= Z^{(2)}(t-h) + \int_{t-h}^t Z^{(1)}(\tau) d\tau \\ &= Z^{(2)}(t-h) + Z^{(1)}(t-h)h + \int_{t-h}^t (t-\tau) dZ^{(1)}(\tau). \end{aligned} \tag{6.59}$$

By proceeding through successive stages, we find that the mth integral is:

$$Z^{(m)}(t) = \sum_{k=0}^{m-1} Z^{(m-k)}(t-h)\frac{h^k}{k!} + \int_{t-h}^t \frac{(t-\tau)^{m-1}}{(m-1)!} dZ^{(1)}(\tau). \tag{6.60}$$

Here, the first term on the right-hand side is a polynomial in h, which is the distance in time from the fixed point a, whereas the second term is the m-fold integral of mean-zero stochastic increments, which constitutes a non-stationary process.

The covariance of the changes $Z^{(j)}(t) - Z^{(j)}(t-h)$ and $Z^{(k)}(t) - Z^{(k)}(t-h)$ of the jth and the kth integrated processes derived from $Z(t)$ is given by:

$$\begin{aligned} C\{z^{(j)}(t), z^{(k)}(t)\} &= \int_{s=t-h}^{t}\int_{r=t-h}^{t} \frac{(t-r)^{j-1}(t-s)^{k-1}}{j!k!} E\{dZ(r)dZ(s)\} \\ &= \sigma^2 \int_{t-h}^{t} \frac{(t-r)^{j+k-2}}{j!k!} dr = \sigma^2 \frac{h^{j+k-1}}{(j+k-1)j!k!}. \end{aligned} \tag{6.61}$$

A straightforward elaboration of the model of a stochastic trend arises when it is assumed that the expected value of the incremental process that is the forcing function has a non-zero mean. Then, $Z(t)$ is replaced by $\mu dt + dZ(t)$. This is the case of stochastic drift. If μ is relatively large, then it will make a significant contribution to the polynomial component, with the effect that the latter may become the dominant component.

6.5.1 Discrete-time representation of an integrated Wiener process

To derive the discretely sampled version of the integrated Wiener process, it may be assumed that values are sampled at regular intervals of h time units. Then, using the alternative notation of $\beta(t) = Z^{(1)}(t)$, equation (6.58) can be written as:

$$\beta(t) = \beta(t-h) + \varepsilon(t), \tag{6.62}$$

where $\varepsilon(t)$ is a white-noise process. With $\tau(t) = Z^{(2)}(t)$, equation (6.59) can be written as:

$$\tau(t) = \tau(t-h) + h\beta(t-h) + \nu(t), \tag{6.63}$$

where $\nu(t)$ is another white-noise process. Together, equations (6.62) and (6.63) constitute a so-called local linear model in which $\tau(t)$ represents the level and $\beta(t)$ represents the slope parameter. On taking the step length to be $h = 1$, the transition equation for this model is:

$$\begin{bmatrix} \tau(t) \\ \beta(t) \end{bmatrix} = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} \tau(t-1) \\ \beta(t-1) \end{bmatrix} + \begin{bmatrix} \nu(t) \\ \varepsilon(t) \end{bmatrix}. \tag{6.64}$$

Using the difference operator $\nabla = 1 - L$, the discrete-time processes entailed in this equation can be written as:

$$\begin{aligned} \nabla\tau(t) &= \tau(t) - \tau(t-1) = \beta(t-1) + \nu(t), \\ \nabla\beta(t) &= \beta(t) - \beta(t-1) = \varepsilon(t). \end{aligned} \tag{6.65}$$

Applying the difference operator a second time to the first of these and substituting for $\nabla\beta(t) = \varepsilon(t)$ gives:

$$\begin{aligned} \nabla^2\tau(t) &= \nabla\beta(t-1) + \nabla\nu(t) \\ &= \varepsilon(t-1) + \nu(t) - \nu(t-1). \end{aligned} \tag{6.66}$$

On the right-hand side of this equation is a sum of stationary stochastic processes, which can be expressed as an ordinary first-order moving-average process. Thus:

$$\varepsilon(t-1) + \nu(t) - \nu(t-1) = \eta(t) + \theta\eta(t-1), \tag{6.67}$$

where $\eta(t)$ is a white-noise process with $V\{\eta(t)\} = \sigma_\eta^2$. Therefore, the sampled version of the integrated Wiener process is a doubly-integrated IMA(2, 1) moving-average model.

The essential task is to find the values of the moving-average parameter θ. Thus is achieved by reference to equation (6.61), which provides the variances and covariances of the terms on the left-hand side of (6.67), from which the autocovariances of the MA process can be found. It can be shown that the variance and the autocovariance at lag 1 of this composite process are given by:

$$\gamma_0 = \frac{2\sigma_\varepsilon^2}{3} = \sigma_\eta^2(1+\theta^2) \qquad \text{and} \qquad \gamma_1 = \frac{\sigma_\varepsilon^2}{6} = \sigma_\eta^2\theta. \tag{6.68}$$

The equations must be solved for θ and σ_η^2. There are two solutions for θ, and we should take the one which fulfils the condition of invertibility: $\theta = 2 - \sqrt{3}$. (See Pollock, 1999.)

When white-noise errors of observation are superimposed upon values sampled from an integrated Wiener process at regular intervals, the resulting sequence can be described by a doubly-integrated second-order moving-average process in discrete time, which is an IMA(2, 2) process. Such a model provides the basis for the cubic smoothing spline of Reinsch (1976), which can be used to extract an estimate of the trajectory of the underlying integrated Wiener process from the noisy data. The statistical interpretation of the smoothing spline is due to Wahba (1978).

The smoothing spline interpolates cubic polynomial segments between nodes that are derived by smoothing a sequence of sampled data points. The segments are joined in such a way as to ensure that the second derivative of the spline function is continuous at the nodes. An account of the algorithm of the smoothing spline and of its derivation from the statistical model has been provided by Pollock (1999). It is shown that the means by which the nodes are obtained from the data amount to a so-called discrete-time Wiener–Kolmogorov (WK) filter.

The Wiener–Kolmogorov principle can also be used to derive the so-called Hodrick–Prescott (HP) filter, which is widely employed in macroeconomic analysis – see Hodrick and Prescott (1980, 1997). The filter, which is presented in section 6.6.2, is derived from the assumption that the process that generates the trend is a doubly-integrated discrete-time white noise. When white-noise errors are added to the sampled values of the process, the observations are once more described by an IMA(2, 2) model, and the nodes that are generated by the WK trend-extraction filter are analogous to those of the smoothing spline.

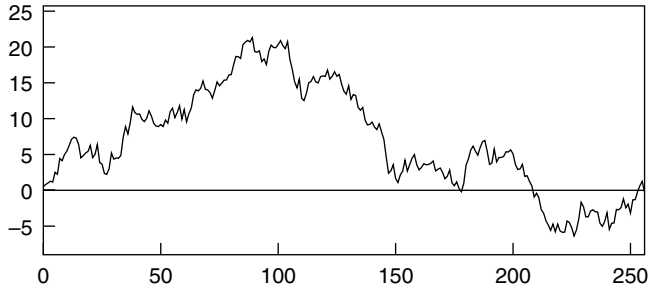

Figure 6.9 The graph of 256 observations on a simulated series generated by a random walk

The trend that is generated by the smoothing spline is an aesthetically pleasing curve, of which the smoothness belies the disjunct nature of the stochastic forcing function. That nature is more clearly revealed in the case of a model that postulates a trend that is generated by an ordinary Wiener process, as opposed to an integrated process. The discrete-time observations, which are affected by white-noise errors, are modeled by an IMA(1, 1) process, which also corresponds to the local level model that has been advocated by Harvey (1985, 1989), amongst others. The function that provides statistical estimates of the trend at the nodes and at the points between them has jointed linear segments.

It should be recognized that, if the forcing function were assumed to be bounded in frequency, then the interpolating function would be a smooth one, generated by a Fourier interpolation, that would have no discontinuities at the nodes.

In section 6.9, we shall return to the question of how best to specify the continuous-time forcing function. In the next section, we shall deal exclusively with discrete-time models, and we shall examine various ways of decomposing into its component parts a model of an aggregate process that combines the trend and the cycles.

Example A Wiener process, which is everywhere continuous but nowhere differentiable, can be represented graphically only via its sampled ordinates. If the sampling is sufficiently rapid to give a separation between adjacent points that is below the limits of visual acuity, then the sampled process, which constitutes a discrete-time random walk, will give the same visual impression as the underlying Wiener process. This is the intended effect of Figure 6.9.

Figure 6.10 depicts the trajectory of the IMA(2, 1) process that represents the sampled version of an integrated Wiener process. This is a much smoother trajectory than that of the random walk. The extra smoothness can be attributed to the effect of the summation operator, of which the squared gain has been depicted in Figure 6.8. The operator amplifies the sinusoidal elements in the lower part of the frequency range and attenuates those in the upper part.

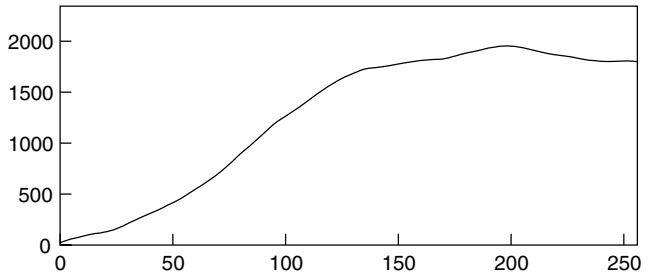

Figure 6.10 The graph of 256 observations on a simulated series generated by an IMA(2, 1) process that correspond to the sampled version of an integrated Wiener process

6.6 Decomposition of discrete-time ARIMA processes

An ARMA model can be represented by the equation:

$$\sum_{i=0}^{p} \phi_i y_{t-i} = \sum_{i=0}^{q} \theta_i \varepsilon_{t-i} \quad \text{with} \quad \phi_0 = \theta_0 = 1, \tag{6.69}$$

where t has whatever range is appropriate to the analysis. To exploit the algebra of polynomial operators, the equation can be embedded within the system:

$$\phi(z)y(z) = \theta(z)\varepsilon(z), \tag{6.70}$$

where $\varepsilon(z) = z^t\{\varepsilon_t + \varepsilon_{t-1}z^{-1} + \cdots\}$ is a z-transform of the infinite white-noise forcing function or disturbance sequence $\{\varepsilon_{t-i}; i = 0, 1, \ldots\}$ and where $y(z)$ is the z-transform of the corresponding data sequence. The embedded equation will be associated with z^t.

The polynomials $\theta(z)$ and $\phi(z)$ must have all their roots outside the unit circle to make their inverses, $\theta^{-1}(z)$ and $\phi(z)^{-1}$, amenable to power series expansions when $|z| \geq 1$. Then, it is possible to represent the system of (6.70) by the equation $y(z) = \phi^{-1}(z)\theta(z)\varepsilon(z)$.

An ARIMA process represents the accumulation of the output of an ARMA process. On defining the (backwards) difference operator $\nabla(z) = 1 - z$, the dth-order model can be represented by:

$$\nabla^d(z)\alpha(z)y(z) = \theta(z)\varepsilon(z). \tag{6.71}$$

The inverse of the difference operator is the summation operator $\nabla^{-1}(z) = \{1 + z + z^2 + \cdots\}$, and this might be used in representing the system of (6.71), alternatively, by the equation $y(z) = \nabla^{-d}(z)\alpha^{-1}(z)\theta(z)\varepsilon(z)$.

The difficulty here is that, if it is formed from an infinite number of independently and identically distributed random variables, the disturbance sequence cannot have a finite sum. For this reason, it appears that the algebra of polynomial operators cannot be applied to the analysis of non-stationary processes.

The usual recourse in the face of this problem is scrupulously to avoid the use of the cumulation operator $\nabla^{-1}(z)$ and to represent the integrated system only in the form of (6.71). This is not a wholly adequate solution to the problem since, to exploit the algebra of the operators, it is necessary to define the inverses of all of the polynomial operators. An alternative solution is to constrain the disturbance sequence to be absolutely summable, which appears to negate the assumption that it is generated by a stationary stochastic process.

The proper recourse is to replace the process of indefinite summation by a definite summation that depends upon supplying the system with initial conditions at some adjacent points in time. To show what this entails, we may consider the system of equations that is derived from (6.69) by setting $t = 0, 1, \ldots, T-1$. The set of T equations can be arrayed in a matrix format as follows:

$$\begin{bmatrix} y_0 & y_{-1} & \cdots & y_{-p} \\ y_1 & y_0 & \cdots & y_{1-p} \\ \vdots & \vdots & \ddots & \vdots \\ y_p & y_{p-1} & \cdots & y_0 \\ \vdots & \vdots & & \vdots \\ y_{T-1} & y_{T-2} & \cdots & y_{T-p-1} \end{bmatrix} \begin{bmatrix} 1 \\ \phi_1 \\ \vdots \\ \phi_p \end{bmatrix} = \begin{bmatrix} \varepsilon_0 & \varepsilon_{-1} & \cdots & \varepsilon_{-q} \\ \varepsilon_1 & \varepsilon_0 & \cdots & \varepsilon_{1-q} \\ \vdots & \vdots & \ddots & \vdots \\ \varepsilon_q & \varepsilon_{q-1} & \cdots & \varepsilon_0 \\ \vdots & \vdots & & \vdots \\ \varepsilon_{T-1} & \varepsilon_{T-2} & \cdots & \varepsilon_{T-q-1} \end{bmatrix} \begin{bmatrix} 1 \\ \theta_1 \\ \vdots \\ \theta_q \end{bmatrix}. \tag{6.72}$$

Apart from the elements $y_0, y_1, \ldots, y_{T-1}$ and $\varepsilon_0, \varepsilon_1, \ldots, \varepsilon_{T-1}$, which fall within the indicated period, these equations comprise the values $y_{-p}, \ldots, y_{-1}$ and $\varepsilon_{-q}, \ldots, \varepsilon_{-1}$, which are to be found in the top-right corners of the matrices, and which constitute the initial conditions at the start-up time of $t = 0$.

Each of the elements within this display can be associated with the power of z that is indicated by the value of its subscripted index. In that case, the system can be represented by equation (6.70) with the constituent polynomials defined as follows:

$$\begin{aligned} y(z) &= y_{-p}z^{-p} + \cdots + y_0 + y_1 z + \cdots + y_{T-1}z^{T-1}, \\ \varepsilon(z) &= \varepsilon_{-q}z^{-q} + \cdots + \varepsilon_0 + \varepsilon_1 z + \cdots + \varepsilon_{T-1}z^{T-1}, \\ \phi(z) &= 1 + \phi_1 z + \cdots + \phi_p z^p \quad \text{and} \\ \theta(z) &= 1 + \theta_1 z + \cdots + \theta_q z^q. \end{aligned} \tag{6.73}$$

This scheme applies regardless of the values of the roots of the polynomial operators $\phi(z)$ and $\theta(z)$. Therefore, it can accommodate the case where $\phi(z) = \nabla^d(z)\alpha(z)$, which is that of equation (6.71). One of the virtues of this notation is that it is not burdened by an explicit representation of the initial conditions. At a later stage, in section 6.7, we shall need to represent the initial conditions explicitly.

A trend has only a tenuous existence within the context of a univariate ARIMA model of the sort represented by equation (6.71). In such a model, it amounts to nothing more that the accumulation of the fluctuations that are created by

applying a filter $\theta(z)/\alpha(z)$ to a white-noise sequence $\varepsilon(t)$ of independently and identically distributed random variables.

If the trend and the transitory motions that accompany it are due to the same motive force, which is the white-noise process, then it is difficult to draw a distinction between them. However, a distinction can be made by attributing the trend to the unit roots within $\nabla^d(z) = (1-z)^d$ and by attributing the transitory motions to the stable roots of the autoregressive operator $\alpha(z)$. This is what the decomposition of Beveridge and Nelson (1981) achieves.

Faced with the insistence that the trend and the fluctuations are due to separate sources, an obvious recourse is to attribute separate and independent ARIMA models to each of them. In that case, the aggregate data are also described by a univariate ARIMA model. Provided that their models have distinct parameters, WK filters may be used tentatively to extract the independent components from the data.

The assumption that the components originate from transformations of white-noise sequences implies that their spectra extend over the entire frequency range $[0, \pi]$. This means that they are bound to overlap substantially. In practice, the spectral structures of the components are often confined to frequency bands that are separated by wide spectral dead spaces. In that case, the separation of one component from another can be achieved in a more decisive manner than the WK filters will usually allow.

6.6.1 The Beveridge–Nelson decomposition

The Beveridge–Nelson decomposition relates to an ARIMA model with first-order integration and with a stochastic drift. This can be represented in z-transform notation by:

$$y(z) = \frac{\mu(z)}{\nabla(z)} + \frac{\theta(z)}{\alpha(z)\nabla(z)}\varepsilon(z). \tag{6.74}$$

If the system has a start-up at $t = 0$, then $\mu(z)$, which represents the drift, is the z-transform of a sequence that is constant over the integers $0, 1, \ldots, t$ and zero-valued for $t < 0$. The operator associated with $\varepsilon(z)$ has the following partial-fraction decomposition:

$$\frac{\theta(z)}{\alpha(z)\nabla(z)} = \frac{\rho(z)}{\alpha(z)} + \frac{\delta}{\nabla(z)}. \tag{6.75}$$

Multiplying both sides by $\nabla(z) = 1 - z$ and setting $z = 1$ gives $\delta = \theta(1)/\alpha(1)$, where the numerator and the denominator are just the sums of the polynomial coefficients. Substituting the result into equation (6.74) creates an additive decomposition of the form $y(z) = \tau(z) + \zeta(z)$, wherein:

$$\tau(z) = \frac{1}{\nabla(z)}\left\{\mu(z) + \delta\varepsilon(z)\right\}, \tag{6.76}$$

$$\zeta(z) = \frac{\rho(z)}{\alpha(z)}\varepsilon(z), \tag{6.77}$$

are respectively the trend component and the transitory component. This is the so-called Beveridge–Nelson decomposition.

The trend component of the Beveridge–Nelson decomposition is a first-order random walk with drift, whereas the transitory component is an ARMA process. The distinguishing feature of the decomposition is that both components have the same forcing function. It is easy to see that:

$$\tau(z) = \frac{\theta(1)}{\alpha(1)}\frac{\alpha(z)}{\theta(z)}y(z), \tag{6.78}$$

which is to say that the estimate of the trend is derived by applying an ordinary linear filter to the data sequence. The effect of the filter is to eliminate the ARMA factor from the data so as to deliver a pure random walk.

A common objection to the Beveridge–Nelson decomposition is that the resulting trend is liable to be too rough. This is a consequence of the fact that a random walk that is an accumulation of independently and identically distributed random variables comprises elements at all frequencies up to the limiting Nyquist frequency of π radians per sample period. Also, the decomposition makes no provision for the presence of seasonal fluctuations in the data. A more elaborate model can be proposed with the aim of overcoming these objections.

Consider the multiplicative seasonal ARIMA model of Box and Jenkins (1976), which can be represented by the equation:

$$\nabla^d(z)\nabla_s^D(z)y(z) = \mu(z) + \frac{\theta(z)\Theta(z^s)}{\alpha(z)A(z^s)}\varepsilon(z). \tag{6.79}$$

Here, $\alpha(z)$ and $\theta(z)$ are the autoregressive and moving-average polynomials that have appeared in equation (6.74), whereas $A(z)$ and $\Theta(z)$ are seasonal operators. Whereas $\nabla(z)$ continues to represent the ordinary difference operator, there is now a seasonal difference operator $\nabla_s(z) = 1 - z^s = (1 - z)S(z)$, which forms the differences between the data from the same season (or month) of two successive years. The factors of this operator are the ordinary difference operator and a seasonal summation operator $S(z) = 1 + z + z^2 + \cdots + z^{s-1}$. A decomposition can now be found of the form $y(z) = \tau(z) + \sigma(z) + \zeta(z)$, where:

$$\tau(z) = \frac{1}{\nabla^{d+D}}\{\mu(z) + \alpha(z)\varepsilon(z)\}, \tag{6.80}$$

$$\sigma(z) = \frac{\beta(z)}{S^D(z)}\varepsilon(z), \tag{6.81}$$

$$\zeta(z) = \frac{\gamma(z)}{\alpha(z)A(z^s)}\varepsilon(z), \tag{6.82}$$

are, respectively, the trend, the seasonal component and the transitory component. If the degree $d + D$ of the (ordinary) difference operator exceeds unity, then the trend is liable to be smoother than one generated by a first-order random walk. Also, the effect of $\alpha(z)$ might be further to attenuate the high-frequency elements of the forcing function, thereby enhancing the smoothness of the trend.

To enhance the smoothness of the trend and of the seasonal component yet further, an irregular component could be incorporated in the decomposition. The irregular elements could be extracted from the trend and the seasonal component and assigned to this additional term, which could be regarded as statistically independent of the primary forcing function $\varepsilon(t)$. However, from this point of view, it is natural to consider a model in which each of the components is driven by a statistically independent forcing function. Such a model is the basis of the Wiener–Kolmogorov methodology for signal extraction.

6.6.2 WK filtering

The modern theory of statistical signal extraction was formulated independently by Wiener (1941) and Kolmogorov (1941), who arrived at the same results in different ways. Whereas Kolmogorov took a time-domain approach to the problem, Wiener worked primarily in the frequency domain. However, the unification of the two approaches was soon achieved, and a modern account of the theory, which encompasses both, has been provided by Whittle (1983).

The purpose of a WK filter is to extract an estimate of a signal sequence $\xi(t)$ from an observable data sequence:

$$y(t) = \xi(t) + \eta(t), \tag{6.83}$$

which is afflicted by the noise $\eta(t)$. According to the classical assumptions, which we shall later amend, the signal and the noise are generated by zero-mean stationary stochastic processes that are mutually independent. Also, the assumption is made that the data constitute a doubly-infinite sequence. It follows that the autocovariance generating function of the data is the sum of the autocovariance generating functions of its two components. Thus:

$$\gamma^{yy}(z) = \gamma^{\xi\xi}(z) + \gamma^{\eta\eta}(z) \quad \text{and} \quad \gamma^{\xi\xi}(z) = \gamma^{y\xi}(z). \tag{6.84}$$

These functions are amenable to the so-called Cramér–Wold factorization, and they may be written as:

$$\gamma^{yy}(z) = \phi(z^{-1})\phi(z), \quad \gamma^{\xi\xi}(z) = \theta(z^{-1})\theta(z), \quad \gamma^{\eta\eta}(z) = \theta_\eta(z^{-1})\theta_\eta(z). \tag{6.85}$$

The estimate x_t of the signal element ξ_t is a linear combination of the elements of the data sequence:

$$x_t = \sum_j \beta_j y_{t-j}. \tag{6.86}$$

The principle of minimum mean square error estimation indicates that the estimation errors must be statistically uncorrelated with the elements of the

information set. Thus, the following condition applies for all k:

$$\begin{aligned} 0 &= E\Big\{y_{t-k}(\xi_t - x_t)\Big\} \\ &= E(y_{t-k}\xi_t) - \sum_j \beta_j E(y_{t-k}y_{t-j}) \\ &= \gamma_k^{y\xi} - \sum_j \beta_j \gamma_{k-j}^{yy}. \end{aligned} \tag{6.87}$$

The equation may be expressed, in terms of the z-transforms, as:

$$\gamma^{y\xi}(z) = \beta(z)\gamma^{yy}(z). \tag{6.88}$$

It then follows that:

$$\begin{aligned} \beta(z) &= \frac{\gamma^{y\xi}(z)}{\gamma^{yy}(z)} \\ &= \frac{\gamma^{\xi\xi}(z)}{\gamma^{\xi\xi}(z) + \gamma^{\eta\eta}(z)} = \frac{\theta(z^{-1})\theta(z)}{\phi(z^{-1})\phi(z)}. \end{aligned} \tag{6.89}$$

Now, by setting $z = \exp\{\mathrm{i}\omega\}$, one can derive the frequency-response function of the filter that is used in estimating the signal $\xi(t)$. The effect of the filter is to multiply each of the frequency elements of $y(t)$ by the fraction of its variance that is attributable to the signal. The same principle applies to the estimation of the residual component. This is obtained using the complementary filter:

$$\beta^c(z) = 1 - \beta(z) = \frac{\gamma^{\eta\eta}(z)}{\gamma^{\xi\xi}(z) + \gamma^{\eta\eta}(z)}. \tag{6.90}$$

The estimated signal component may be obtained by filtering the data in two passes according to the following equations:

$$\phi(z)q(z) = \theta(z)y(z), \quad \phi(z^{-1})x(z^{-1}) = \theta(z^{-1})q(z^{-1}). \tag{6.91}$$

The first equation relates to a process that runs forwards in time to generate the elements of an intermediate sequence, represented by the coefficients of $q(z)$. The second equation represents a process that runs backwards to deliver the estimates of the signal, represented by the coefficients of $x(z)$.

The Wiener–Kolmogorov methodology can be applied to non-stationary data with minor adaptations. A model of the processes underlying the data can be adopted that has the form:

$$\begin{aligned} \nabla^d(z)y(z) &= \nabla^d(z)\{\xi(z) + \eta(z)\} = \delta(z) + \kappa(z) \\ &= (1+z)^n\zeta(z) + (1-z)^m\varepsilon(z), \end{aligned} \tag{6.92}$$

where $\zeta(z)$ and $\varepsilon(z)$ are the z-transforms of two independent white-noise sequences $\zeta(t)$ and $\varepsilon(t)$. The condition $m \geq d$ is necessary to ensure the stationarity of $\eta(t)$,

which is obtained from $\varepsilon(t)$ by differencing $m - d$ times. Then, the filter that is applied to $y(t)$ to estimate $\xi(t)$, which is the d-fold integral of $\delta(t)$, takes the form:

$$\beta(z) = \frac{\sigma_\zeta^2(1+z^{-1})^n(1+z)^n}{\sigma_\zeta^2(1+z^{-1})^n(1+z)^n + \sigma_\varepsilon^2(1-z^{-1})^m(1-z)^m}, \tag{6.93}$$

regardless of the degree d of differencing that would be necessary to reduce $y(t)$ to stationarity.

Two special cases are of interest. By setting $d = m = 2$ and $n = 0$ in (6.92), a model is obtained of a second-order random walk $\xi(t)$ affected by white-noise errors of observation $\eta(t) = \varepsilon(t)$. The resulting lowpass WK filter, in the form:

$$\beta(z) = \frac{1}{1 + \lambda(1-z^{-1})^2(1-z)^2} \quad \text{with} \quad \lambda = \frac{\sigma_\eta^2}{\sigma_\delta^2}, \tag{6.94}$$

is the HP filter. The complementary highpass filter, which generates the residue, is:

$$\beta^c(z) = \frac{(1-z^{-1})^2(1-z)^2}{\lambda^{-1} + (1-z^{-1})^2(1-z)^2}. \tag{6.95}$$

Here, λ, which is described as the smoothing parameter, is the single adjustable parameter of the filter.

By setting $m = n$, a filter for estimating $\xi(t)$ is obtained that takes the form:

$$\begin{aligned}\beta(z) &= \frac{\sigma_\zeta^2(1+z^{-1})^n(1+z)^n}{\sigma_\zeta^2(1+z^{-1})^n(1+z)^n + \sigma_\varepsilon^2(1-z^{-1})^n(1-z)^n} \\ &= \frac{1}{1 + \lambda\left(\mathrm{i}\dfrac{1-z}{1+z}\right)^{2n}} \quad \text{with} \quad \lambda = \frac{\sigma_\varepsilon^2}{\sigma_\zeta^2}.\end{aligned} \tag{6.96}$$

This is the formula for the Butterworth lowpass digital filter. The filter has two adjustable parameters and, therefore, is a more flexible device than the HP filter. First, there is the parameter λ. This can be expressed as:

$$\lambda = \{1/\tan(\omega_d)\}^{2n}, \tag{6.97}$$

where ω_d is the nominal cut-off point of the filter, which is the mid-point in the transition of the filter's frequency response from its pass band to its stop band. The second of the adjustable parameters is n, which denotes the order of the filter. As n increases, the transition between the pass band and the stop band becomes more abrupt.

These filters can be applied to the non-stationary data sequence $y(t)$ in the manner indicated by equation (6.91), provided that the appropriate initial conditions are supplied with which to start the recursions. However, by concentrating on the estimation of the residual sequence $\eta(t)$, which corresponds to a stationary process,

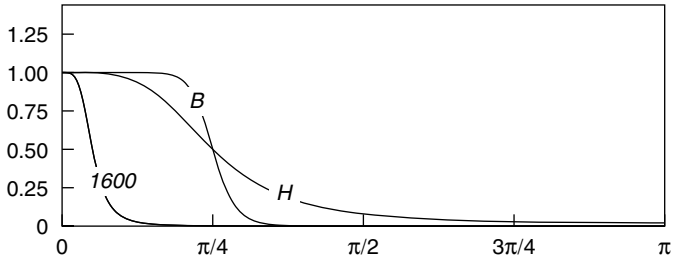

Figure 6.11 The gain of the HP filter H and of the Butterworth filter B with nominal cut-off points at $\pi/4$ radians, together with the gain of an HP filter with a smoothing parameter of 1600

it is possible to avoid the need for non-zero initial conditions. The estimate of $\eta(t)$ can then be subtracted from $y(t)$ to obtain the estimate of $\xi(t)$.

The HP filter has many antecedents. Its invention cannot reasonably be attributed to Hodrick and Prescott (1980, 1997), who cited Whittaker (1923) as one of their sources. Leser (1961) also provided a complete derivation of the filter at an earlier date. The Butterworth filter is a commonplace of electrical engineering. The digital version of the filter has been described in an econometric context by Pollock (2000) and by Gómez (2001). It has been applied to climatological data by Harvey and Mills (2003).

Example Figure 6.11 shows the gain functions of the three filters overlaid on the same diagram. The lowpass HP filter with a smoothing parameter of $\lambda = 1600$ is commonly recommended for estimating the trend in quarterly economic data. The corresponding gain function is marked in the diagram by the number 1600.

An alternative to specifying the smoothing parameter directly is to specify the frequency value ω_d for which the gain is $\beta(\omega_d) = 0.5$. For the HP filter, the correspondence between ω_d and λ is as follows:

$$\lambda = \frac{1}{4\{1 - \cos(\omega_d)\}^2} \quad \text{and} \quad \omega_d = \cos^{-1}(1 - 1\sqrt{4\lambda}). \tag{6.98}$$

The frequency ω_d corresponds to the mid-point in the transition between the pass band and the stop band of the filter. This might be described as the nominal cut-off frequency, but, in the case of the HP filter, this is a misnomer, on account of the very gradual transition of the gain. The Butterworth filter is capable of a much more rapid transition. The curve labeled B corresponds to the gain of a Butterworth filter with $n = 6$ and $\omega_d = \pi/4$.

6.6.3 Structural ARIMA models

The HP filter and the Butterworth filter are appropriate to the task of extracting the trend or the trend/cycle component from a data sequence without regard to the

structure of the residual component. More elaborate filters are available that also take account of a seasonal component.

Consider, therefore, a seasonal ARIMA model of the form:

$$y(z) = \frac{\theta(z)}{\phi(z)}\varepsilon(z) = \frac{\theta(z)}{\phi_S(z)\phi_T(z)}\varepsilon(z), \tag{6.99}$$

where $\phi_S(z)$ contains the seasonal autoregressive factors and $\phi_T(z)$ contains the non-seasonal factors.

The denominator contains both an ordinary differencing operator $\nabla^d(z)$ and a seasonal differencing operator $\nabla_s^D(z) = \nabla^D(z)S^D(z)$. The operator $\nabla_s(z) = 1 - z^s = (1-z)S(z)$ forms the differences between the data from the same season (or month) of two successive years. Its factors are the ordinary difference operator and a seasonal summation operator $S(z) = 1 + z + z^2 + \cdots + z^{s-1}$. The factorization of the seasonal operator implies that the overall degree of differencing within the ARIMA model is $d + D$. The factor $\nabla^{d+D}(z)$ is assigned to $\phi_T(z)$, whereas $S^D(z)$ belongs to $\phi_S(z)$.

On the assumption that the degree of the moving-average polynomial $\theta(z)$ is at least equal to that of the denominator polynomial $\phi(z)$, there is a partial-fraction decomposition of the autocovariance generating function of the model into three components, which correspond to the trend effect, the seasonal effect and an irregular influence. Thus:

$$\frac{\theta(z^{-1})\theta(z)}{\phi_S(z^{-1})\phi_T(z^{-1})\phi_T(z)\phi_S(z)} = \frac{Q_T(z)}{\phi_T(z^{-1})\phi_T(z)} + \frac{Q_S(z)}{\phi_S(z^{-1})\phi_S(z)} + R(z). \tag{6.100}$$

Here, the first two components on the right-hand side represent proper rational fractions, whereas the final component is an ordinary polynomial. If the degree of the moving-average polynomial is less than that of the denominator polynomial, then the irregular component is missing from the decomposition in the first instance.

To obtain the spectral density function of $y(t)$, we set $z = e^{-i\omega}$, where $\omega \in [0, \pi]$. (This function is more properly described as a pseudo-spectrum in view of the singularities occasioned by the unit roots in the denominators of the first two components.) The spectral decomposition corresponding to equation (6.100) can be written as:

$$f(\omega) = f(\omega)_T + f(\omega)_S + f(\omega)_R, \tag{6.101}$$

where $f(\omega) = \theta(e^{i\omega})\theta(e^{-i\omega})/\{\phi(e^{i\omega})\phi(e^{-i\omega})\}$.

Let $\nu_T = \min\{f(\omega)_T\}$ and $\nu_S = \min\{f(\omega)_S\}$. These correspond to the elements of white noise embedded in $f(\omega)_T$ and $f(\omega)_S$. The principle of canonical decomposition is that the white-noise elements should be reassigned to the residual component. On defining:

$$\begin{aligned} \gamma_T(z)\gamma_T(z^{-1}) &= Q_T(z) - \nu_T\phi_T(z)\phi_T(z^{-1}), \\ \gamma_S(z)\gamma_S(z^{-1}) &= Q_S(z) - \nu_S\phi_S(z)\phi_S(z^{-1}), \\ \text{and} \quad \rho(z)\rho(z^{-1}) &= R(z) + \nu_T + \nu_S, \end{aligned} \tag{6.102}$$

the canonical decomposition of the generating function can be represented by:

$$\frac{\theta(z)\theta(z^{-1})}{\phi(z)\phi(z^{-1})} = \frac{\gamma_T(z)\gamma_T(z^{-1})}{\phi_T(z)\phi_T(z^{-1})} + \frac{\gamma_S(z)\gamma_S(z^{-1})}{\phi_S(z)\phi_S(z^{-1})} + \rho(z)\rho(z^{-1}). \tag{6.103}$$

There are now two improper rational functions on the right-hand side, which have equal degrees in their numerators and denominators.

According to Wiener–Kolmogorov theory, the optimal signal-extraction filter for the trend component is:

$$\begin{aligned}\beta_T(z) &= \frac{\gamma_T(z)\gamma_T(z^{-1})}{\phi_T(z)\phi_T z^{-1})} \times \frac{\phi_S(z)\phi_T(z)\phi_T(z^{-1})\phi_S(z^{-1})}{\theta(z)\theta(z^{-1})} \\ &= \frac{\gamma_T(z)\gamma_T(z^{-1})\phi_S(z)\phi_S(z^{-1})}{\theta(z)\theta(z^{-1})} = \frac{C_T(z)}{\theta(z)\theta(z^{-1})}.\end{aligned} \tag{6.104}$$

This has the form of the ratio of the autocovariance generating function of the trend component to the autocovariance generating function of the process $y(t)$. This formulation presupposes a doubly-infinite data sequence, so it must be translated into a form that can be implemented with finite sequences.

The approach to the estimation of unobserved components that adopts the principle of canonical decompositions has been advocated by Hillmer and Tiao (1982) and Maravall and Pierce (1987). It has been implemented in the TRAMO–SEATS program of Gómez and Maravall (1996) and Caporello and Maravall (2004), which builds upon the work of Burman (1980).

6.6.4 The state-space form of the structural model

In the foregoing approach to modeling the components of a structural time series model, an aggregate univariate process is first estimated and then decomposed into its components. An alternative approach is to model the individual components from the start as separate entities, which are described by independent linear stochastic models.

Provision can be made for a cyclical component which is distinct from the trend component, but, if this is omitted, then the disaggregated model commonly takes the form of $y(z) = \tau(z) + \sigma(z) + \eta(z)$, where:

$$\tau(z) = \frac{(1+\alpha z)}{\nabla^2(z)}\zeta(z), \tag{6.105}$$

$$\sigma(z) = \frac{1}{S(z)}\omega(z). \tag{6.106}$$

$\tau(t)$ is the trend, $\sigma(t)$ is the seasonal component and $\eta(t)$ is the irregular noise. Here there are three independent white-noise processes driving the model, which are $\zeta(t)$, $\omega(t)$ and $\eta(t)$. The model has been described by Harvey (1989) as the basic structural model. A reason for omitting the cyclical or business-cycle component from this model is the difficulty in separating it from the trend component.

The trend process is usually depicted as the product of two processes that constitute the so-called local linear model, which has already been described in section 6.5.1:

$$\tau(t) = \tau(t-1) + \beta(t) + \nu(t), \tag{6.107}$$

$$\beta(t) = \beta(t-1) + \varepsilon(t). \tag{6.108}$$

The first of these describes the level of the trend process and the second describes its slope.

A more elaborate seasonal model is available that generates more regular cycles. A moving-average operator $M(z)$ can be included in the numerator of the expression on the right-hand side of (6.106) to give $\sigma(z) = \{M(z)/S(z)\}\omega(z)$. The autoregressive operator may be factorized as $S(z) = \prod_{j=1}^{s-1}(1 - e^{2\pi j/s})$, where s is the number of observations per annum. The complementary moving-average operator will have the form of $M(z) = \prod_{j=1}^{s-1}(1 - \rho e^{2\pi j/s})$, where $\rho < 1$ is close to unity. The zeros of the moving-average operator will serve largely to negate the effects of the poles of the autoregressive operator, except at the seasonal frequencies, where prominent spectral spikes will be found.

The basic structural model, without the elaboration of a seasonal moving-average component, can be represented in a state-space form that comprises a transition equation, which describes a first-order vector autoregressive process, and an accompanying measurement equation. For notational convenience, let $s = 4$, which corresponds to the case of quarterly observations on annual data. Then the transition equation, which gathers together equations (6.106), (6.107) and (6.108), is:

$$\begin{bmatrix} \tau(t) \\ \beta(t) \\ \sigma(t) \\ \sigma(t-1) \\ \sigma(t-2) \end{bmatrix} = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & -1 & -1 & -1 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} \tau(t-1) \\ \beta(t-1) \\ \sigma(t-1) \\ \sigma(t-2) \\ \sigma(t-3) \end{bmatrix} + \begin{bmatrix} \nu(t) \\ \varepsilon(t) \\ \omega(t) \\ 0 \\ 0 \end{bmatrix}. \tag{6.109}$$

This incorporates the transition equation of the non-seasonal local linear model that has been given by (6.64). The observation equation, which combines the current values of the components, is:

$$y(t) = \begin{bmatrix} 1 & 0 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} \tau(t) \\ \beta(t) \\ \sigma(t) \\ \sigma(t-1) \\ \sigma(t-2) \end{bmatrix} + \eta(t). \tag{6.110}$$

The state-space model is amenable to the Kalman filter and the associated smoothing algorithms, which can be used in estimating the parameters of the model and in extracting estimates of the so-called unobserved components $\tau(t)$, $\sigma(t)$ and $\varepsilon(t)$. These algorithms have been described by Pollock (2003a).

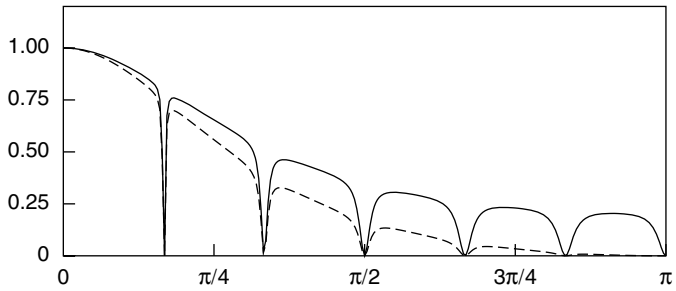

Figure 6.12 The gain function of the trend-extraction filter obtained from the STAMP program (solid line) together with that of the canonical trend-extraction filter (broken line)

Disaggregated structural time-series models have been treated at length in Harvey (1989). The methodology has been implemented in the STAMP program, which is described by Koopman *et al.* (2007). A similar approach has been pursued in a program within the Captain MATLAB Toolbox, which has been described by Pedregal, Taylor and Young (2004). A comparative analysis of the STAMP and TRAMO–SEATS programs has been provided by Pollock (2002b).

Example Figure 6.12 shows the gain of the trend extraction filter that is associated with a disaggregated structural model that has been applied to the monthly airline passenger data of Box and Jenkins (1976).

The solid line represents the gain of the ordinary filter and the broken line represents the gain of the filter that is obtained when the principle of canonical decomposition is applied to the components of the model. In that case, the white noise that is contained in the components is removed and reassigned to the residual component.

The indentations in the gain function at the seasonal frequencies $\pi j/6; j = 1, \ldots, 6$ are due to the zeros of the filter that are to be found on the circumference of the unit circle and which are effective in removing the seasonal fluctuations from the trend.

Disregarding these indentations, the gain of the filters is reduced only gradually as frequency increases. In particular, the ordinary unadjusted filter is liable to transmit a higher proportion of the high-frequency noise of the data. However, given that such high-frequency noise is largely absent from the airline passenger data, it transpires that the effect upon the estimated trend of adopting the principle of canonical decomposition is a minor one.

6.7 Finite-sample signal extraction

The classical theory of linear filtering relies heavily upon the simplifications that are afforded by the assumption that the data constitute a doubly infinite sequence. The assumption is an acceptable one in the case of finite impulse response (FIR) filters that can be realized via low-order moving-average operators. When such a

filter has only a short span, it matters little which assumptions are made about the length of the data sequence. Only at the ends of the data sequence are there liable to be problems.

The assumption of a double-infinite data sequence also sustains the theory of time-invariant infinite impulse response (IIR) rational filters, such as the Butterworth and HP filters of section 6.6.2, which correspond to moving averages of infinite order. These are not so easily applied to short sequences. Nevertheless, if the data sequence is sufficiently lengthy to allow the transient effects of the arbitrary start-up values to disappear, then such filters can be implemented successfully via bidirectional feedback procedures which comprise only a handful of recent data values. (In effect the start-up values purport to summarize the history of the infinite data sequence, insofar as it affects the IIR filter.)

In econometric applications, attention is often focused upon the most recent observations at the upper end of a short data sequence. In such cases, a theory of filtering is called for that fully recognizes the finite nature of the data sequence. Also, in cases where the data are trended, it becomes essential to supply appropriate non-zero initial conditions to the filter, and these should be the products of a finite-sample theory.

The theory that we shall expound here depends upon replacing the symbol z within the various polynomial operators by a matrix lag operator. However, it is immediately apparent that this replacement alone is insufficient for the purpose of creating adequate finite-sample filters.

To demonstrate the effects of the replacement, let $L_T = [e_1, e_2, \ldots, e_{T-1}, 0]$ be the matrix version of the lag operator, which is formed from the identity matrix $I_T = [e_0, e_1, e_2, \ldots, e_{T-1}]$ of order T by deleting the leading column and by appending a column of zeros to the end of the array. Then, the matrix of order T that corresponds to the pth difference operator $\nabla^p(z) = (1 - z)^p$ is:

$$\nabla_T^p = (I - L_T)^p. \tag{6.111}$$

We may partition this matrix so that $\nabla_T^p = [Q_*, Q]'$, where Q_*' has p rows. If y is a vector of T elements, then:

$$\nabla_T^p y = \begin{bmatrix} Q_*' \\ Q' \end{bmatrix} y = \begin{bmatrix} g_* \\ g \end{bmatrix}, \tag{6.112}$$

and g_* is liable to be discarded, whereas g will be regarded as the vector of the pth differences of the data.

The inverse matrix is partitioned conformably to give $\nabla_T^{-p} = [S_*, S]$. It follows that:

$$\begin{bmatrix} S_* & S \end{bmatrix} \begin{bmatrix} Q_*' \\ Q' \end{bmatrix} = S_* Q_*' + S Q' = I_T, \tag{6.113}$$

and that:

$$\begin{bmatrix} Q_*' \\ Q' \end{bmatrix} \begin{bmatrix} S_* & S \end{bmatrix} = \begin{bmatrix} Q_*'S_* & Q_*'S \\ Q'S_* & Q'S \end{bmatrix} = \begin{bmatrix} I_p & 0 \\ 0 & I_{T-p} \end{bmatrix}. \tag{6.114}$$

If g_* is available, then y can be recovered from g via:

$$y = S_*g_* + Sg. \tag{6.115}$$

The lower-triangular Toeplitz matrix $\nabla_T^{-p} = [S_*, S]$ is completely characterized by its leading column. The elements of that column are the ordinates of a polynomial of degree $p-1$, of which the argument is the row index $t = 0, 1, \ldots, T-1$. Moreover, the leading p columns of the matrix ∇_T^{-p}, which constitute the submatrix S_*, provide a basis for all polynomials of degree $p-1$ that are defined on the integer points $t = 0, 1, \ldots, T-1$.

It follows that $S_*g_* = S_*Q_*'y$ contains the ordinates of a polynomial of degree $p-1$, which is interpolated through the first p elements of y, indexed by $t = 0, 1, \ldots, p-1$, and which is extrapolated over the remaining integers $t = p, p+1, \ldots, T-1$.

6.7.1 Polynomial regression and HP filtering

A polynomial that is designed to fit the data should take account of all of the observations in y. Imagine, therefore, that $y = \phi + \eta$, where ϕ contains the ordinates of a polynomial of degree $p-1$ and η is a disturbance term with $E(\eta) = 0$ and $D(\eta) = \Sigma$. Then, in forming an estimate $f = S_*r_*$ of ϕ, we should minimize the sum of squares $\eta'\Sigma^{-1}\eta$. Since the polynomial is fully determined by the elements of a starting value vector r_*, this is a matter of minimizing:

$$(y-\phi)'\Sigma^{-1}(y-\phi) = (y - S_*r_*)'\Sigma^{-1}(y - S_*r_*), \tag{6.116}$$

with respect to r_*. The resulting values are:

$$r_* = (S_*'\Sigma^{-1}S_*)^{-1}S_*'\Sigma^{-1}y \quad \text{and} \quad \phi = S_*(S_*'\Sigma^{-1}S_*)^{-1}S_*'\Sigma^{-1}y. \tag{6.117}$$

An alternative representation of the estimated polynomial is available, which avoids the inversion of Σ. This is provided by the identity:

$$\begin{aligned} P_* &= S_*(S_*'\Sigma^{-1}S_*)^{-1}S_*'\Sigma^{-1} \\ &= I - \Sigma Q(Q'\Sigma Q)^{-1}Q' = I - P_Q, \end{aligned} \tag{6.118}$$

which gives two representations of the projection matrix P_*. The equality follows from the fact that, if $\text{Rank}[R, S_*] = T$ and if $S_*'\Sigma^{-1}R = 0$, then:

$$S_*(S_*'\Sigma^{-1}S_*)^{-1}S_*'\Sigma^{-1} = I - R(R'\Sigma^{-1}R)^{-1}R'\Sigma^{-1}. \tag{6.119}$$

Setting $R = \Sigma Q$ gives the result. It follows that the ordinates of the polynomial fitted to the data by generalized least-squares regression can be represented by:

$$\phi = y - \Sigma Q(Q'\Sigma Q)^{-1}Q'y. \tag{6.120}$$

A more general method of curve fitting, which embeds polynomial regression as a special case, is one that involves the minimization of a combination of two sums of squares. Let x denote the vector of fitted values, which is a sequence of the ordinates of points, equally spaced in time, through which a continuous curve might be interpolated. The criterion for finding the vector is to minimize:

$$L = (y - x)'\Sigma^{-1}(y - x) + x'Q\Omega^{-1}Q'x. \tag{6.121}$$

The first term penalizes departures of the resulting curve from the data, whereas the second term imposes a penalty for a lack of smoothness in the curve.

The second term comprises $d = Q'x$, which is the vector of pth-order differences of x. The matrix Ω^{-1} serves to generalize the overall measure of the curvature of the function that has the elements of x as its sampled ordinates, and it serves to regulate the penalty, which may vary over the sample.

Differentiating L with respect to x and setting the result to zero, in accordance with the first-order conditions for a minimum, gives:

$$\begin{aligned}\Sigma^{-1}(y - x) &= Q\Omega^{-1}Q'x \\ &= Q\Omega^{-1}d.\end{aligned} \tag{6.122}$$

Multiplying the equation by $Q'\Sigma$ gives $Q'(y - x) = Q'y - d = Q'\Sigma Q\Omega^{-1}d$, whence $\Omega^{-1}d = (\Omega + Q'\Sigma Q)^{-1}Q'y$. Putting this into the equation $x = y - \Sigma Q\Omega^{-1}d$ gives:

$$x = y - \Sigma Q(\Omega + Q'\Sigma Q)^{-1}Q'y. \tag{6.123}$$

By setting $\Omega = \lambda^{-1}I$ and $\Sigma = I$ and letting Q' denote the second-order difference operator, the HP filter is obtained in the form of:

$$x = y - Q(\lambda^{-1}I + Q'Q)^{-1}Q'y. \tag{6.124}$$

This form is closely related to that of the infinite-sample filter $\beta(z) = 1 - \beta^c(z)$ which invokes equation (6.95). In the finite-sample version of the filter, the submatrix Q' of $\nabla_T^2 = (I - L_T)^2$ replaces the difference operator $(1 - z)^2$, and Q replaces $(1 - z^{-1})^2$.

If $\Omega = 0$ in (6.123), and if Q' is the matrix version of the second-difference operator, then the generalized least squares interpolator of a linear function is derived, which is subsumed under (6.120).

6.7.2 Finite-sample WK filters

To provide a statistical interpretation of the formula of (6.123), consider a data sequence $y = \xi + \eta$, where $\xi = \phi + \zeta$ is a trend component, which is the sum of a vector ϕ, containing the ordinates of a polynomial of degree p at most, and of a vector ζ from a stochastic process with p unit roots that is driven by a zero-mean forcing function. The term η stands for a vector sampled from a mean-zero stationary stochastic process which is independent of the process driving ξ such that:

$$E(\eta) = 0, \quad D(\eta) = \Sigma \quad \text{and} \quad C(\eta, \xi) = 0. \tag{6.125}$$

If Q' is the pth difference operator, then $Q'\phi = \mu\iota$, with $\iota = [1, 1, \ldots, 1]'$, will contain a constant sequence of values, which will be zeros if the degree of ϕ is less than p. Also, $Q'\zeta$ will be a vector sampled from a mean-zero stationary process. Therefore, $\delta = Q'\xi$ is from a stationary process with a constant mean. Thus, there is:

$$\begin{aligned} Q'y &= Q'\xi + Q'\eta \\ &= \delta + \kappa = g, \end{aligned} \tag{6.126}$$

where:

$$\begin{aligned} &E(\delta) = \mu\iota, \quad D(\delta) = \Omega, \\ &E(\kappa) = 0, \quad D(\kappa) = Q'\Sigma Q. \end{aligned} \tag{6.127}$$

Now consider the conditional expectation of η given $g = Q'y$, which is also its minimum mean square error estimator on the assumption that the various stochastic processes are normally distributed. This is:

$$\begin{aligned} E(\eta|g) &= E(\eta) + C(\eta, g)D^{-1}(g)\{g - E(g)\} \\ &= \Sigma Q(\Omega + Q'\Sigma Q)^{-1}\{Q'y - \mu\iota\}. \end{aligned} \tag{6.128}$$

If the vector $E(g) = \mu\iota$ is non-zero it will, nevertheless, be virtually nullified by the matrix $\Sigma Q(\Omega + Q'\Sigma Q)^{-1}$, which is a matrix version of a highpass filter. Therefore, it may be deleted from the expressions of (6.128). Next, since $\xi = y - \eta$, the estimate of the trend is $x = E(\xi|g) = y - E(\eta|g)$, which is exactly equation (6.123).

The HP filter may be derived by specializing the statistical assumptions of (6.125) and (6.127). It is assumed that:

$$D(\eta) = \Sigma = \sigma_\eta^2 I, \quad D(\delta) = \Omega = \sigma_\delta^2 I \quad \text{and} \quad \lambda = \frac{\sigma_\eta^2}{\sigma_\delta^2}. \tag{6.129}$$

Putting these details into equation (6.123) gives equation (6.124).

It is straightforward to derive the dispersion matrices that are found within the formulae for the finite-sample estimators from the corresponding autocovariance generating functions. Let $\gamma(z) = \{\gamma_0 + \gamma_1(z + z^{-1}) + \gamma_2(z^2 + z^{-2}) + \cdots\}$ denote the autocovariance generating function of a stationary stochastic process. Then, the corresponding dispersion matrix for a sample of T consecutive elements drawn from the process is:

$$\Gamma = \gamma_0 I_T + \sum_{\tau=1}^{T-1} \gamma_\tau (L_T^\tau + F_T^\tau), \tag{6.130}$$

where $F_T = L_T'$ is in place of z^{-1}. Since L_T and F_T are nilpotent of degree T, such that $L_T^q, F_T^q = 0$ when $q \geq T$, the index of summation has an upper limit of $T - 1$.

6.7.3 The polynomial component

The formula (6.123) tends to conceal the presence of polynomial components within the sequences that are generated by filtering the nonstationary data. An alternative procedure, which we have already adopted in detrending the logarithmic consumption data of the UK in the example following (6.14), is to extract a polynomial trend from the nonstationary data before applying a filter to the residual sequence, which will have the characteristics of a sequence generated by a stationary process, provided that the polynomial is of a sufficient degree.

Another procedure that can be followed requires the data to be reduced to stationarity by a process of differencing, before it is filtered. The filtered output can be reinflated thereafter to obtain estimates of the components of the non-stationary process. It transpires that, in the context of WK filtering, such a procedure produces estimates that are identical to those that are delivered by the finite-sample filter of (6.123).

To demonstrate this result, we shall assume that, within $y = \xi + \eta$, the vector ξ is generated by a stochastic process with p unit roots driven by a mean-zero white-noise process. The vector η is assumed to be from a stationary process. Therefore, the specifications of (6.125) and (6.127) remain, but we may choose to set $E(\delta) = 0$, if only to confirm that the polynomial component will arise just as surely in the absence of stochastic drift.

Let the estimates of ξ, η, $\delta = Q'\xi$ and $\kappa = Q'\eta$ be denoted by x, h, d and k respectively. Then the Wiener–Kolmogorov minimum mean square error estimates of the differenced components are:

$$E(\delta|g) = d = D(\delta)\{D(\delta) + D(\kappa)\}^{-1}g = \Omega(\Omega + Q'\Sigma Q)^{-1}Q'y, \tag{6.131}$$

$$E(\kappa|g) = k = D(\kappa)\{D(\delta) + D(\kappa)\}^{-1}g = Q'\Sigma Q(\Omega + Q'\Sigma Q)^{-1}Q'y. \tag{6.132}$$

The estimates of ξ and η may be obtained by integrating, or re-inflating, the components of the differenced data to give

$$x = S_*d_* + Sd \quad \text{and} \quad h = S_*k_* + Sk, \tag{6.133}$$

where S_*d_* and S_*k_* are vectors of the ordinates of polynomials of degree p. For this representation, the polynomial parameters, in the form of the starting values d_* and h_*, are required.

The initial conditions in d_* should be chosen so as to ensure that the estimated trend is aligned as closely as possible with the data. The criterion is:

$$\text{Minimize} \quad (y - S_*d_* - Sd)'\Sigma^{-1}(y - S_*d_* - Sd) \quad \text{with respect to} \quad d_*. \tag{6.134}$$

The solution for the starting values is:

$$d_* = (S_*'\Sigma^{-1}S_*)^{-1}S_*'\Sigma^{-1}(y - Sd). \tag{6.135}$$

The equivalent starting values of k_* are obtained by minimizing the (generalized) sum of squares of the fluctuations:

$$\text{Minimize} \quad (S_*k_* + Sk)'\Sigma^{-1}(S_*k_* + Sk) \quad \text{with respect to} \quad k_*. \tag{6.136}$$

The solution is:

$$k_* = -(S_*'\Sigma^{-1}S_*)^{-1}S_*'\Sigma^{-1}Sk. \tag{6.137}$$

The starting values k_* and d_* can be eliminated from the expressions for x and h in (6.133), which provide the estimates of the components. Thus, using expression $I - P_* = P_Q$ from (6.118), we get:

$$\begin{aligned} h &= Sk + S_*k_* \\ &= (I - P_*)Sk = P_QSk. \end{aligned} \tag{6.138}$$

Then, by using the expression for k from (6.132) together with the identity $Q'S = I_T$, we get:

$$h = \Sigma Q(\Omega + Q'\Sigma Q)^{-1}Q'y. \tag{6.139}$$

This agrees with (6.128) in the case where $\mu = 0$. The condition that $x + h = y$, which is that the sum of the estimated components equals the data vector, indicates that:

$$\begin{aligned} x &= y - h \\ &= y - \Sigma Q(\Omega + Q'\Sigma Q)^{-1}Q'y, \end{aligned} \tag{6.140}$$

which is equation (6.123) again.

Observe that the filter matrix $Z_\eta = \Sigma Q(\Omega + Q'\Sigma Q)^{-1}$ of (6.140), which delivers $h = Z_\eta g$, differs from the matrix $Z_\kappa = Q'Z_\eta$ of (6.132), which delivers $k = Z_\kappa g$, only in respect of the matrix difference operator Q'. The effect of omitting the operator is to remove the need for reinflating the filtered components and thus to remove the need for the starting values. These matters have been discussed at greater length by Pollock (2006).

6.8 The Fourier methods of signal extraction

If the data are generated by a stationary stochastic process, then it may be reasonable to regard them as the product of a circular process, of which the Fourier representation is readily available. There are some advantages in exploiting the Fourier representation by performing the essential filtering operations in the frequency domain – for these are usually aimed at suppressing or attenuating some of the cyclical elements of the data. It is also straightforward to provide a time-domain interpretation of the frequency domain operations, and the possibility exists of performing the equivalent operations in either domain.

The dispersion matrix of a circular stochastic process is obtained from the autocovariance generating function $\gamma(z)$ by replacing the argument z by the circulant matrix $K_T = [e_1, \ldots, e_{T-1}, e_0]$, which is formed from the identity matrix $I_T = [e_0, e_1, \ldots, e_{T-1}]$ by moving the leading column to the back of the array. In

this way, the generating function $\gamma(z)$ gives rise to the matrix:

$$\begin{aligned}\Gamma^\circ &= \gamma(K_T)\\ &= \gamma_0 I_T + \sum_{\tau=1}^{\infty} \gamma_\tau (K_T^\tau + K_T^{-\tau})\\ &= \gamma_0 I_T + \sum_{\tau=1}^{T-1} \gamma_\tau^\circ (K_T^\tau + K_T^{-\tau}).\end{aligned} \tag{6.141}$$

It can be seen from this that the circular autocovariances would be obtained by wrapping the sequence of ordinary autocovariances around a circle of circumference T and adding the overlying values. Thus:

$$\gamma_\tau^\circ = \sum_{j=0}^{\infty} \gamma_{jT+\tau}, \quad \text{with} \quad \tau = 0, \ldots, T-1. \tag{6.142}$$

Given that $\lim(\tau \to \infty)\gamma_\tau = 0$, it follows that $\gamma_\tau^\circ \to \gamma_\tau$ as $T \to \infty$, which is to say that the circular autocovariances converge to the ordinary autocovariances as the circle expands.

The circulant autocovariance matrix is amenable to a spectral factorization of the form:

$$\Omega^\circ = \gamma(K_T) = \bar{U}\gamma(D)U, \tag{6.143}$$

wherein U and $\bar{U}$ are the unitary matrices defined by (6.20) and:

$$D = \operatorname{diag}(\exp\{\mathrm{i}2\pi j/T\}; j = 0, \ldots, T-1), \tag{6.144}$$

is a diagonal matrix whose elements are the T roots of unity, which are found on the circumference of the unit circle in the complex plane. Then, $\gamma(D)$ is the diagonal matrix formed by replacing the argument z within $\gamma(z)$ by D.

The jth element of the diagonal matrix $\gamma(D)$ is:

$$\gamma(\exp\{\mathrm{i}\omega_j\}) = \gamma_0 + 2\sum_{\tau=1}^{\infty} \gamma_\tau \cos(\omega_j \tau). \tag{6.145}$$

This represents the cosine Fourier transform of the sequence of the ordinary autocovariances; it corresponds to an ordinate (scaled by 2π) sampled at the point $\omega_j = 2\pi j/T$, which is a Fourier frequency, from the spectral density function of the linear (that is, non-circular) stationary stochastic process.

The theory of circulant matrices has been described by Gray (2002) and by Pollock (2002a). Both authors provide abundant additional references.

The method of WK filtering can also be implemented using the circulant dispersion matrices that are given by:

$$\begin{aligned}&\Omega_\delta^\circ = \bar{U}\gamma_\delta(D)U, \quad \Omega_\kappa^\circ = \bar{U}\gamma_\kappa(D)U \quad \text{and}\\ &\Omega^\circ = \Omega_\delta^\circ + \Omega_\kappa^\circ = \bar{U}\{\gamma_\delta(D) + \gamma_\kappa(D)\}U,\end{aligned} \tag{6.146}$$

wherein the diagonal matrices $\gamma_\delta(D)$ and $\gamma_\kappa(D)$ contain the ordinates of the spectral density functions of the component processes. By replacing the dispersion matrices of (6.131) and (6.132) by their circulant counterparts, we derive the following formulae:

$$d = \bar{U}\gamma_\delta(D)\{\gamma_\delta(D) + \gamma_\kappa(D)\}^{-1}Ug = P_\delta g, \tag{6.147}$$

$$k = \bar{U}\gamma_\kappa(D)\{\gamma_\delta(D) + \gamma_\kappa(D)\}^{-1}Ug = P_\kappa g. \tag{6.148}$$

We may note that P_δ and P_κ are circulant matrices.

The filtering formulae may be implemented in the following way. First, a Fourier transform is applied to the (differenced) data vector g to give Ug, which resides in the frequency domain. Then, the elements of the transformed vector are multiplied by those of the diagonal weighting matrices $J_\delta = \gamma_\delta(D)\{\gamma_\delta(D) + \gamma_\kappa(D)\}^{-1}$ and $J_\kappa = \gamma_\kappa(D)\{\gamma_\delta(D) + \gamma_\kappa(D)\}^{-1}$. Finally, the products are carried back into the time domain by the inverse Fourier transform, which is represented by the matrix $\bar{U}$. (An efficient implementation of a mixed-radix fast Fourier transform, which is designed to cope with samples of arbitrary sizes, has been provided by Pollock, 1999. The usual algorithms demand a sample size of $T = 2^n$.)

An advantage of the Fourier method is that it is possible to effect a total suppression of the elements within the stop band of the desired frequency response. Also, the transition between the pass band and the stop band can be confined to the interval between adjacent Fourier frequencies, which means that it can be perfectly abrupt.

Neither of these features are available to the ordinary finite-sample WK filters. Nevertheless, it is possible to achieve both of these effects by working in the time domain. This fact is manifest in the formulae of (6.147) and (6.148) which entail the equations $d = P_\delta g$ and $k = P_\kappa g$ respectively.

In effect, a pair of wrapped filters can be applied to the data in the time domain via processes of circular convolution. If we can imagine the leading rows of the matrices P_δ and P_κ disposed around a circle of circumference T, then each of the succeeding rows is derived from its predecessor via an anticlockwise rotation through an angle of $2\pi/T$ radians.

Example It is commonly believed that, in the case of samples of finite length T, it is impossible to design a filter that will preserve completely all elements within a specified range of frequencies and that will remove all elements outside it. A filter that would achieve such an objective is described as an ideal filter. The ideal lowpass filter with a cut-off frequency of $\omega_d = 2\pi d/T$ has the following frequency response over the interval $[-\pi, \pi]$:

$$\phi(\omega) = \begin{cases} 1, & \text{if } \omega \in [-\omega_d, \omega_d], \\ 0, & \text{otherwise.} \end{cases} \tag{6.149}$$

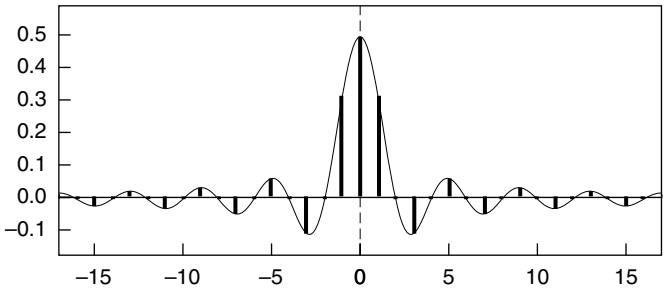

Figure 6.13 The central coefficients of the Fourier transform of the frequency response of an ideal lowpass filter with a cut-off point at $\omega = \pi/2$. The sequence of coefficients extends indefinitely in both directions. The coefficients are the sampled ordinates of a sinc function

The coefficients of the filter are given by the discrete-time sinc function, which is the (inverse) Fourier transform of the periodic frequency response function:

$$\beta_k = \frac{1}{2\pi}\int_{-\omega_d}^{\omega_d} e^{i\omega k}d\omega = \begin{cases} \dfrac{\omega_d}{\pi}, & \text{if } k = 0; \\ \dfrac{\sin(k\omega_d)}{\pi k}, & \text{if } k \neq 0. \end{cases} \tag{6.150}$$

Such a frequency response presupposes a doubly-infinite data sequence, insofar as it represents the relative amplification and attenuation of trigonometrical functions that are defined over the entire real line.

The coefficients of (6.150) form a doubly infinite sequence, of which a central part is illustrated in Figure 6.13. In order to obtain a practical filter, it seems that one must truncate the sequence, retaining only a limited number of its central elements. This truncation gives rise to a filter of which the frequency response has certain undesirable characteristics. (See Figure 6.19 for an example.)

In particular, there is a ripple effect whereby the gain of the filter fluctuates within the pass band, where it should be constant with a unit value, and within the stop band, where it should be zero-valued. Within the stop band, there is a corresponding problem of leakage whereby the truncated filter transmits elements that ought to be blocked.

However, it is clear that an ideal filter can be implemented in the frequency domain by preserving the ordinates of the Fourier transform of the data that are associated with frequencies less than ω_d and by setting all other ordinates to zero. This is a matter of applying the following set of weights to the Fourier ordinates:

$$\lambda_j = \begin{cases} 1, & \text{if } j \in \{-d, \ldots, d\}, \\ 0, & \text{otherwise.} \end{cases} \tag{6.151}$$

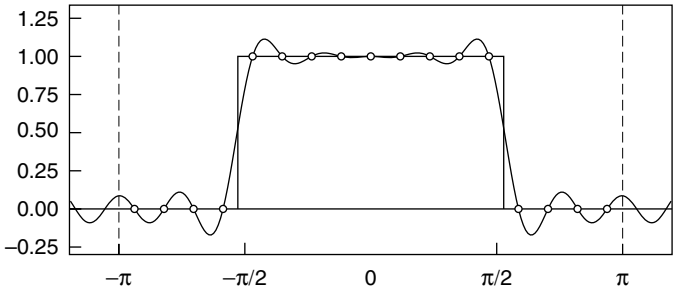

Figure 6.14 The frequency response of the 17-point wrapped filter defined over the interval $[-\pi, \pi)$. The values at the Fourier frequencies are marked by circles

By applying an inverse discrete Fourier transform to these weights, the coefficients of a circular filter are obtained, of which the values are given by:

$$\beta^{\circ}(k) = \begin{cases} \dfrac{2d+1}{T}, & \text{if k = 0,} \\ \dfrac{\sin([d+1/2]\omega_1 k)}{T\sin(\omega_1 k/2)}, & \text{for k = 1, … , [T/2],} \end{cases} \tag{6.152}$$

where $\omega_1 = 2\pi/T$. These coefficients would be obtained by wrapping coefficients of (6.150) around a circle of circumference T and adding the overlying values:

$$\beta_k^{\circ} = \sum_{j=-\infty}^{\infty} \beta_{jT+k}. \tag{6.153}$$

Applying the wrapped filter to the finite data sequence via a circular convolution is equivalent to applying the original filter to an infinite periodic extension of the data sequence.

The function of (6.152) is just an instance of the Dirichlet kernel – see Pollock (1999), for example. Figure 6.14 depicts the frequency response for this filter at the Fourier frequencies, where $\lambda_j = 0, 1$ in the case where $\omega_d = \pi/2$. It also depicts the continuous frequency response that would be the consequence of applying an ordinary filter with these coefficients to a doubly-infinite data sequence.

6.8.1 Applying the Fourier method to trended data

In an ideal application of the Fourier method, it should be possible to wrap the data sequence $y_t; t = 0, \ldots, T-1$ seamlessly around the circle, such that there is no disjunction at the point where the head of the sequence joins the tail. To achieve such an effect, it is common to taper the data so as reduce both ends to zero. To avoid corrupting the sample data, the taper can be applied to some extrapolations of the ends of the sample. However, a data sequence that follows a linear trend is not amenable to tapering, since there is liable to be a radical disjunction at the point where the head joins the tail.

The periodic extension of the linearly trended sequence, which would be generated by traveling around the circle indefinitely, has a saw-tooth profile. The corresponding spectrum or periodogram has a *one-over-f* profile that descends, as the frequency increases, in the manner of a rectangular hyperbola, from a high point that is adjacent to the zero frequency to a low point at the limiting frequency. Unless the data are adequately detrended, such a spectrum will serve to conceal all but the most prominent of the harmonic characteristics of the data.

There are two simple ways in which the data may be detrended. The first, which has been described already in section 6.7.3, is to apply the difference operator to the data as many times as are necessary to reduce them to stationarity. The components that are extracted by filtering the differenced data can be reinflated, in the manner indicated by equations (6.133)–(6.137), to obtain the components of the original data.

We denote the data by y and their differences by $g = Q'y$. The filtered sequence that underlies the trend is denoted by d and the vector of initial conditions by d_*. Then, if we set $\Sigma = I$, the relevant equations for delivering the estimate x of the trend component are:

$$x = S_*d_* + Sd \quad \text{and} \quad d_* = (S_*'S_*)^{-1}S_*'(y - Sd). \tag{6.154}$$

The detrended sequence is $h = y - x$. Underlying the detrended sequence is the filtered sequence $k = g - d$, from which the detrended data component may be obtained directly via the equations:

$$h = S_*k_* + Sk \quad \text{and} \quad k_* = -(S_*'S_*)^{-1}S_*'Sk. \tag{6.155}$$

Another way of reversing the effects of a differencing operation that has been applied to the data to reduce them to stationarity is to re-inflate the Fourier ordinates of the filtered sequence, using values from the frequency response function of the anti-differencing summation operator. Once the ordinates had been reinflated within the frequency domain, they can be transformed into the time domain to produce the filtered sequence.

This method is applicable only to components that are bounded away from the zero frequency, since the summation operator has infinite gain at zero. (See Figure 6.8.) However, if one wishes to apply a lowpass filter to the data, then one has the option of applying the complementary highpass filter and of subtracting the filtered sequence from the original data to generate the lowpass component.

The second way of detrending the data is to extract a polynomial component via an ordinary or a generalized least squares regression according to the formula of (6.120). The formula will allow greater weight to be given to the points at both ends of the sample, to ensure that the interpolated curve passes through their midst. This can be achieved by allowing Σ^{-1} to be a diagonal matrix with large values at the ends. In this way, a disjunction in the wrapped version of the residual sequence, or in its periodic extension, can be avoided.

Example Figure 6.15 shows the logarithms of the data on aggregate household expenditure in the UK for the years 1956–2005, through which a smooth trajectory

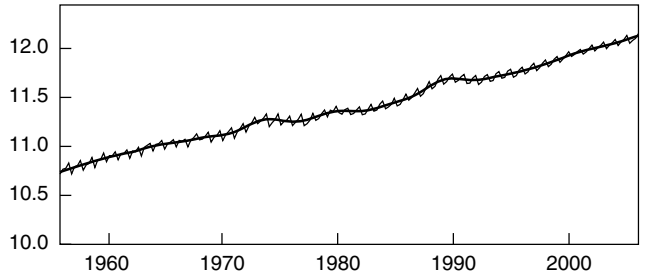

Figure 6.15 The logarithms of quarterly household expenditure in the UK, for the years 1956–2005, together with an interpolated trend

has been interpolated. This has been obtained by selecting the Fourier coefficients of the twice-differenced data that correspond to frequencies in the interval $[0, \pi/8]$. This frequency band has been chosen in the light of the periodogram of Figure 6.6, which shows that it contains an isolated spectral structure.

The sequence that has been synthesized from these coefficients has been reinflated in the manner indicated by (6.154) to produce the trajectory. The result of this procedure is a composite of the trend and the business cycle. The same trajectory of aggregate expenditure would have been obtained by adding the business cycle that is depicted in Figure 6.5 to the linear trend of Figure 6.4.

6.9 Band-limited processes

The majority of the methods that we have described for extracting the components of an econometric data sequence presuppose that the data can be described by a univariate ARIMA model. The spectral density function of an ARIMA process is supported on the entire frequency interval $[0, \pi]$, where its ordinates are strictly positive with the possible exception of a few zero-valued ordinates that constitute a set of measure zero. Such zero values will be attributable to the presence of unit roots within the moving-average operator.

It is commonly assumed that the component parts of an aggregate econometric sequence can also be described by ARIMA models. It is on this basis that the WK filters are derived. However, reference to the periodogram of Figure 6.6 and to others like it suggests that the components often reside within strictly limited frequency bands which are separated by dead spaces where the spectral ordinates are virtually zeros.

In many circumstances, the disparity between the assumptions underlying the WK filters and the nature of the data to which they are applied has no adverse effects. A lowpass filter that achieves a gradual transition from a pass band to a stop band within the region of a spectral dead space will be as effective in extracting a low-frequency trend component as is a frequency-domain filter that achieves an abrupt transition between two adjacent Fourier frequencies.

The ordinates at times $t = 0, \ldots, T-1$ of the business cycle that is represented in Figure 6.5 have been obtained by a Fourier method; but they might have been obtained by applying the Butterworth filter of order $n = 6$ and with a nominal cut-off frequency of $\omega_d = \pi/4$ radians, of which the gain is depicted in Figure 6.11. The principal advantage of the Fourier method, in this context, lies in the ease with which a continuous function can be synthesised from the Fourier coefficients.

Difficulties do arise when an attempt is made to estimate the parameters of an ARMA model from data such as those of Figure 6.5. A natural objective is to attempt to characterize the business cycle via the parameters of a fitted ARMA model. Such a model is liable to be applied to a seasonally adjusted version of the data, for which the periodogram will lack the spectral spike at the seasonal frequency of $\pi/2$ and at the harmonic frequency of π.

An AR(2) model with complex roots is the simplest of the models that might be appropriate to the purpose. The modulus of its roots should reveal the damping characteristics of the cycles, and their argument should indicate the angular velocity or, equivalently, the length, of the cycles. However, such a model will invariably deliver estimates that imply real-valued roots, which fail adequately to represent the dynamics of the business cycle. (See Pagan, 1997, for example.)

The problem of estimating the business cycle also affects the model-based approaches to econometric signal extraction, which depend upon the prior estimation of an aggregate ARIMA model or upon the estimation of ARIMA components. A business cycle component is usually missing from such models, since the estimation fails to deliver the appropriate complex roots. However, it is straightforward to include a business cycle component with a pre-specified frequency in a disaggregated structural model. (See Harvey, 1985, for example.)

To obtain parametric estimates of the business cycle, it is necessary to remove from the data all but the relevant low-frequency components. This is achieved by selecting the relevant Fourier coefficients from which the business cycle can be constituted via a Fourier synthesis in the manner of (6.14). Thereafter, it is necessary to sample the continuous function at a rate that will ensure that the Nyquist frequency π corresponds to the highest frequency that is present in the component. A successful ARMA model which represents the complex dynamics of the business cycle can be estimated from the resampled data sequence.

The Shannon–Whittaker sampling theorem indicates that the resampled data contains sufficient information to reconstitute the continuous business cycle function.

6.9.1 The Shannon–Whittaker sampling theorem

Let $x(t)$ be a square integrable continuous signal of which the Fourier transform $\xi(\omega)$ is band limited to the frequency interval $[-\omega_d, \omega_d]$. Then the signal can be recovered from its sampled ordinates provided that these are separated by a time interval of no more than π/ω_d, which is to say that the sinusoidal element of the highest frequency within the signal must take at least two sampling intervals to complete a cycle.

To demonstrate this result, we must consider the Fourier representation of a real-valued square-integrable function $x(t)$ defined over the real line. The following are the corresponding expressions for the function $x(t)$ and its Fourier transform $\xi(\omega)$:

$$x(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{\mathrm{i}\omega t}\xi(\omega)d\omega \longleftrightarrow \xi(\omega) = \int_{-\infty}^{\infty} e^{-\mathrm{i}\omega t}x(t)dt. \tag{6.156}$$

By sampling $x(t)$ at intervals of π/ω_d, a sequence:

$$\{x_\tau = x(\tau[\pi/\omega_d]); \tau = 0, \pm 1, \pm 2, \ldots\},$$

is generated. The elements of the sequence and their Fourier transform $\xi_S(\omega)$ are given by:

$$\begin{aligned} x_\tau &= \frac{1}{2\omega_d}\int_{-\omega_d}^{\omega_d} \exp\{\mathrm{i}\omega\tau[\pi/\omega_d]\}\xi_S(\omega)d\omega \\ &\longleftrightarrow \\ \xi_S(\omega) &= \sum_{\tau=-\infty}^{\infty} x_\tau \exp\{-\mathrm{i}\omega\tau[\pi/\omega_d]\}. \end{aligned} \tag{6.157}$$

Since $\xi(\omega) = \xi_S(\omega)$ is a continuous function defined on the interval $[-\omega_d, \omega_d]$, it may be regarded as a function that is periodic in frequency, with a period of $2\omega_d$. Putting the right-hand side of (6.157) into the left-hand side of (6.156), and taking the integral over $[-\omega_d, \omega_d]$ in consequence of the band-limited nature of the function $x(t)$, gives:

$$\begin{aligned} x(t) &= \frac{1}{2\pi}\int_{-\omega_d}^{\omega_d}\left\{\sum_{\tau=-\infty}^{\infty} x_\tau e^{-\mathrm{i}\omega\tau[\pi/\omega_d]}\right\}e^{\mathrm{i}\omega t}d\omega \\ &= \frac{1}{2\pi}\sum_{\tau=-\infty}^{\infty} x_\tau \int_{-\omega_d}^{\omega_d} e^{\mathrm{i}\omega(t-[\tau\pi/\omega_d])}d\omega. \end{aligned} \tag{6.158}$$

The integral on the right-hand side is evaluated as:

$$\int_{-\omega_d}^{\omega_d} e^{\mathrm{i}\omega(t-[\tau\pi/\omega_d])}d\omega = 2\frac{\sin(t\omega_d - \tau\pi)}{t - \tau[\pi/\omega_d]}. \tag{6.159}$$

Putting this into the right-hand side of (6.158) gives:

$$x(t) = \sum_{\tau=-\infty}^{\infty} x_\tau \frac{\sin(t\omega_d - \tau\pi)}{\pi(t - \tau[\pi/\omega_d])} = \sum_{k=-\infty}^{\infty} x_\tau \phi_d(\tau - k), \tag{6.160}$$

where:

$$\phi_d(t-\tau) = \frac{\sin(t\omega_d - \tau\pi)}{\pi(t - \tau[\pi/\omega_d])}. \tag{6.161}$$

When $\tau = 0$, this becomes an ordinary sinc function that is a continuous function of t, and which is the Fourier transform of the following frequency function:

$$\phi_d(\omega) = \begin{cases} 1, & \text{if } |\omega| \in [0, \omega_d]; \\ 0, & \text{otherwise.} \end{cases} \tag{6.162}$$

When $\tau \neq 0$, it represents a sinc function that has been displaced in time by τ intervals of length π/ω_d. The set of such displaced sinc functions constitutes an orthogonal basis for all continuous functions that are band-limited to the frequency interval $[-\omega_d, \omega_d]$.

In the case of a stationary stochastic process, the sampled sequence is not square summable and, therefore, in a strict sense, this proof of the interpolation via the Nyquist–Shannon theory does not apply. However, the convergence of the interpolation formula of (6.160), when $x(\tau) = \{x_\tau; \tau = 0, \pm 1, \pm 2, \ldots\}$ is a stationary sequence, can be confirmed by considering a sum with $\tau \in [-N, N]$ for some finite integer N. The variance of the sum of discarded terms can be made arbitrarily small by increasing the value of N.

The reconstruction of a continuous function from its sampled ordinates in the manner suggested by the sampling theorem is not possible in practice, because it requires forming a weighted sum of an infinite number of sinc functions, each of which is supported on the entire real line. Nevertheless, a continuous band-limited periodic function defined on a finite interval – which corresponds to the circumference of a circle – can be reconstituted from a finite number of wrapped or periodic sinc functions, which are Dirichlet kernels by another name. However, the most practical means of reconstituting the function is by a simple Fourier synthesis of the sort described by equation (6.14).

Example The analysis of the example following (6.14) suggests that the business cycle of the detrended logarithmic consumption data fits within the frequency band $[0, \pi/8]$. If this structure can be isolated and thereafter mapped into the frequency interval $[0, \pi]$, then it will be capable of being described by an ordinary linear stochastic model of the ARMA variety. For this purpose, the spectral elements that fall outside the frequency range of the business cycle must first be removed. This operation, which constitutes an anti-alias filtering, may be carried out either in the time domain or in the frequency domain.

Given the availability of the spectral ordinates of the data, it is straightforward to operate in the frequency domain by setting the rejected ordinates to zeros. Then, a continuous low-frequency function can be synthesized from the selected ordinates. An example is provided by the interpolated function in Figure 6.5. The synthesized function can be resampled at a rate that corresponds to the maximum frequency within the spectral structure of the business cycle.

There is some advantage in fitting a trend function that is more flexible than the straight line of Figure 6.5. Therefore, a fourth degree polynomial has been fitted to

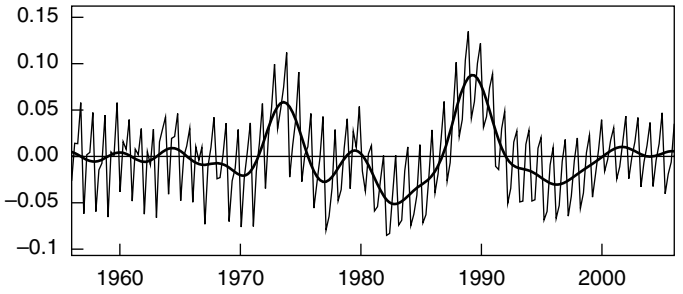

Figure 6.16 The residuals from fitting a polynomial of degree 4 to the logarithmic expenditure data. The interpolated line, which represents the business cycle, has been synthesized from the Fourier ordinates in the frequency interval $[0, \pi/8]$

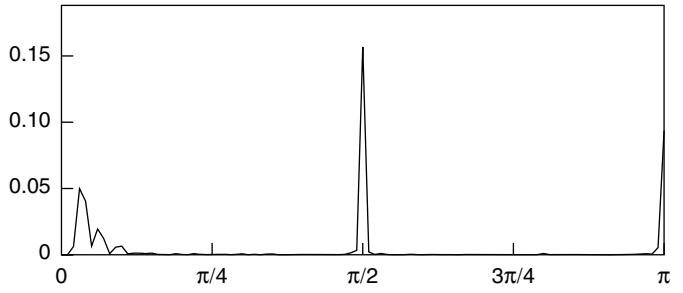

Figure 6.17 The periodogram of the data sequence of Figure 6.16

the data by a least squares regression. The effect is to remove some of the power from the Fourier ordinates adjacent to the zero frequency.

The residual sequence from this polynomial interpolation is show in Figure 6.16, together with an interpolated function that has been synthesized from the Fourier ordinates that lie in the interval $[0, \pi/8]$. This, function, which purports to represent the business cycle, is devoid of any seasonal fluctuations. Figure 6.17 displays the periodogram of the residual sequence.

After the removal of all elements of frequencies in excess of $\pi/8$ the data may be resampled at 1/8th of the original rate of observation. This simple fractional rate is a convenient one, since it implies taking one in every eight of the anti-aliased data points. In that case, there is no need to synthesize a continuous function for the purpose of resampling the data.

The periodogram of the sub-sampled anti-aliased data is show in Figure 6.18 with the parametric spectrum of an estimated AR(3) model superimposed. The periodogram represents a rescaled version of the part of the periodogram of Figure 6.17 that occupies the frequency range $[0, \pi/8]$ and it appears to be well represented by the parametric spectrum.

The continuous band-limited function of Figure 6.16 can be recovered from the sub-sample by associating to each of its elements an appropriately scaled Dirichlet

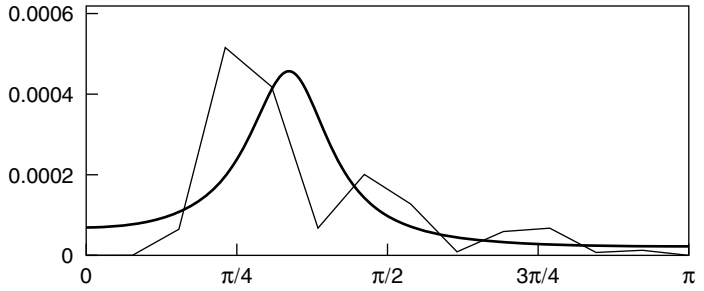

Figure 6.18 The periodogram of the sub-sampled anti-aliased data with the parametric spectrum of an estimated AR(3) model superimposed

kernel and, thereafter, by adding these kernels. This demonstrates the one-to-one correspondence that exists between the continuous function and the sub-sampled sequence. This is precisely the one-to-one correspondence that exists between the periodic function $z(t)$, synthesized by equation (6.14), and its sampled ordinates $\{z_\tau = z(\tau T/N); \tau = 0, 1, \ldots, N-1\}$.

The AR(3) model that underlies the spectral density function of Figure 6.18 provides a statistical description both of the continuous band-limited function of Figure 6.16 and of the ordinates sampled from it at the rate of one observation in eight sample periods.

6.10 Separating the trend and the cycles

The remaining issue to be discussed in this chapter is the matter of separating the trend of an economic data sequence from the cycles that surround it. This is a difficult problem. The trend and the cycles are combined within the same spectral structure and there is rarely any indication, within the periodogram, of where the trend ends and the cycles begin. In the absence of objective criteria for achieving a separation, the definition of the trend is liable to reflect the purposes of the study as well as the circumstances of the economy over the period in question.

A simple prescription that was offered by the pioneering econometrician Tintner (1940, 1953) is that the trend should contain no cyclical motions. This can be interpreted to mean that, if the trend is a differentiable function, then its first derivative should have no more than one local maximum or one local minimum. Such a function can be described as a pure trend. A polynomial function of low degree fitted to the data by least squares regression is liable to fulfill the requirement and it can provide an appropriate benchmark for measuring the cyclical variations.

An example of such a trend is the linear function of Figure 6.5, which has been applied to logarithmic data. When a quadratic function was fitted to the data by least squares regression, the result was virtually a straight line. The data are

from a period that was characterized by uninterrupted economic growth at annual rates that varied little. Therefore, the method of polynomial detrending works well.

In other eras, where there have been marked disruptions, the polynomial method is less appropriate. In order to serve as a benchmark for the ensuing periods of stability, the trend must be made to absorb the disruptions, which implies that it must have a segmented structure. In section 6.10.2 we will describe a method for achieving this.

A prescription that is to be found in the pioneering work of Burns and Mitchell (1946) is that the business cycle should be defined in terms of a limited band of frequencies. A modern interpretation of this is that the band should comprise the sinusoidal elements of the data that have cyclical durations of no more that eight years and of no less than a year and a half. Such cycles can be extracted from the data via a bandpass filter, as we will discuss below.

The definition seems arbitrary, but it might be justified by proposing that the reactions of economic agents to cycles within the frequency band differ from their reactions to cycles at other frequencies. Thus, it might be argued that their adaptations to cycles of more than eight years' duration occur mainly at a subconscious level, whereas cycles of a lesser duration incite conscious reactions.

The growth of an economy may be likened to a process of biological growth, which is affected by events that occur in the course of its evolution. Therefore, a stochastic trend based on the accumulation of random increments has been seen as an appropriate model for an economic trend. This idea has inspired the Beveridge–Nelson decomposition of an ARIMA process, which depicts the trend as an accumulation of disturbances that also give rise to accompanying fluctuations.

In practice, the Beveridge–Nelson decomposition depends upon a linear filter that is applied to the data sequence like any other filter. However, the filtered sequence that represents the trend is liable to include a substantial proportion of the high-frequency elements of the data and for that reason it may be regarded as unacceptable.

6.10.1 Bandpass filters

In an attempt to separate a business cycle component from the trend, economists have been resorting increasingly to the use of bandpass filters to implement the definition of Burns and Mitchell (1946). This appears to be in response to the fact that the structural time series methods, which use ARIMA models to represent the unobserved components, fail to isolate the business cycle.

An ideal bandpass filter that transmits all elements within the frequency range $[\alpha, \beta]$, and blocks all others, has the following frequency response:

$$\psi(\omega) = \begin{cases} 1, & \text{if } |\omega| \in (\alpha, \beta); \\ 0, & \text{otherwise.} \end{cases} \tag{6.163}$$

The coefficients of the corresponding time-domain filter are obtained by applying an inverse Fourier transform to this response to give:

$$\begin{aligned}\psi(k) = \int_{\alpha}^{\beta} e^{\mathrm{i}k\omega} d\omega &= \frac{1}{\pi k}\{\sin(\beta k) - \sin(\alpha k)\} \\ &= \frac{2}{\pi k}\cos\{(\alpha+\beta)k/2\}\sin\{(\beta-\alpha)k/2\} \\ &= \frac{2}{\pi k}\cos(\gamma k)\sin(\delta k).\end{aligned} \tag{6.164}$$

Here, $\gamma = (\alpha+\beta)/2$ is the centre of the pass band and $\delta = (\beta-\alpha)/2$ is half its width.

The final equality, which follows from the identity $\sin(A+B) - \sin(A-B) = 2\cos A \sin B$, suggests two interpretations. On the left-hand side is the difference between the coefficients of two lowpass filters with cut-off frequencies of β and α respectively. On the right-hand side is the result of shifting a lowpass filter with a cut-off frequency of δ so that its center is moved from $\omega = 0$ to $\omega = \gamma$.

The process of frequency shifting is best understood by taking account of both positive and negative frequencies when considering the lowpass filter. Then the pass band covers the interval $(-\delta, \delta)$. To convert to the bandpass filter, two copies of the pass band are made that are shifted so that their new centers lie at $-\gamma$ and γ. In the limiting case, the copies are shifted to the centers $-\pi$ and π. There they coincide, and we have $\psi(k) = 2\cos(\pi k)\sin(\delta k)/\pi k$, which constitutes an ideal highpass filter. A bandpass filter can also be expressed as the difference of two such highpass filters.

The coefficients of (6.164) constitute an infinite sequence, which needs to be truncated to produce a practical filter. Alternatively, a wrapped or circular filter may be obtained by sampling the frequency response at a set of equally spaced points in the frequency range $[-\pi, \pi)$, equal in number to the elements of the data sequence. The wrapped filter is obtained by applying the discrete Fourier transform to the sampled ordinates and it can be applied to the data sequence by circular convolution.

The z-transform of a set of filter coefficients that are symmetric about the central point and that sum to zero incorporates the factor $(1-z)(1-z^{-1}) = -z^{-1}(1-z)^2$. This operator is effective in nullifying a linear trend and in reducing a quadratic trend to a constant. Therefore, such a filter can be applied by linear convolution to a trended data sequence in the expectation that it will produce a stationary filtered sequence.

This is one of the attractions of the truncated bandpass filter that has been proposed to economists by Baxter and King (1999). To ensure that the coefficients of the truncated filter do sum to zero, the filter can be expressed as the difference between two truncated versions of the ideal lowpass filter, of which the coefficients have been scaled so as to sum to unity.

The truncated filter has several disadvantages. In the first place, the truncation leads to the phenomenon of leakage that has already been described in section 6.8. This is illustrated by Figure 6.19. Also, a finite-order moving-average filter with

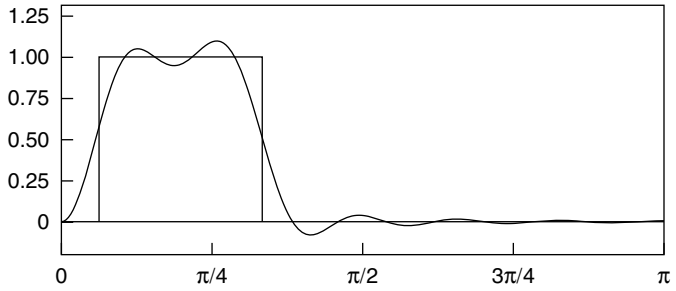

Figure 6.19 The frequency response of the truncated bandpass filter of 25 coefficients superimposed upon the ideal frequency response. The lower cut-off point is at $\pi/15$ radians (11.25°), corresponding to a period of 6 quarters, and the upper cut-off point is at $\pi/3$ radians (60°), corresponding to a period of 32 quarters

constant coefficients is incapable of reaching the ends of the sample. This problem occasions a trade-off between the accuracy of the approximation to the ideal filter, which increases with the number of coefficients, and the end-of-sample problem, which is exacerbated by increasing the span of the filter.

There are numerous ways of overcoming the end-of sample problem, including the obvious recourse of extrapolating the sample by forecasting and backcasting it with the help of an ARIMA model that purports to describe the data. Another recourse is to extend the sample by attaching its symmetric reflection to either end. However, if the data are strongly trended this will tend to increase the values at the beginning of the sample and to decrease the values at the end, relative to the values obtained via a linear extrapolation of the sample.

A circular filter should not be applied directly to a trended data sequence. When such a sequence is wrapped around a circle there is liable to be a radical disjunction where the beginning and the end of the sample are joined. The effects of this disjunction are liable to be carried into the filtered sequence in a manner that does not affect the ordinary linear filter. One way of overcoming this difficulty is to apply the circular filter to data that have been reduced to stationarity by differencing. Thereafter, the filtered differenced sequence can be cumulated to obtain an estimate of the business cycle component.

Example The filter of Baxter and King (1999) is a time-invariant moving average comprising $2q + 1$ of the central coefficients of the ideal infinite-order bandpass filter, which are symmetrically disposed around the central value. These coefficients should rescaled so that they sum to zero.

The elements of the filtered sequence are given by:

$$\begin{aligned} x_t = \phi_q y_{t-q} + \phi_{q-1} y_{t-q+1} + \cdots + \phi_1 y_{t-1} + \phi_0 y_t \\ + \phi_1 y_{t+1} + \cdots + \phi_{q-1} y_{t+q-1} + \phi_q y_{t+q}. \end{aligned} \tag{6.165}$$

Given a sample $y_0, y_1, \ldots, y_{T-1}$ of T data points, only $T - 2q$ processed values $x_q, x_{q+1}, \ldots, x_{T-q-1}$ are available, since the filter cannot reach the ends of the sample, unless some extrapolations are added to it.

To overcome this difficulty, Christiano and Fitzgerald (2003) have used a filter that comprises selections of the coefficients of the ideal filter which vary as one moves through the sample. At all times, the central coefficient of the ideal filter is aligned with the current data value. The remainder of the selection consists of the coefficients on either side that fall within the data window. Thus, the filtered values are weighted combinations of all of the sample elements.

In the case of data that might have been generated by a random-walk process, it is proposed to supplement the weighted sum by two additional terms based on the first and the final sample elements, which are the appropriate predictors of the elements of the process that fall outside the data window. In that case, the elements of the filtered sequence will be given by:

$$\begin{aligned} x_t = {} & Ay_0 + \phi_t y_0 + \cdots + \phi_1 y_{t-1} + \phi_0 y_t \\ & + \phi_1 y_{t+1} + \cdots + \phi_{T-1-t} y_{T-1} + By_{T-1}, \end{aligned} \tag{6.166}$$

where A and B are sums of the coefficients of the ideal filter that lie beyond either end of the data window. Since the filter coefficients must sum to zero, it follows that:

$$A = -\left(\frac{1}{2}\phi_0 + \phi_1 + \cdots + \phi_t\right) \quad \text{and} \quad B = -\left(\frac{1}{2}\phi_0 + \phi_1 + \cdots + \phi_{T-t-1}\right). \tag{6.167}$$

For data that appear to have been generated by a first-order random walk with a constant drift, it is appropriate to extract a linear trend before filtering the residual sequence. In fact, this has proved to be the usual practice in most circumstances.

It has been proposed to subtract from the data a linear function $f(t) = \alpha + \beta t$ interpolated through the first and the final data points, such that $\alpha = y_0$ and $\beta = (y_{T-1} - y_0)/T$. In that case, there should be $A = B = 0$. This procedure is appropriate to seasonally adjusted data. For data that manifest strong seasonal fluctuations, such as the UK expenditure data, a line can be fitted by least squares through the data points of the first and the final years. Figure 6.20 shows the effect of the application of the filter to the UK data adjusted in this manner.

Figure 6.20 can be compared with Figure 6.5 and Figure 6.16, both of which also purport to show the business cycles that affected the data in question. It is clear that the bandpass filter fails to transmit the appropriate cyclical fluctuations. An explanation for the failure can be found in Figure 6.6, which shows the periodogram of the linearly detrended data.

The highlighted band in Figure 6.6 covers the frequency interval $[\pi/16, \pi/3]$ which, according to Baxter and King (1999), is the frequency range that defines the business cycle. However, this figure indicates that only a small part of the low-frequency component falls within the interval. Therefore, it appears that the definition is at fault. In fact, the leakage that is associated with the filter does allow some of the low-frequency power of the elements that reside in the interval $[0, \pi/16]$ to pass into the filtered sequence.

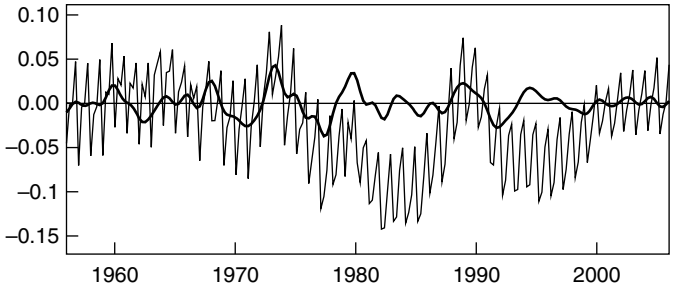

Figure 6.20 A filtered sequence obtained by applying the bandpass filter of Christiano and Fitzgerald to the logarithms of UK household expenditure

6.10.2 Flexible trends and structural breaks

Over a period of a century or so, one can expect to see occasional disturbances that disrupt the steady progress of the economy. To highlight the effects of such breaks, a firm trend function can be fitted to the data to characterize the progress of the economy broadly over the entire period. Such a trend will not be deflected by temporary disruptions, which will be seen in the residual deviations of the data from the trend.

Alternatively, it may be appropriate to absorb the breaks within the trend function. In that case, the trend will not be thrown off course for long by a break and, therefore, it should serve as a benchmark against which to measure cyclical variations when the economy resumes its normal progress. At best, the residual sequence will serve to indicate how the economy might have behaved in the absence of the break.

Numerous devices have been proposed by economists for accommodating structural breaks, which give rise to segmented trend functions. Mills (2003) has illustrated the effects of some of them by applying them to a common data sequence, which is annual UK output from 1855 to 1999. He has also provided references to an extensive literature in economics concerning structural breaks.

A common theme that unites many of the methods is their use of polynomial segments to represent the trends within sub-intervals of the data period. There is a problem of how the transition between two adjacent sub-periods should be modelled. This issue has been discussed by Granger and Teräsvirta (1993) and by Teräsvirta (1998). Others have focused on devising tests to determine the points in time when one statistical regime that describes the data should be replaced by another. Work in this area has been summarized by Perron (2006).

When a smoothing spline is used to interpolate a continuous segmented polynomial function through the data, the smoothness of the function is maintained by imposing the condition that, at the points where they join, the adjacent segments should have equal derivatives, up to some specified order.

The most common smoothing spline is that of Reinsch (1976), which is subject to the condition that the first and second derivatives of adjacent cubic segments

should be equal at the joints, which are described as the knots or the nodes. Breaks can be accommodated within such a spline by placing successive nodes in close proximity. Considerable effort has been devoted to developing algorithms that will ensure the optimal placement of the nodes. (See, for example, Luo and Wahba, 1997.)

When the abscissae of the nodes correspond to the sample dates, it is possible to increase the flexibility of the spline function by allowing local variations to occur in the smoothing parameter. The same recourse can be used to lend additional flexibility to the HP filter, which is a device that is appropriate for extracting from noisy data a trend that is generated by a discrete-time process or by a process limited in frequency to the Nyquist value.

The finite-sample version of the HP filter is provided by equation (6.124). Its generalization is provided by:

$$x = y - Q(\Lambda^{-1} + Q'Q)^{-1}Q'y, \tag{6.168}$$

where $\Lambda = \text{diag}\{\lambda_0, \lambda_1, \ldots, \lambda_{T-3}\}$ is a diagonal matrix of smoothing parameters and Q' is the matrix of the twofold difference operator. In modifying the underlying statistical model of the HP filter, which is specified by (6.129), it is the variance σ_δ^2 of the process driving the trend that is allowed to vary, whereas the variance σ_η^2 of the process that is responsible for the errors of observation remains constant.

Setting $\Lambda^{-1} = \lambda^{-1}I$ in (6.168), which gives the smoothing parameter a globally constant value, produces the HP filter. Setting λ_t to a high value where the trend should be stiff and allowing it to take low values where the trend should be flexible will produce a device that can easily absorb structural breaks.

On the assumption that the underlying trend process is limited in frequency by the Nyquist value, it is appropriate to use the method of Fourier interpolation to create a continuous trend based on the elements of the vector x.

Example An example of a function that fails to accommodate structural breaks is provided by the polynomial of degree 4 that has been interpolated through the logarithms of 129 annual observations of the real GDP of the UK. This is shown in Figure 6.21. Figure 6.22 shows the residual sequence. In both figures, three major events can be recognized. The first is the end of World War I in 1918, which is followed by a sharp decline in GDP. The second is the recession of 1929 and the third is the end of World War II, which is also succeeded by a reduction in income. The recession has less of an impact than one might expect.

Figure 6.23 shows a trend function that has been fitted using a variable smoothing parameter. In this case, only the end-of-war breaks have been accommodated, leaving the disruptions of the 1929 recession to be expressed in the residual sequence. The effect has been achieved by attributing a greatly reduced value to the smoothing parameter in the vicinity of the post-war breaks. In the areas that are marked by shaded bands, the smoothing parameter has been given a value

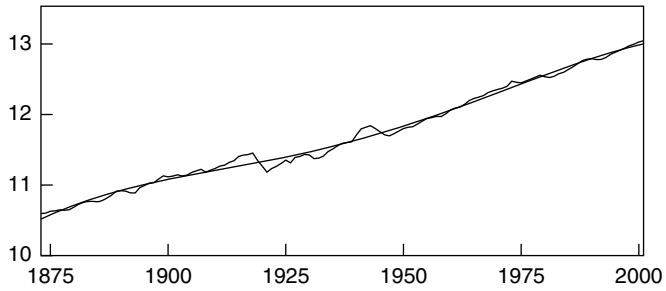

Figure 6.21 The annual series of the logarithms of real GDP in the UK, at constant prices, for the years 1873–2001. A polynomial of degree 4 has been fitted to the data by least squares regression

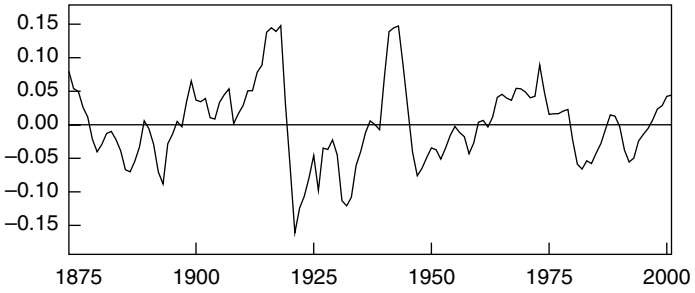

Figure 6.22 The residual obtained from fitting a polynomial of degree 4 to the logarithmic GDP data of Figure 6.21

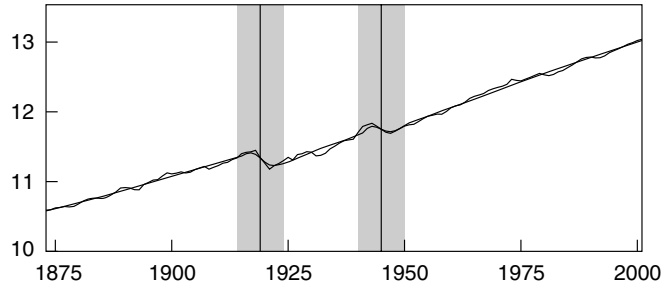

Figure 6.23 The logarithms of annual UK real GDP from 1873 to 2001 with an interpolated trend. The trend is estimated via a filter with a variable smoothing parameter

of 5. Elsewhere, it has been given a high value of 100,000, which results in trend segments that are virtually linear.

6.11 Summary and conclusions

When confronted by the wide variety of methods that are available for extracting the components of an econometric data sequence, a practitioner is liable to ask for a recommendation of the best method. In the case of business cycle analysis, there can be no unequivocal answer. The choice of an appropriate method will depend both on the nature of the data and on the purpose of the analysis. It may also depend on the aesthetic preferences of the analyst.

Nevertheless, the choice of a method ought to be made with a view to its effects in the frequency domain. Econometricians working with temporal sequences are, nowadays, paying increasing attention to the frequency aspects of their analyses, and this is where the major emphasis of the present chapter has been placed.

One of the difficulties in analyzing business cycles is that there is no unequivocal definition of what constitutes a trend. Often, a clearly defined structure that combines the trend and the cycles can be discerned within the data. An example of the successful extraction of a combination of trend and cycles that has been identified by spectral methods is provided by Figure 6.15. However, there is hardly ever a case where the data indicates a point within the frequency spectrum of this structure where the trend ends and the cycles begin.

The only unequivocal definition of the trend that might be offered is that it must have a monotonic trajectory that is devoid of cycles, which means, in practice, that it should be modeled by a polynomial of low degree. This was the practice of the generation of pioneering econometricians to which Tintner belonged.

Latterly, this approach has fallen out of favour amongst econometricians. Nowadays, they are liable to describe polynomial trends as deterministic trends, which are contrasted with stochastic trends. The latter are regarded as capable of more realistic representations of economic behavior. In particular, a stochastic trend can represent a cumulation of random events that effect the development of an economy in the course of time, in the way that the circumstances of their early lives can affect the physical statures of human beings.

Polynomial trends are an essential element within linear models of stochastic accumulation, whether they be represented in continuous time or in discrete time. Therefore, although the conceptual distinction may be a clear one, the practical distinction between a stochastic trend generated by an ARIMA process and a polynomial trend buried in noise is by no means as clear cut as, at first, it might seem to be.

The distinction becomes even more tenuous in the case of an ARIMA model that incorporates stochastic drift. Therefore, notwithstanding the recent efforts of several econometricians, it does not seem to us to be fruitful to employ statistical tests in an attempt to determine which of these alternative statistical structures actually underlies the data.

An opinion to which we adhere in this chapter is that the trend is best regarded as an analytic device, as opposed to an object that subsists within the data that might be uncovered by an appropriate technique. If the trend is to be regarded as an artificial benchmark, then its definition depends largely on what one is intending to measure.

In some cases, when the economy has had an uninterrupted progress, it is straightforward to define an appropriate benchmark. A case in point has been the UK economy over the years 1956–2005, of which the aggregate consumption is portrayed in Figures 6.4–6.6. For that period, a log-linear trend function provides a datum about which to measure the cyclical variations in consumption.

In other eras and over longer periods, where there have been substantial disruptions to the progress of the economy, the matter becomes more complicated. To highlight the major disruptions, it is appropriate to fit a polynomial of a limited degree over the entire span of the data. An example is provided by Figure 6.21. There, a fourth-degree polynomial, which adheres quite well to the data in the main, also reveals the uncommon circumstances in the periods surrounding the ends of the two world wars.

If the purpose is also to illustrate the normal workings of the economy, then it may be appropriate to fit similar polynomial trends of low degrees to the sub-periods that did not experience any disruptions. The overall result will be a segmented curve; and the issue arises of how to join the segments.

The answer that is favored in this chapter is illustrated in Figure 6.23, which shows the effect of a filter with a variable smoothing parameter. The resulting curve comprises segments that are virtually straight lines, interspersed by short segments with rapidly changing slopes.

The disjunctions that occur within the data sequence as a consequence of disruptions and breaks give rise to spectra that extend over the entire frequency range. Unless the breaks are absorbed within the trend, the residual sequence will fail to manifest the band-limited structure that we might expect to see in normal periods. Therefore, one of the criteria of a successful elimination of a break is the restoration of a band-limited spectral structure to the trend cycle component within the residual sequence.

The recognition that, at least for limited periods, the trend cycle complex is liable to be confined to a limited frequency band gives rise to further opportunities, but it also poses additional problems. The opportunities arise from the possibility of using a Fourier synthesis to create a continuous analytic function to represent the business cycle in isolation or the trend and cycle in combination.

In Figure 6.5, the business cycle has been synthesized from a limited number of the low-frequency Fourier ordinates of the linearly detrended logarithmic data. The combination of the trend and the cycle can be formed by adding the business cycle function to the linear trend of Figure 6.4. The result is shown in Figure 6.15.

The analytic nature of these functions means that they are amenable to differentiation, and their turning points are identified as the points where the first derivatives are zero-valued. This method of finding the turning points may be contrasted with the very different procedure of Bry and Boschan (1971), which had

been widely adopted by governmental statistical offices, but which often reaches doubtful conclusions.

A problem posed by band-limited processes is that they cannot easily be represented by the ARMA models that are ubiquitous in time series analysis. Such models are based on the assumption that the spectra of the processes that they represent are supported on a frequency interval that extends as far as the Nyquist frequency, which represents the limit of what is observable in sampled data.

It is often supposed that a discrete-time ARMA process is representing an underlying continuous-time process that has an unbounded frequency range. If that were the case, then the spectral density function defined over the Nyquist interval would be the product of a process of aliasing, whereby the elements of the continuous process that fall outside the Nyquist interval are attributed to frequencies that are inside.

In section 6.5, we have described a correspondence that would exist between processes that are unbounded in frequency and the discrete time models that would serve to represent them. Nevertheless, we have expressed doubts about the relevance to business cycle analysis of such unbounded processes.

In section 6.9, we have argued that processes that are limited in frequency to subintervals of the Nyquist interval, in the way that the business cycle is limited, can be resampled at a reduced rate so as to map their limited supports onto the full Nyquist interval. Thereafter, the ordinary methods of ARMA modeling can be applied to the resampled data. In that case, the Nyquist–Shannon sampling theorem indicates that there is a one-to-one correspondence between the discretely sampled process and an equivalent process in continuous time.

By these means one should be able to find an ARMA model that will capture the dynamics of the business cycle and reveal them in terms of the estimated parameters. In particular, the modulus and the arguments of the roots of the autoregressive operator should reveal the damping characteristics of the cycles and their average periods.

A modern interpretation by Baxter and King (1999) of a prescription of Burns and Mitchell (1946) is that the business cycle should be defined as a band-limited process containing cyclical elements of durations of no less than one and a half years and not exceeding eight years. This appears, at first sight, to be an unequivocal definition. However, there are difficulties in implementing it accurately. Thus, it is commonly believed that the filter that would be required to realize this definition must comprise an infinite number of coefficients, which is not practical.

In place of the infinite-order filter, a truncated approximation is commonly employed that comprises a limited number of the central coefficients. Such a filter is beset by the phenomenon of leakage, whereby the powerful low-frequency elements that would be blocked by the ideal filter find their way into the estimated business cycle. (In fact, a superior approximation is available in the form of a rational filter. See Pollock, 2003b, for example, where a rational function is employed to create a sharp lowpass filter.)

However, it has been show here that the bandpass definition can be fulfilled by selecting the appropriate ordinates of the Fourier transform of the detrended data.

The equivalent filter in the time domain is a wrapped or circular filter. Whereas such filters avoid the leakage that besets approximate bandpass filters, they deliver inappropriate estimates of the business cycle when they adhere strictly to the Baxter–King bandpass definition. Moreover, it seems that any success that the approximate bandpass filter may have in representing the business cycle must be due, in some measure, to the leakage.

The conclusion that we have reached ultimately is that, whereas it is sometimes possible to identify a trend-cycle complex within the data, there can be no definitive definition of what constitutes the trend and what, in consequence, must constitute the cyclical component. Therefore, it seems that one must be liberal in allowing any definitions that seem to fulfil their intended purposes. Even when the purpose is mistaken or unfulfilled, we should not automatically reject the resulting definition or the estimates to which it gives rise.

Economic Cycles: Asymmetries, Persistence, and Synchronization

Joe Cardinale and Larry W. Taylor

Abstract

Marking upswings and downswings for a time series $\{y_t\}$ provides insights that are not immediately obvious, but may be meaningful to academics, policy makers, and the general public. The mean and standard deviation of durations, as well as the amplitude and steepness of a given phase, yield fruitful insights about cycle asymmetries and persistence. Expansions and contractions in one series can then be compared to those in another to determine whether their respective cycles are synchronized. However, our primary focus here is on classical nonparametric methods for the analysis of duration, dating back to the seminal work of Burns and Mitchell (1946), Cutler and Ederer (1958), Bry and Boschan (1971), and Cox (1972). Although our specific application is to unemployment cycles, the ideas and techniques discussed in this chapter apply to a wide variety of micro- and macroeconometric studies.

7.1 Introduction

An event history is a longitudinal record of specified events. Examples at the individual level include dates of schooling, marriage, birth of children, job change, illness, promotion, retirement and migration. Examples at the aggregate level include dates of militarized disputes, riots, revolution, economic expansions and contractions, bull and bear markets, and massive layoffs. Regardless of the underlying activity, an event consists of a qualitative change that marks a new phase for either the individual or the collective. Consider that the beginning of a bull market marks the end of a bear market and that the beginning of a militarized interstate dispute marks the end of placid relations between states with diplomatic ties.

A pertinent issue is whether the probability of exiting a phase, or *state*, depends on its duration. For instance, is a four-hour riot more likely to end within the next hour than a one-hour riot? Does the likelihood of changing jobs decrease with the time invested in the current job? Is a young economic expansion more robust to failure than an old one? If so, we anticipate the end of an old expansion, but are surprised by the end of a young one.

The demographer sees each of the above questions answered best by a life table analysis, the biostatistician by a survival analysis, and the engineer by a reliability or failure-time analysis. The economist tends to view the individual-specific questions on job change as somehow different from the aggregate-level question on business cycles, with the question on riots fitting perhaps somewhere in between. In fact, these questions are generally handled by various sub-disciplines, as the microeconometrician examines individual employment while the macroeconometrician examines the overall business cycle. Despite the initial segregation, however, it is now understood that life table, survival, and reliability analyses are intellectually very similar, and that the analysis of business cycles can be handled in much the same way as that involving promotion and job change.[1]

7.2 Marking time

One important distinction between microeconometric and macroeconometric event studies lies in the complexity of marking time. For individual level or microeconometric events such as marriage, job change, promotion, birth and death, it is relatively easy to pinpoint when the qualitative change occurs. In contrast, for national unemployment, economic expansions and contractions, and bull and bear markets, the timing of change is less certain. Consider the Business Cycle Dating Committee of the National Bureau of Economic Research (NBER). The committee is comprised of experts who mark time – that is, mark the *turning points* – in economic activity by consensus. They examine trends in real gross domestic product (GDP), real income, employment, industrial production and wholesale–retail sales, in conjunction with their collective reasoning that an economic contraction, or *recession*, must last more than a few months.[2]

The NBER derives its method from the graphically oriented approach of Burns and Mitchell (1946), who define the *classical cycle*. The graphical approach is based on marking turning points for several specific cycles, then aggregating that information to form a reference cycle. In formalizing the graphical approach, however, Harding and Pagan (2002) observe that Burns and Mitchell would have *preferred* to use a single series, namely GDP, had that been available to them. The single series approach seems especially appropriate for low frequency data.

Harding and Pagan (2002) thus employ a modified version of the Bry and Boschan (BB) (1971) algorithm to mark turning points for quarterly GDP observations. Their BBQ algorithm again leads to the so-called classical cycle, though defined in a more rigorous, non-qualitative manner.[3] Harding and Pagan (2006) use a similar nonparametric approach to codify the methods for deriving the NBER reference cycle. Regardless of whether single or multiple series are employed to mark time, Harding and Pagan observe that using algorithms is largely immune from deleterious compositional effects of dating committees, such as the NBER Dating Committee. Consider that Artis, Marcellino and Proietti (2004) employ a modified version of BBQ for use in their study of European business cycles.

Parametric models complement the nonparametric analysis. Pagan (1997) examines some simple linear statistical models and shows they are capable of replicating the observed phase *durations* of classical cycles in Australia, the United Kingdom and the United States. He demonstrates that realistic linear statistical models of national output have (i) deterministic trend growth, but of low magnitude, if any; (ii) near-unit-root behavior in the deterministically detrended data, if not exactly unit-root behavior; and (iii) innovations of a certain magnitude. Economic models with final equations for output that match these specifications are observationally equivalent, and this explains why King and Plosser (1994, p. 436) find it difficult to distinguish between the Klein–Goldberger model and a neoclassical real business cycle model. Despite potential identification problems, however, it is only by melding quantitative analysis with economic theory that one can hope to distill the relative importance of monetary, real, expectational, and international shocks. To do so, Harding and Pagan (2000) emphasize the production of

statistics that directly address the ability of a model to replicate business cycle characteristics.

7.2.1 Reasons for marking time

Let $y_t = \log(GDP_t)$, and consider mapping $\{y_t\}$ to a binary time series, $\{S_t\}$, with $S_t = 0$ for recessions and $S_t = 1$ for expansions. Pagan (2004) and Harding and Pagan (2007) offer the following rationale for the reader's interest in $\{S_t\}$:

1. *S_t frequently emphasizes features of y_t that are not immediately obvious.* Observing the behavior of y_t over different phases affords us a better understanding of its features.
2. *S_t may be more meaningful to decision makers than y_t.* Reaction to an economic downturn is often strong among the electorate, and it is of interest to determine whether the probability of exiting a downturn depends on how long one has been in it and whether such exit probabilities, or *hazards*, have changed in fundamental ways in recent history.
3. *S_t may be the object of interest if questions are asked about the synchronization of cycles across sectors or countries.* If S_t is derived from many underlying series, it is often more convenient to compare the representative S_t values than to compute a large number of correlations from the underlying series.
4. *S_t is generally more robust than y_t to relatively unimportant short-lived shocks.* Such shocks may substantially affect statistics based on GDP growth rates but have little impact on overall trends. In contrast, S_t emphasizes the qualitative trend, up or down.

7.2.2 Techniques for marking time

In short, mapping $\{y_t\}$ to $\{S_t\}$ yields fruitful insights about cycle asymmetries, persistence, and synchronization. Some nonparametric rules for marking time are exceptionally simple. For yearly aggregate data, Neftci (1984) and Cashin and McDermott (2002) employ the calculus rule, $S_t = 1(\Delta y_t > 0)$. For quarterly data, one often-used rule in the popular press is the extended Okun rule. The rule states that, for a recessionary phase, termination is signified by two successive quarters of positive growth, $(\Delta y_{t+1} > 0, \Delta y_{t+2} > 0)$. Similarly, for an expansionary phase, termination is signified by two successive quarters of negative growth, $(\Delta y_{t+1} < 0, \Delta y_{t+2} < 0)$. The simplicity of such rules is very attractive, and any limitations of such rules are quickly revealed by visual inspection of the observed series. In fact, regardless of the rule employed, the constructed turning points should visually coincide with those apparent in a plot of the observed time series, $\{y_t\}$.

7.2.2.1 BBQ

To locate turning points in the *level* of GDP, the BBQ algorithm first determines a potential set of local peaks and troughs. Time t is a local peak if:

$$(y_t - y_{t-2} > 0, y_t - y_{t-1} > 0, y_t - y_{t+1} > 0, y_t - y_{t+2} > 0),$$

with the inequality reversed for troughs. The algorithm ensures that peaks and troughs alternate, so that an expansion is immediately followed by a contraction, and vice versa. Finally, the algorithm considers combining phases, or creating new phases, according to a set of predetermined rules. For instance, a censoring rule for business cycles is that either a contraction or expansion must last a minimum of two quarters and complete cycles must last a minimum of five quarters.

BBQ can also mark turning points for other types of series. For example, to locate a potential peak for the *growth* cycle in GDP, replace the requirement that $y_t - y_{t-2} > 0$ with the requirement that $\Delta y_t - \Delta y_{t-2} > 0$, and so on. Pagan and Sossounov (2003) modify BBQ to factor in the *magnitude* of growth rates in financial series. Other applications of nonparametric methods to mark the turning points include Lunde and Timmermann (2004) and Ohn, Taylor and Pagan (2004), who investigate bull and bear markets; Cashin, McDermott and Scott (2002), who investigate booms and slumps in commodity markets; Eichengreen, Rose and Wyplosz (1995), who investigate exchange rate crises; and Ibbotson, Sindelar and Ritter (1994), who examine hot and cold IPO markets.

7.2.2.2 Markov chain models

Hamilton's (1989) innovative Markov chain switching-regime model can also be employed to mark time. For the parametric switching-regime model, a latent random variable, s_t^*, governs the state or *regime* with, say, $s_t^* = 0$ indicating low or negative average growth, and $s_t^* = 1$ indicating high or positive average growth. Two states, signifying negative and positive average growth rates, are adequate to mark the turning points since $\Delta y_t < 0$ indicates a downswing and $\Delta y_t > 0$ indicates an upswing in the level of GDP.

Consider a simple latent-structure model for GDP:

$$\Delta y_t - \mu_{s_t^*} = \phi(\Delta y_{t-1} - \mu_{s_{t-1}^*}) + \varepsilon_t. \tag{7.1}$$

The mean of the growth-rate process switches between "low" and "high," with $\mu_0 < \mu_1$. For each date t in the sample, Hamilton shows how to obtain an estimate of $P(s_t^* = 0|F_T)$, where F_T contains the past, or even the *complete*, sample history of growth rates, $\{\Delta y_t\}_{t=1,\ldots,T}$.

Define $S_t^* = 1[0.5 - P(s_t^* = 0|F_T)]$, so that $S_t^* = 1$ during projected high-growth phases, and $S_t^* = 0$ during low-growth phases. The observed binary series, $\{S_t^*\}$, can be used in a survival, or *duration*, analysis to determine whether the probability of remaining in a given phase, either contraction or expansion, depends on how long one has been in it. An important consideration is that Hamilton's (1989) model is such that s_t^* evolves with the probability of remaining in a given phase independent of its duration, so that contractions and expansions are assumed to be *duration independent*. Of course, this makes $\{S_t^*\}$ less than ideal to represent phases that may actually be *duration dependent*.

Although Durland and McCurdy (1994), Filardo (1994), Diebold, Lee and Weinbach (1994), Macheu and McCurdy (2000) and Jensen and Liu (2006) generalize Hamilton's assumptions in various directions, no parametric model matches

the flexibility and transparency of BBQ to mark time. In particular, for the purpose of solely *marking* the turning points in an observed series such as GDP, it is unnecessary to consider a latent-structure model with or without covariates that helps *predict* the turning points. That is, there is no need to proxy $\{S_t\}$ with $\{S_t^*\}$ for the purpose of a duration analysis.

This is not to say, however, that Markov-switching (MS) models describing fluctuations in y_t are uninformative. In fact, MS models are alternatives to the linear models emphasized by Pagan (1997).[4] Hamilton (2005) argues that linear models are incapable of replicating the cyclical pattern in key economic aggregates, and he devises a simple nonlinear model for unemployment. In particular, linear models cannot capture the fact that the unemployment rate rises more quickly than it falls over the business cycle. Although technology, the labor force, and the capital stock are all key determinants of long-run growth, the forces that contribute to a business downturn can be quite different, and they typically introduce asymmetric behavior that necessitates a nonlinear dynamic representation. Harding and Pagan (2002) also note the deficiency of linear models for replicating the *shapes* of expansions in the business cycle. The point that is often lost is that a duration analysis complements the empirical results from either linear or nonlinear models of y_t; and for the purpose of a duration analysis, it is unnecessary to specify the model for y_t.

7.2.3 Detrending the series

Likewise, there is generally no need to detrend the series to obtain $\{S_t\}$. Cooley and Prescott (1995) first remove the trend prior to marking the turning points. The trend is typically thought of as a permanent effect, and the remainder as a temporary effect. Unfortunately, confusion is likely to ensue when one attempts to separate permanent from temporary effects, because not all temporary components measure the same thing.

For example, consider decomposing aggregate output so that $y_t = P_t + z_t$, where y_t is the logarithm of GDP, P_t is the permanent effect and z_t is the temporary effect. The permanent effect captures slow-moving low-frequency movements in y_t, and the temporary effect captures the faster-moving high-frequency movements. The term P_t is typically an integrated or I(1) stochastic series, but it can just as easily be defined as some type of deterministic trend. The interpretation of z_t, either as an output gap or some function of growth rates, depends on how P_t is defined.

7.2.3.1 Output gaps versus growth rates

Consider first defining the permanent component as the deterministic trend, $P_t = a + bt$. The temporary effect is the output gap, $z_t = y_t - a - bt$, and the time trend captures steady increases in capital and labor that feed into the aggregate production function. In other words, the output gap defines the difference in actual and potential GDP. Marking time by the sign of z_t determines phases of output above or below the trend. On the other hand, if we define the perma-

nent component as $P_t = y_{t-1}$, the temporary effect is now the growth rate since $z_t = \Delta y_t = y_t - y_{t-1}$. Marking time by examining positive and negative values of z_t defines the classical business cycle.

We make a distinction here between growth cycles and gap or *deviation* cycles. For growth cycles, we seek turning points in Δy_t; there is no reason to specify a trend curve. For gap cycles, however, we seek deviations from a specified trend curve. In contrast, Zarnowitz and Ozyildirim (2006), among others, classify a gap cycle as a special type of growth cycle. For their gap analysis, Zarnowitz and Ozyildirim recommend that the trend curve be determined by the classical nonparametric phase-average-trend (PAT) algorithm of Boschan and Ebanks (1978). Zarnowitz and Ozyildirim then argue that a gap analysis is more informative than a direct growth-rate analysis in the study of national output. First, they argue that growth rates over short time spans are very erratic and must be smoothed with complex moving averages that potentially distort patterns. Second, they find that the timing of growth rates is very different from that of the corresponding level series. Of course, an alternative interpretation of the second finding is that the growth cycle is providing different information than is the classical business cycle.

7.2.3.2 Filtering procedures

The specification of any trend curve is somewhat arbitrary. However, Zarnowitz and Ozyildirim (2006) find that the PAT algorithm produces a nonlinear trend curve that smoothly transits from higher to lower growth. They also find that the trend from the PAT algorithm fits as well as a log-linear trend, the stochastic Beveridge and Nelson (1981) trend, the local linear trend of Harvey (1989), the Hodrick–Prescott (1997) trend, and Rotemberg's (1999) heuristic trend.

Intuitively, different types of trends produce different types of temporary components. For instance, King and Rebelo (1993) show that the temporary component from the Hodrick–Prescott (HP) trend is a two-sided weighted average of growth rates. However, if the data-generating process is the pure random walk, $y_t = y_{t-1} + \epsilon_t$, Harding and Pagan (2005) show that the HP temporary component is well represented by a weighted average of current and lagged values of the growth rates with slowly declining weights. In contrast, the Beveridge–Nelson temporary component for the random walk is degenerate since the permanent component is y_t.

The point is this. It is easy to think that all temporary components are measuring the same thing as long as each is a stationary process; however, this is not the case. For business cycles, the litmus test appears to be whether the turning points match well with those of the NBER. Consider that, for quarterly observations on GDP, Hamilton (1989) compares his estimated latent-structure probabilities with turning points in aggregate activity. He demonstrates that his estimate of $P(s_t^* = 0|F_T)$ is generally greater than 0.5 during recessions and less than 0.5 during expansions. On the other hand, the very flexible BBQ algorithm of Harding and Pagan (2002) also yields turning points that accord well with those of the NBER.[5]

7.3 The discrete-time hazard function

Duration data for economic cycles are invariably discrete since data are collected at discrete intervals of time, for example, weekly, monthly, quarterly, or yearly. Although data for markets such as housing or financial markets are available at short intervals, the more interesting questions about such cycles are typically best captured by intervals of at least a month. Consider also that a discrete-time duration analysis can be viewed as an approximation to a continuous-time analysis, or vice versa, and general notions about one apply to the other.[6] A discrete-time framework has the advantage of being more natural for the types of data encountered at the aggregate level; the framework is inherently semiparametric and is easy to understand and implement. Since formal statistical inference depends on the framework, it is best to adopt that of discrete-time if data are measured at long intervals.

Consider a random sub-sample of n observations $(T_1, T_2, \ldots, T_n)$ from a discrete, cumulative distribution F, such that $F(a) = 0$ for $a < 0$.[7] The probability-distribution function, or *density function*, is $f(t) = P(T = t)$, and the discrete-time *hazard function* is:

$$h(t) = P(T = t | T \geq t) = f(t)/G(t), \tag{7.2}$$

where $h(t)$ is the hazard function, and $G(t) = P(T \geq t)$ is the *survival function*. The density function, $f(t)$, gives the probability that a duration will last *exactly* t periods, the survival function, $G(t)$, gives the probability that a duration will last *at least* t periods, and the hazard function, $h(t)$, gives the conditional probability that a phase will terminate in period t, given that it has lasted t *or more* periods. If rising or falling, the hazard provides useful information about the likelihood of a change in phase. Using over 100 years of annual data, Mills (2001) finds several instances of non-constant hazards in the business cycles of 22 countries.

The hazard may also be useful in the assessment of general market conditions. For instance, Diebold and Rudebusch (1990) and Ohn, Taylor and Pagan (2004) observe that post-World War II contractions are more prone to revert to expansion than pre-World War II contractions. One explanation for this finding is that policy makers are now much better able to manage potential economic crises. A second explanation is that individuals and firms are better able to smooth shocks due to innovation and financial deregulation. On the other hand, Watson (1994) finds that, for most individual sectors of the economy, the average contraction and expansion durations for the pre-war and post-war periods are similar; and, more recently, Stock and Watson (2003) suggest that favorable market conditions in the modern era are more likely due to good luck than to good management or innovation.[8] This is especially true for recent times as there have been relatively few long-lived supply disruptions since the 1970s.

7.3.1 Hazard plots

It is generally informative to plot the hazard function, with hazard rates easily computed by the nonparametric life table method of Cutler and Ederer (1958). The

computer package LIMDEP 7.0 constructs such life tables, with an approximate, but intuitive, explanation of the procedure as follows:

- Place the contractions in ascending order by length.
- Construct the hazard rate at time "t" as the ratio of the number of contractions terminating in month "t" over the number of contractions lasting at least "t" months.

Sample information is thus used to estimate $P(T = t)/P(T \geq t)$ in a straightforward manner. A contraction that terminates is said to *exit* the sample, while those contractions lasting at least t months are said to be still *at risk*. Of course, the pool of contractions still *at risk* decreases with t. This implies that the effective sample size for estimating the hazard rates for relatively long contractions is less than for short contractions. Formal statistical tests are thus necessary to avoid spurious conclusions from inspecting the graphs alone.

7.3.2 Benchmark hazards

Nevertheless, graphs convey important information about the general shape of the hazard function. Hollander and Proschan (1975) and Hollander and Wolfe (1999) provide some important benchmarks:

1. Constant Failure Rate: CFR
2. Increasing (Decreasing) Failure Rate: IFR, DFR
3. Increasing (Decreasing) Failure Rate on Average: IFRA, DFRA
4. New Better (Worse) than Used: NBU, NWU.

Figure 7.1 depicts hazard functions from CFR, IFR, IFRA, and NBU *life distributions*.[9] Because there is a one-to-one relationship between the hazard function and the probability density function, a comparison of hazard rates is a natural way of analyzing the nature of exit probabilities, more so than a comparison of density functions. In particular, the CFR hazard is almost always given special consideration in any duration analysis.

CFR hazards correspond to the geometric density. New economic expansions are no more or less likely to terminate than mature ones. In contrast, if expansions are IFR, the hazard, or *failure,* rate is never decreasing, and our illustrated IFR hazard implies an ever more likely chance of termination, or *mortality*.

IFR hazards are not the only ones that have a tendency to rise. Although the depicted IFRA hazard has periods of decline, IFRA has the same overall upward trend. For example, militarized interstate disputes initially have a decreasing hazard rate for a short period, but then exhibit increasing hazards over most of the duration due, perhaps, to a more concentrated effort to either negotiate or impose settlement.

In contrast to IFRA, the depicted NBU hazard function rises above and then falls back to the initial value. There is no overall trend in either direction. Because the hazard function never falls below the initial value, new phases have the greatest chance of surviving an *additional* week or month. An NBU hazard may arise due to

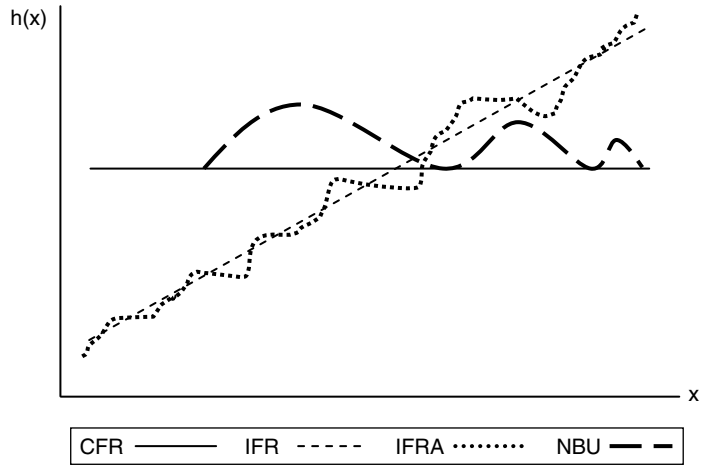

Figure 7.1 Hazard functions for various life distributions

seasonal effects such as holidays or inclement weather, and IFRA hazards are special cases of NBU hazards. A completely analogous situation holds for DFR, DFRA and NWU distributions.

The graphical approach of Cutler and Ederer (1958) is nonparametric and avoids some of the dangers of relying too heavily on parametric methods. For instance, in the emerging area of forensic economics, Bonanomi, Gaughan and Taylor (1998) use the flexible nonparametric life table method in the estimation of lost profits when the plaintiff claims lost customers due to an alleged transgression. However, in the general economics literature, Sichel (1991) advocates using parametric methods to increase the power of tests for duration dependence. In the political science literature, Bennett (1999) and Zorn (2000) observe that the parametric Weibull model is the most widely-used form. Bennett also cautions that Cox's semiparametric proportional hazards model does not allow for *precision* concerning the hazard function.

Precisely wrong results, however, are hardly helpful. Ohn, Taylor and Pagan (2004) show that the Weibull model is insufficient to capture the richness of economic contractions and expansions, and Taylor (2007) shows that the Weibull model is highly misleading for militarized interstate disputes. Attempts to apply more flexible continuous-time methods have met with mixed success. Diebold, Rudebusch and Sichel (1993), for example, apply their nonlinear exponential linear model to business cycle data that mostly duplicates the results from the Weibull model. Zuehlke (2003) applies the nonlinear model of Mudholkar, Srivastava and Kollia (1996) that allows hazards to be monotonically increasing, monotonically decreasing, U-shaped or inverted U-shaped. However, Ohn, Taylor and Pagan (2004) observe that none of these shapes adequately describes the hazard functions for pre-World War II constructions and expansions. Even for the small samples encountered in the business cycle literature, nonparametric analysis provides valuable insights that parametric analysis fails to uncover.

7.4 Testing for duration dependence

The direction of duration dependence is easily obtained from a sample of durations. First, if the mean duration equals the sample standard deviation, there is no evidence of duration dependence; that is, there is *a constant hazard*. Second, if the mean duration is greater than the sample standard deviation, there is evidence of *positive* duration dependence, or a generally increasing hazard. Finally, if the mean duration is less than the sample standard deviation, there is evidence of *negative* duration dependence, or a generally decreasing hazard.

7.4.1 The nature of duration independence

Duration independence is considered the neutral case. Long expansions have no greater chance of ending than short expansions; long bear markets have no greater chance of ending than short ones; and long housing slumps have no greater chance of ending than short slumps. The duration of the phase has no predictive power in determining the end of the phase. Because of neutrality, the constant hazard is the standard benchmark, and a graph of the hazard function is frequently employed to see if the hazard function appears roughly constant. If so, there is *duration independence,* and the hazard function does not depend on t. In other words, the null hypothesis is:

$$H_0 : h(t) = p \quad \text{for some } 0 < p < 1 \text{ and all } t > 0. \tag{7.3}$$

The density *must* be geometric for constant hazards, and the above null hypothesis is equivalent to:

$$H_0 : f(t) = P(T = t) = (1-p)^t p \text{ for } 0 \leq t \leq \infty. \tag{7.4}$$

In other words, testing for duration independence is equivalent to testing whether the durations follow the geometric density. A *direct*, or *strong-form*, test for the geometric density is the usual chi-square goodness-of-fit test employed by Ohn, Taylor and Pagan (2004).

Finally, for the geometric density, $E(T) = (1-p)/p$ and $V(T) = (1-p)/p^2$, leading to a third null hypothesis for duration dependence:

$$H_0 : V(T) - [E(T)]^2 - E(T) = 0. \tag{7.5}$$

7.4.2 Weak-form tests

Pagan (1998) and Mudambi and Taylor (1991, 1995) devise tests for duration dependence based on the *consistency relationship* as in (7.5). Such tests are called *weak-form* tests and have close links with continuous-time tests for the *exponential* density. Although the exponential density is simply the continuous-time equivalent of the discrete-time geometric density, there is one rather important difference between the two. The consistency relationship for the exponential density is $V(T) - [E(T)]^2 = 0$ rather than $V(T) - [E(T)]^2 - E(T) = 0$, and thus the choice between the discrete-time and continuous-time tests is important except when p is close to either 0 or 1, since then $V(T) \approx [E(T)]^2$.

7.4.2.1 The GMD test

Mudambi and Taylor (1995) devise a generalized method of moments (GMM) estimator based on the moment condition, $V(T) - [E(T)]^2 - E(T) - \gamma = 0$. For the geometric density, $\gamma = 0$, and they determine whether GMD = $(1/n) \sum_{i=1}^{n} (T_i - \overline{T})^2 - \overline{T}^2 - \overline{T}$ is statistically significant from zero. Once normalized, GMD is asymptotically $N(0, 1)$, and should be especially sensitive to IFRA and DFRA alternatives since it is completely analogous to a continuous-time test based on $V(T) - [E(T)]^2 = 0$ that is designed for such alternatives. Because GMD is highly skewed in finite samples, however, simulations are necessary to obtain finite-sample critical values.

7.4.2.2 The SB test

Closely related to the GMD test is the *state-based* SB test proposed by Pagan (1998), which has a number of positive attributes:

1. SB focuses directly on the conditional probabilities.
2. SB involves a regression and so is easy to explain to a nonspecialist.
3. SB can be used to examine prediction issues.
4. SB can be used to study how the exit probabilities have changed over time since the parameters can be recursively estimated.
5. SB can be easily modified to estimate discrete-time hazard functions, with or without covariates.

Although SB can be applied to whole cycles, it is best to apply the test to the separate half cycles, or phases. In other words, one should apply SB first to contractions and then to expansions. In fact, Mudambi and Taylor (1991) show that it is incompatible for expansions, contractions, and whole cycles *all* to follow a constant-hazard geometric distribution. So, if expansions and contractions are duration independent, it is certain that whole cycles are duration dependent. Likewise, if whole cycles are duration independent, there is necessarily some form of statistical dependence in the half-cycle components.

Consider a small sample of *contractions* observed at monthly intervals. In the example below, there are gaps in the time line because most months of expansion are excluded from the sample. In fact, the only included months of expansion are those that correspond to a turning point.

	Jan	Feb	Mar	Apr	...	Sep	Oct	Nov	Dec	Jan	Feb	...	Jun	Jul
S_t	0	0	0	1	...	0	0	0	0	0	1	...	0	0
d_{t-1}	0	1	2	3	...	0	1	2	3	4	5	...	0	1

$S_t = 0$ indicates a month of economic contraction, and $S_t = 1$ indicates a month of economic expansion. For instance, the first complete contraction began in January and ended in March, with April as the turning point. The string of S_t values represents two complete contractions and one incomplete, or *censored,* contraction. The durations of the contractions are $T_1 = 3, T_2 = 5$, and $T_3 = 2$. Any censored observations will invariably be at the beginnning and/or end of the string, and

such incomplete observations are dropped from the sample. For the sub-sample of expansions, we consider instead $1-S_t$, so that $(1-S_t)=1$ marks the turning point of an economic expansion.

An economic expansion or contraction is a *phase* of the business cycle. Define d_t as the number of months in a given phase. The above table demonstrates values for lagged d_t. Now drop those observations from the sample if $d_{t-1}=0$, and define m as the number of remaining S_t values. For our example, $m=8$ since we drop two observations because $d_{t-1}=0$ and we drop the last contraction due to censoring. A straightforward test for duration dependence in contractions is obtained by testing the null hypothesis, $H_0:\beta_1=0$, in the simple regression equation:

$$S_t=\beta_0+\beta_1 d_{t-1}+\epsilon_t, \tag{7.6}$$

where $E_{t-1}(\epsilon_t)=0$.

For constant hazards, $\beta_1=0$ and $\beta_0=p_{01}$, where $p_{01}=P(S_t=1|S_{t-1}=0)$. The term d_{t-1} captures autonomous changes in the hazard function. The resulting model can be written as:

$$S_t=p_{01}+\nu_t. \tag{7.7}$$

Hamilton (1994, p. 684) shows how to write such an equation if one is considering complete cycles rather than half-cycles. For the purpose of a duration analysis, however, it is only necessary to consider half-cycles: expansions or contractions, bull or bear markets, upswings or downswings.

For non-constant hazards, $\beta_1\neq 0$, and the termination probability depends on d_{t-1}, the length of time in the specified phase. Ohn, Taylor and Pagan (2004) show that the SB t-test is appropriate for testing $H_0:\beta_1=0$. We argue here the same point, but from a different approach. In particular, by the definition of the binary indicator, S_t, the duration of an expansion must be at least one month. The geometric density is thus left-censored at unity. The censored probability function is $P(T=t)=(1-p)^{t-1}p$ for $1\leq t\leq\infty$, with $E(T)=1/p$ and $V(T)=(1-p)/p^2$. Let n be the number of turning points. Then $\overline{T}=(1/n)\sum_{i=1}^{n}T_i$ is a consistent estimator for $E(T)$, $\widetilde{\sigma}^2=(1/n)\sum_{i=1}^{n}(T_i-\overline{T})^2$ is a consistent estimator for $V(T)$, and $\overline{S}$ is a consistent estimator for p.

The least squares estimator of β_1 is:[10]

$$\widehat{\beta}_1=\frac{\frac{1}{m}\sum_{t=1}^{m}(S_t-\overline{S})d_{t-1}}{\frac{1}{m}\sum_{t=1}^{m}(d_{t-1}-\overline{d})^2}, \tag{7.8}$$

where $\overline{S}=\frac{1}{m}\sum_{t=1}^{m}S_t=n/m$ and $\overline{d}=\frac{1}{m}\sum_{t=1}^{m}d_{t-1}$.

Our goal is to show that $p\lim\widehat{\beta}_1=0$ under the null hypothesis that durations follow the geometric density. To do so, consider the numerator of the least

squares estimator:

$$\frac{1}{m}\sum_{t=1}^{m}(S_t-\overline{S})d_{t-1} \tag{7.9}$$

$$=\frac{1}{m}\sum_{t=1}^{m}S_t d_{t-1}-\overline{S}\,\overline{d} \tag{7.10}$$

$$=\frac{n}{m}\overline{T}-(\frac{n}{m})^2\frac{1}{n}\sum_{i=1}^{n}\frac{(T_i+1)T_i}{2} \tag{7.11}$$

$$=\overline{S}\frac{1}{2}\{2\overline{T}-\overline{S}[\widetilde{\sigma}^2+\overline{T}^2+\overline{T}]\}. \tag{7.12}$$

Since, for the geometric distribution, $p\lim\overline{T}=1/p$ and $p\lim\widetilde{\sigma}^2=(1-p)/p^2$, it follows that:

$$p\lim\overline{S}\frac{1}{2}\{2\overline{T}-\overline{S}[\widetilde{\sigma}^2+\overline{T}^2+\overline{T}]\}=p\frac{1}{2}\left\{2\frac{1}{p}-p\left[\frac{(1-p)}{p^2}+(1/p)^2+\frac{1}{p}\right]\right\}=0. \tag{7.13}$$

An immediate implication is that $p\lim\widehat{\beta}_1=0$ for a constant-hazard function. On the other hand, just as with GMD, the distribution of SB is skewed right in finite samples, and thus it is necessary to use simulations to obtain finite-sample critical values.

In spite of their skewed distributions, GMD and SB are asymptotically pivotal; that is, asymptotically they do not depend on unknown parameters. For asymptotically pivotal statistics, the bootstrapped critical values are generally more accurate than those based on first-order asymptotic theory. Horowitz (2001) and Davidson and MacKinnon (2006) explain why it is desirable to use pivotal statistics when bootstrapping.

7.4.3 Strong-form tests

Diebold and Rudebusch (1991) and Ohn, Taylor and Pagan (2004) employ the chi-square goodness-of-fit test to determine if durations follow the geometric density. The test statistic is $\chi^2=\sum_{j=1}^{K}[(O_j-E_j)^2/E_j]$, where O_j is the observed frequency in the jth bin and E_j is the expected frequency in the jth bin. The expected frequency is derived under the null distribution, in this case the geometric density. A well-known rule of thumb is that the expected frequency, E_j, should be at least 5 for all bins (see Hoel, 1954). To be on the safe side, Ohn, Taylor and Pagan (2004) use 6 instead of 5. If one adheres to this rule-of-thumb, long-term experience suggests that χ^2 approximately follows its asymptotic chi-square distribution with K-1 degrees of freedom. Nonetheless, both Diebold and Rudebusch (1991) and Ohn, Taylor and Pagan (2004) employ simulation to obtain finite-sample critical values.

7.5 Modeling with covariates

Most researchers using aggregate-level data segment the time line to control for heterogeneity of the exit probabilities. For example, Edwards, Biscarri and

de Gracia (2003) segment the time line for Latin American and Asian countries to determine the effect of financial liberalization on stock market cycles. Models that employ covariates have not been as popular and the studies that do use them generally assume duration independence. For instance, Estrella and Mishkin (1998) employ a discrete-time analysis to examine various financial variables as predictors of US recessions, and Chin, Geweke and Miller (2000) use a similar analysis to predict turning points in the civilian unemployment rate. Conditional upon the right-hand-side variables, however, both studies assume the hazard function is independent of time.[11]

The strong assumption of duration independence in models with covariates is defensible in some circumstances. In the political science literature, Bennett (1999, p. 262) goes so far as to argue that including covariates to effectively eliminate duration dependence is a laudable goal:

> Unless we can anthropomorphize and assume that the phenomenon we are examining truly has a life of its own, then the pattern or covariation over time that we observe is somehow, somewhere, driven by a variable or set of variables that characterizes the world. If the causal factor driving duration dependence is measured and included in the model as an independent variable, then unexplained duration dependence ... may disappear.

Bennett's view aligns with the concept of *probabilistic reduction* that Spanos (1995) traces back to the biometric tradition of Galton and Pearson; see also Spanos (2006) and Hoover (2006). In the regression framework, probabilistic reduction implies that a complete theory must induce white-noise disturbances in the model. In practice, whether covariates can account for the observed duration dependence in any binary series is surely an empirical question that cannot be assumed away for the model at hand. Complete theories are ideal but rare.

Another reason that duration dependence is frequently ignored for discrete-time analysis is that many researchers apparently believe that it is not possible to incorporate such dependence. For instance, Bennett (1999, p. 259) argues that the logit model is insufficient for the analysis of duration data because "it assumes that no duration dependence exists." Below we show that a slightly modified logit model is suitable to capture autonomous changes in the discrete-time hazard as well as changes due to covariates.

Probit models are alternatives to logit models. There is no need, however, to adopt any type of latent structure for either probit or logit. In other words, it is neither necessary nor desirable to insist that there exists some type of latent variable, y_t^*, such that $S_t = 1$ if $y_t^* > 0$, and $S_t = 0$ if $y_t^* \leq 0$. Although such an assumption *is* desirable in the discrete-choice literature, where y_t^* is interpreted as a utility function, it only unnecessarily complicates a duration analysis. In fact, to mark time for economic cycles, we frequently map an *observed* series,$\{ y_t\}$, to $\{S_t\}$. Thus, the unobservables of true interest in either the logit or probit probability models are the estimable parameters controlling the termination probabilities of $\{S_t\}$.[12]

7.5.1 The logit model

Following Allison (1984), let $P(t)$ represent the discrete-time hazard function. We use $P(t)$ here rather than $h(t)$ because it is more natural to do so for logistic regression. For the logit hazard model:

$$\log(P(t)/(1 - P(t)) = a(t) + \beta_1 x_1 + \beta_2 x_2(t). \tag{7.14}$$

where $a(t)$ represents a set of dummies, one for each of the observed exit periods, that account for autonomous changes in the exit probabilities; x_1 represents a set of covariates that do not change over the course of a given contraction; and $x_2(t)$ represents a set of covariates that do change over the course of a given contraction. In other words, $a(t)$ allows for non-constant hazards, conditional upon the x values. For constant hazards, one should substitute a single intercept parameter, a, for the time-varying $a(t)$.

7.5.1.1 The LSB test

Define d_t as the number of consecutive months (that is, duration) spent in a contraction up and *through* time t, and consider a very simple model with just one $x(t)$, namely d_{t-1}, as defined for the SB test:

$$\log(P(t)/(1 - P(t)) = \beta_0 + \beta_1 d_{t-1}. \tag{7.15}$$

Drop observations from the sample if $d_{t-1} = 0$. A restriction from the assumption of duration independence is $H_0 : \beta_1 = 0$, with the test statistic computed by the corresponding asymptotic t-ratio. The constant-hazard test from logit regression, call it LSB, is obviously closely related to Pagan's regression-based SB test. The potential advantages of using SB are that it is very straightforward, the least squares algorithm is very stable, and many computer packages recursively estimate least squares (but not logit) coefficients.

Stability is an important consideration for small samples since the number of observations with $S_t = 1$ is usually small for macroeconomic data. Consider, for example, that there are only about ten post-World War II economic expansions in the American business cycle. For these expansions, the number of observations with $S_t = 0$ is large because of a low termination probability, hence the proportion of observations with $S_t = 1$ is small. With a very low proportion of observations with $S_t = 1$, small samples can be especially problematic for logistic regression.

For sufficiently large samples, however, the logit model is preferred to the linear model. For the linear model, the predicted probabilities can lie outside of the unit interval from 0 to 1, and it is well known that least squares estimators are not efficient if the dependent variable is binary. In contrast, logit probabilities are always bounded on the unit interval; and since logit estimation is based on maximum likelihood, the estimators from logit are asymptotically efficient.

7.5.1.2 A comparison with Cox's model

Thompson (1977) presents another compelling argument in favor of logit estimation. As the discrete-time intervals become smaller and smaller, the logit model

converges to Cox's (1972) continuous-time proportional hazards model. Cox's model can be written as:

$$\log h(t) = a(t) + \beta x, \tag{7.16}$$

where $h(t)$ is the continuous-time hazard rate, similar to $P(t)$, and x represents a set of covariates that do not vary over time. Like the discrete-time logit model, $a(t)$ can be any function of time. The term *proportional hazard* comes from the fact that, for any t and any two individuals i and j:

$$h_i(t)/h_j(t) = \exp(\beta x_i)/\exp(\beta x_j) = \exp(\beta(x_i - x_j)). \tag{7.17}$$

This function does not vary with time because the autonomous time-varying term, $a(t)$, cancels out. Cox's model, however, is not just limited to proportional hazards, since the model is no longer proportional if some of the x values vary with time. Some computer packages allow for time-varying covariates while others do not. Fortunately, this is not a concern to us since it is always possible to allow for time-varying covariates in logistic regression.

Cox's proportional hazards model is semiparametric because the autonomous time-varying term, $a(t)$, does not have to be specified. Although the estimators of β are asymptotically unbiased and normally distributed, they are not *fully* efficient because the exact functional form of $a(t)$ is not specified. However, Efron (1977) shows that the loss of efficiency is typically so small that it is not of practical concern. The importance of Cox's model for duration analysis is well-summarized by Allison (1984, p. 35):

> It is difficult to exaggerate the impact of Cox's work on the practical analysis of event history data. In recent years, his 1972 paper has been cited well over 100 times a year in the world scientific literature. In the judgment of many, it is unequivocally the best all-around method for estimating regression models with continuous-time data.

In practice, time is always measured in discrete intervals, although the intervals may be irregular for individual histories. Consider also that, if two or more individuals experience events at the same time, that is, if we observe a *tie*, then the model proposed by Cox (1972) is the logit model. Therefore, although some authors have argued that continuous-time methods are preferable to discrete-time methods on theoretical grounds, or have completely ignored discrete-time methods altogether, the lack of attention to the logit model seems rather unfortunate. The preference for continuous-time models is largely based on computational grounds, but this is certainly less of an issue today than it was 25 years ago!

7.5.2 Predetermined variables and unobserved heterogeneity

An important issue is the number and choice of covariates. Consider, for example, economic expansions. If the length of the prior expansion and/or contraction influences the exit probability of the current expansion, then the length of the

prior expansion and/or contraction should be included in the set of explanatory variables. The usual asymptotic t-ratio can then be employed to determine if such effects are important. Thus, with a set of appropriate explanatory variables, either predetermined or strictly exogenous, one can account for certain types of dependence that cannot be handled by simply segmenting the time line.

Unobserved, or neglected, heterogeneity is inherently a problem of omitted variables. As a practical consideration, however, the sample sizes encountered in the study of economic cycles are generally too small to consider many explanatory variables. Explanatory variables are used to control for heterogeneity in the exit probabilities. Bover, Arellano and Bentolila (2002) develop logistic discrete hazard models that can accommodate unobserved heterogeneity. In their microeconometric study of about 27,000 unemployment spells of Spanish men, they explicitly control for unemployment benefits, age, education, head of household status, and dummies for economic sector and year of unemployment. A second model is estimated with time-varying macroeconomic variables, such as the growth rate in GDP and sectoral unemployment rates, substituting for the sectoral and time dummy variables. Autonomous shift dummies, $a(t)$, are included in both models to capture flexible additive duration dependence. A dummy variable is included for each possible exit time, with time marked at monthly intervals.

Bover, Arellano and Bentolila (2002) treat the length of unemployment benefits as predetermined, though not strictly exogenous, since knowledge about future benefits can influence job choice and especially the decision to re-enter the labor market. The distinction between predetermined and strictly exogenous variables is fairly unimportant unless there is unobserved heterogeneity. In that case, predetermined variables are effectively endogenous, and it is necessary to maximize the joint mixture likelihood for the unemployment and benefit durations. This is accomplished, in part, by introducing a discrete unobserved random variable with finite support. Additional parameters are thus included to model the unobserved heterogeneity.

In the macroeconometrics literature on business cycles, however, post-war sample sizes of about ten spells preclude the possibility of estimating models that are rich in parameters. As a partial solution, segmenting the time line into pre-war and post-war is sufficient to control for omitted variables that vary across, but not within, the segments. Since any residual heterogeneity induces *negative* duration dependence, expansions and contractions may appear to be self-perpetuating even if this premise is false. On the other hand, Diebold and Rudebusch (1990) and Ohn, Taylor and Pagan (2004) find evidence of *positive*, not negative, duration dependence in the American business cycle. Thus, at least the *direction* of such duration dependence cannot be caused by residual, or neglected, heterogeneity.

7.6 The shape of cycles

Duration dependence concerns the shape of the hazard function. If the hazard function slopes upward, there is positive duration dependence; if downward, there

is negative duration dependence; if flat, there is no duration dependence. However, the shape of the hazard function is but one example of the types of shapes associated with cycles. In particular, Harding and Pagan (2002) and Pagan and Sossounov (2003) discuss the typical shapes of phases, either contractions or expansions. They address the following issues:

1. Amplitudes of phases
2. Cumulative movements within phases
3. Asymmetric behavior of phases.

After marking the turning points, the binary series, $\{S_t\}$, is employed along with the observed underlying series, $\{y_t\}$, to describe the shape of a phase. For example, during economic expansions, GDP is observed to rise quickly at first and then slows its ascent before finally reversing direction, thus marking the beginning of a contraction.

In Figure 7.2, we present a stylized economic expansion. The y axis represents log(GDP), or *amplitude*, and the x axis represents time spent in an expansionary phase, or *duration*. On the time axis, time A represents the first turning point, the trough, and time B the second turning point, the peak. The amplitude of the expansion is the vertical distance between points A and B, measuring the change in GDP from trough to peak. In this instance the amplitude is $\log(GDP_B) - \log(GDP_A)$. The hypotenuse of the triangle is a benchmark representing a constant increase in amplitude, with increases in amplitude proportional to the time spent in the expansionary phase.

Descriptive measures of interest include the average duration and average amplitude of the expansions in the sample, measures of the variability in durations and amplitudes, and a measure to show how closely growth in GDP adheres to the hypotenuse depicted in Figure 7.2. For our sample of n expansions, we observe the durations $\{T_1, T_2, \ldots, T_n\}$, and the amplitudes $\{A_1, A_2, \ldots, A_n\}$.

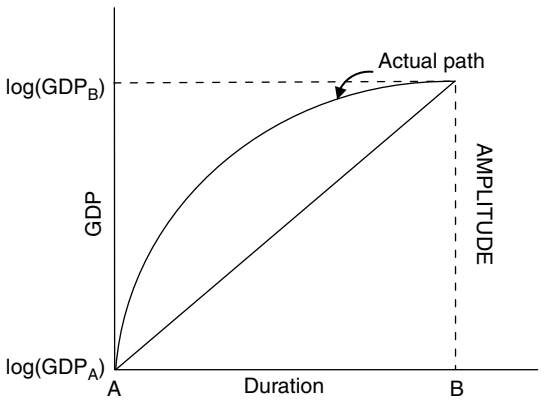

Figure 7.2 Stylized expansion phase

7.6.1 Durations

Assume that durations and amplitudes constitute random samples. If so, the $T_i's$ follow identical distributions, $T_i \backsim D(\mu_T, \sigma_T^2)$, with T_i statistically independent from T_j for $i \neq j$. Further, $\overline{T} = \frac{1}{n}\sum_{i=1}^{n} T_i$ is a consistent estimator for μ_T and $\overline{T} \overset{a}{\backsim} N(\mu_T, \sigma_T^2/n)$. This assumes, of course, that the time line has been successfully segmented to ensure that each of the $T_i's$ follows the same distribution, that is, with no mixing of distributions.

Small sample inference, however, is particularly problematic for durations. Consider that the $T_i's$ rarely come from the normal distribution. In fact, for the discrete case with constant hazards, the $T_i's$ follow the geometric distribution, $T_i \backsim GEOM(\mu_T, \mu_T^2 - \mu_T)$, with $\mu_T = 1/p$, where p is the constant hazard. However, since the geometric distribution is considerably right-skewed, for very small samples it is generally unwise to construct confidence intervals on μ_T by employing the *t*-distribution, since normality of the durations is one of the assumptions supporting its use. Simulations by Pagan and Sossounov (2003) also suggest that $\overline{T}$ is significantly skewed in small samples.

7.6.2 Amplitudes

Amplitudes are less problematic. For the *i*th expansion, the amplitude is calculated as $A_i = y_{T_i} - y_0 = \sum_{j=1}^{T_i} \Delta y_j$, with $\Delta y_1 = y_1 - y_0$, $\Delta y_2 = y_2 - y_1$, and so on. In Figure 7.2, y_0 equals $\log(GDP_A)$ and y_{T_i} equals $\log(GDP_B)$. The amplitude of the expansion is thus the sum of the growth rates from time A to B. Although Harding and Pagan (2002) convincingly argue that GDP growth rates are not statistically independent, their sum may be approximately normally distributed by either Gordin's (1969) or Hannan's (1973) Central Limit Theorems (CLT) for stationary ergodic processes; see also White (1984, Ch. V). Thus, approximate normality for the amplitudes, A_i, is more plausible than normality for the durations, T_i, provided that expansions are sufficiently long to allow the CLT to work for each A_i.

7.6.3 Cumulative gain

Another measure of interest is the *cumulative* gain from trough to peak, that is, the area under the curve that describes the actual path of GDP. An approximation to this gain is obtained by adding together the area in rectangles of unit length and height equal to $y_j - y_0$. The approximation, however, is too large since each such rectangle overstates the actual area by approximately $(y_j - y_{j-1})/2$. Correcting for the overstatement, Harding and Pagan (2002) approximate the cumulative gain for the *i*th expansion by:

$$F_i = \sum_{j=1}^{T_i} \left[(y_j - y_0) - (y_j - y_{j-1})/2 \right] \tag{7.18}$$

$$= \left[\sum_{j=1}^{T_i} (y_j - y_0) \right] - A_i/2, \tag{7.19}$$

where $A_i = y_{T_i} - y_0$. A benchmark for F_i is the cumulative area under the hypotenuse depicted in Figure 7.2. The area of this right triangle is easily calculated as $AREA_i = (T_i \cdot A_i)/2$. Taking the difference, $F_i - AREA_i$, and then dividing by the duration of the ith expansion, one obtains:

$$E_i = (F_i - AREA_i)/T_i. \tag{7.20}$$

A positive value of E_i indicates that growth rates generally increase at a decreasing rate over the life of the expansion, and a negative value of E_i indicates that growth rates generally increase at an increasing rate over the life of the expansion. A positive value for $\overline{E} = \frac{1}{n}\sum_{i=1}^{n} E_i$ indicates that most of the growth occurs at the beginning of the typical expansion, and a negative value of $\overline{E}$ indicates that most of the growth occurs at the end of the typical expansion. If $\overline{E} = 0$, then neither characterization is accurate; instead, the actual path for y tends to oscillate around the hypotenuse. $\overline{E}$ is thus a useful descriptive measure of the average shape, or curvature, of expansions. A similar interpretation holds for $\overline{C}$, the average shape of contractions. In the literature on business cycles, Sichel (1994) documents the rapid recovery of an expansion that leads to a positive value for $\overline{E}$. In the financial literature, Edwards, Biscarri and de Gracia (2003) observe that the excess index (equation 7.20) is particularly useful in characterizing stock market behavior.

7.7 Synchronization of cycles

The cyclic characteristics of a single series, $\{y_t\}$, are of interest because they yield insights about the underlying series. Consider also that the cyclic relationship between *two* underlying series, $\{y_{1t}\}$ and $\{y_{2t}\}$, is of like interest to both academics and policy makers. For example, do short periods of financial crisis influence the business cycle? Are cycles in foreign economies closely tied to the American business cycle? Are cycles in national unemployment related to cycles in GDP? Finally, are cycles in oil prices related to the world economic or political (dis)order? Each of these questions can be answered, in part, by examining the observed binary time series, $\{S_{1t}\}$ and $\{S_{2t}\}$, that respectively correspond to $\{y_{1t}\}$ and $\{y_{2t}\}$.[13]

7.7.1 The coincidence indicator

One way to measure the correspondence between $\{S_{1t}\}$ and $\{S_{2t}\}$ is to employ the *coincidence indicator* of Harding and Pagan (2002):

$$\widehat{I} = 1/T\sum_{t=1}^{T}[S_{1t}S_{2t} + (1 - S_{1t})(1 - S_{2t})], \tag{7.21}$$

where T is the total number of periods in the sample interval, regardless of phase. Consistent with the notation of Harding and Pagan (2002, 2006), we use T in this section to denote the sample size rather than duration. It follows that $\widehat{I}$ is the fraction of periods that $\{S_{1t}\}$ and $\{S_{2t}\}$ are synchronized. Harding and Pagan (2006) note that there is *perfect positive synchronization* between $\{S_{1t}\}$ and $\{S_{2t}\}$ if

$\widehat{I} = 1$, and there is *perfect negative synchronization* if $\widehat{I} = 0$. Beyond the literature on national output, Edwards, Biscarri and de Gracia (2003) observe that financial synchronization, or *concordance*, among Latin American countries has substantially increased after financial liberalization.

7.7.2 Correlation analysis

The sample correlation coefficient between S_1 and S_2, call it r_s, conveys similar information to $\widehat{I}$. If $r_s = 1$, there is evidence in favor of the null hypothesis, H_0 : $\rho_s = 1$, since $S_{1t} = S_{2t}$ for every paired observation in the sample. Of course, if there is a single case where $S_{1t} \neq S_{2t}$, there is reason to reject the hypothesis that the cycles are *perfectly* positively synchronized. Similar reasoning holds true for perfect negative synchronization. A formal test of $H_0 : \rho_s = 1$ is presented by Harding and Pagan (2006).

As perfect synchronization will be empirically atypical, it is still useful to compute either or both of the sample correlation coefficient and coincidence indicator to see how closely two series move in tandem. Graphing the series may also reveal an obvious translation of $\{S_{1t}\}$ that will more closely synchronize $\{S_{1t}\}$ with $\{S_{2t}\}$. For instance, consider $\{S_{3t}\} = \{S_{1,t\pm l}\}$ for some integer $l > 0$. The concordance between $\{S_{3t}\}$ and $\{S_{2t}\}$ may be considerably higher than the concordance between $\{S_{1t}\}$ and $\{S_{2t}\}$ if lagged effects are important. Alternatively, it may be that changing just a few turning points could lead to near-perfect concordance between two series. If so, sensitivity analysis is worthwhile.

7.7.2.1 Tests based on the method of moments

It is important to formally test for no synchronization $H_0 : \rho_s = 0$, since this implies that $\{S_{1t}\}$ and $\{S_{2t}\}$ are unrelated series with no common cycle. As a case in point, the business cycles of the United States and the United Kingdom could have high concordance simply because most of the time these economies are expanding, not contracting. On the other hand, whether these two economies actually *move together* is a different issue. In other words, although $\{S_{1t}\}$ and $\{S_{2t}\}$ may be highly synchronized, this does not by itself imply a common cycle.

Under classical conditions, several tests for $H_0 : \rho_s = 0$ are equivalent. For instance, we can employ:

$$t_r = r_s \sqrt{\frac{T-2}{1-r_s^2}} \overset{a}{\sim} N(0,1). \tag{7.22}$$

Numerically equivalent test statistics are the standard t-ratios for the slope coefficients in either $S_{1t} = \alpha + \beta S_{2t} + \varepsilon_{1t}$ or $S_{2t} = \gamma + \delta S_{1t} + \varepsilon_{2t}$. However, the situation is complicated by the fact that S_1 is serially correlated, as is S_2, and thus the independence assumption associated with the traditional t-test of zero-correlation is compromised. Therefore, the statistic used to test $H_0 : \rho_s = 0$ must be made robust to serial correlation and heteroskedasticity.[14] Harding and Pagan (2006) recommend that the test statistic be constructed via GMM with a robust variance estimate to account for serial correlation and heteroskedasticity.

A multivariate version of the GMM test for several *S*-series is presented by Harding and Pagan (2006), but with the GMM estimator for the bivariate case based only on the moment conditions:

$$E[S_{jt}] = \mu_j,\ j = 1, 2 \tag{7.23}$$

$$E\left[\frac{(S_{1t} - \mu_1)(S_{2t} - \mu_2)}{\sqrt{\mu_1(1-\mu_1)\mu_2(1-\mu_2)}} - \rho_s\right] = 0. \tag{7.24}$$

Stack the above three moment conditions into a $3x1$ vector, $h_t(\theta, S_{1t}, S_{2t})$, such that:

$$h_t(\theta, S_{1t}, S_{2t})' = \left[S_{1t} - \mu_1,\ S_{2t} - \mu_2,\ \frac{(S_{1t} - \mu_1)(S_{2t} - \mu_2)}{\sqrt{\mu_1(1-\mu_1)\mu_2(1-\mu_2)}} - \rho_s\right], \tag{7.25}$$

with parameter vector $\theta' = [\mu_1, \mu_2, \rho_S]$, and take the average:

$$g(\theta, \{S_{1t}, S_{2t}\}_{t=1}^T) = \frac{1}{T}\sum_{t=1}^{T} h_t(\theta, S_{1t}, S_{2t}). \tag{7.26}$$

The covariance matrix of $\sqrt{T}g(\theta, \{S_{1t}, S_{2t}\}_{t=1}^T)$ is consistently estimated by:

$$V = \Gamma_0 + \sum_{k=1}^{m}\left[1 - \frac{k}{m+1}\right][\Gamma_k + \Gamma_k'], \tag{7.27}$$

where:

$$\Gamma_k = \frac{1}{T}\sum_{t=k+1}^{T} h_t(\theta, S_{1t}, S_{2t}) h_{t-k}(\theta, S_{1t}, S_{2t})'. \tag{7.28}$$

Harding and Pagan (2006) recommend the window width, m, to be the integer part of $(T-1)^{1/3}$.

Let $\theta_0' = [\mu_1, \mu_2, 0]$ be the restricted parameter vector for $H_0 : \rho_S = 0$, with no common cycle between S_1 and S_2 under this null hypothesis. The test statistic:

$$W_{SNS} = \sqrt{T}g\left(\theta_0, \{S_{1t}, S_{2t}\}_{t=1}^T\right)' V^{-1} \sqrt{T}g\left(\theta_0, \{S_{1t}, S_{2t}\}_{t=1}^T\right), \tag{7.29}$$

follows an asymptotic chi-square distribution with one degree of freedom. Substituting sample means, $\widehat{\mu}_1$ and $\widehat{\mu}_2$, and the sample correlation, r_s, for their population counterparts does not affect the asymptotic distribution of W_{SNS}. Substituting sample moments for population moments reduces W_{SNS} to:

$$W_{SNS} = T(r_s - 0)\widehat{v}^{-1}(r_s - 0), \tag{7.30}$$

where $\widehat{v}$ is the lower right-hand element of $\widehat{V}$. An equivalent test statistic is the asymptotic t-ratio, $t_{SNS} = T^{1/2}\widehat{v}^{-1/2} r_s \overset{a}{\sim} N(0,1)$.

Closely related tests are the market-timing test of Pesaran and Timmermann (1992) and Pearson's chi-square test for independence. For instance, Artis,

Kontolemis and Osborn (1997) and Artis, Krolzig and Toro (2004) use either Pearson's test or a transformation of the concordance index to test whether the series $\{S_{1t}\}$ and $\{S_{2t}\}$ are unrelated. However, consider that the method of moments test essentially examines the moment condition implied by the covariance, that is, $E(S_1S_2) - E(S_1)E(S_2) - \sigma_s = 0$. The null hypothesis is $H_0 : \sigma_s = 0$. Observe, however, that $\sigma_s = p_{12} - p_1p_2$, where $p_{12} = P(S_1 = 1, S_2 = 1)$, $p_1 = P(S_1 = 1)$, and $p_2 = P(S_2 = 1)$. The method of moments test thus effectively determines whether S_1 and S_2 are statistically independent, $p_{12} = p_1p_2$, and this is exactly the goal of Pearson's test.

Of course, a critical assumption behind Pearson's test is that *observations* in the sample are statistically independent. This assumption clearly fails in this case since the state variables, S_1 and S_2, exhibit strong serial dependence; see, for example, Kedem (1980). Since the market timing and concordance index tests also assume that observations are statistically independent, the robust covariance matrix of Harding and Pagan's method of moments test offers an improvement since it allows for serial correlation and heteroskedasticity of unspecified type.

7.7.2.2 Regression-based tests

On the other hand, the problems induced by serial correlation and heteroskedasticity can be significantly lessened by separating contractions from expansions and by incorporating time dependency into the model. The very nature of duration dependence will most surely differ across expansions and contractions; even if both phases exhibit constant hazards, regression disturbances are generally heteroskedastic if observations on expansions are not separated from those on contractions. So, when testing for synchronization, we should separate expansions from contractions. Define the dependent binary variable so that $S_{2t} = 0$ if the contraction continues and $S_{2t} = 1$ if the contraction terminates. For expansions, consider $1 - S_{2t}$ instead of S_{2t}. Our sub-sample thus consists of strings like:

	Jan	Feb	Mar	Apr	...	Sep	Oct	Nov	Dec	Jan	Feb	...	Jun	Jul
S_{2t}	0	0	0	1	...	0	0	0	0	0	1	...	0	0
S_{1t}	0	0	1	1	...	0	1	1	1	0	0	...	0	0

In this example, for S_2 there are two complete contractions of respective length $T_1 = 3$ and $T_2 = 5$, and one incomplete contraction of length $T_3 = 2$. The number 1 signifies the beginning of a new phase, in this case an expansion. Of course, $S_{1t} = S_{2t}$ should be the predominant case if there is a high concordance. By considering the phases separately, we are able to address problems of time dependency and heterogeneity. The statistical method we propose employs logistic regression and is similar in spirit to Pagan's (1998) regression-based test. To test for dependence between S_1 and S_2, let S_2 be the dependent variable in the logistic regression:

$$\log(P(t)/(1 - P(t)) = a(t) + \beta S_{1t}. \tag{7.31}$$

The term $a(t)$ consists of a set of dummy variables, one for each possible exit period, that controls for autonomous changes in the exit probability, $P(t)$. That is, $a(t)$ accounts for the duration dependence, or serial correlation, in the series $\{S_{2t}\}$. Having removed the time dependence captured by $a(t)$, the slope coefficient,

β, captures the statistical dependence between S_2 and S_1. Our null hypothesis, $H_0 : \beta = 0$, corresponds to statistical independence, and thus to $H_0 : \sigma_s = 0$. The form of the above regression is identical for expansions, and completely analogous regressions can be employed for the alternative dependent variable, S_1. Finally, it is possible to use linear regression rather than logistic regression. For large samples, however, estimation efficiency is improved by using logistic regression.

7.8 Unemployment cycles

If the most important measure of aggregate economic well-being is output, then surely the second most important is unemployment. Although unemployment cycles are interesting to academics, policy makers, and the general public, most of the attention in the academic literature is on output cycles. Exceptions are Boldin (1994), Chin, Geweke and Miller (2000), and Hamilton (2005), whose work focuses on unemployment cycles.

Even though we anticipate high unemployment during GDP contractions and low unemployment during GDP expansions, the output and unemployment series offer separate pieces of information about the economy. Even if we use the same rules to mark turning points for unemployment and output, we do not expect perfect negative synchronization – that is, necessarily *increasing* levels of unemployment during periods of *decreasing* output, and vice versa. It is thus of interest to determine the degree of synchronization, to compare the shapes of output and unemployment cycles, and to perform a separate duration analysis for the unemployment series.

7.8.1 Cycle shapes

Our data are the logarithmic monthly Bureau of Labor Statistics (BLS) seasonally adjusted *civilian unemployment rate* series from 1948:1 through 2007:1.[15] Figure 7.3 plots the unemployment rate series and for comparison marks the NBER dated business cycle recessions. Table 7.1 presents the unemployment rate reference dates determined by the BBQ algorithm. We set the minimum phase to 9 months and the minimum cycle to 18 months. These censoring rules visually mark the turning points in unemployment much better than those employed by Harding and Pagan (2002) to mark the turning points in output – namely, a minimum phase of 6 months and a minimum cycle of 15 months. Our censoring rules also mark the turning points in unemployment much better than does the Extended Okun Rule that considers only whether there are two consecutive months opposite the prevailing phase. There are 10 post-war completed spells of contraction, or *downswings*, in the unemployment rate, lasting an average of 48 months with a standard deviation of 30 months. There are 9 post-war completed spells of expansion, or *upswings*, in the unemployment rate, lasting an average of 22 months with a standard deviation of 10 months. Similar results are obtained from using quarterly data with a minimum phase of 3 quarters and a minimum cycle of 6 quarters.

The average amplitudes of upswings and downswings are the same in magnitude. The average amplitude of downswings is -0.55 with a coefficient of variation of

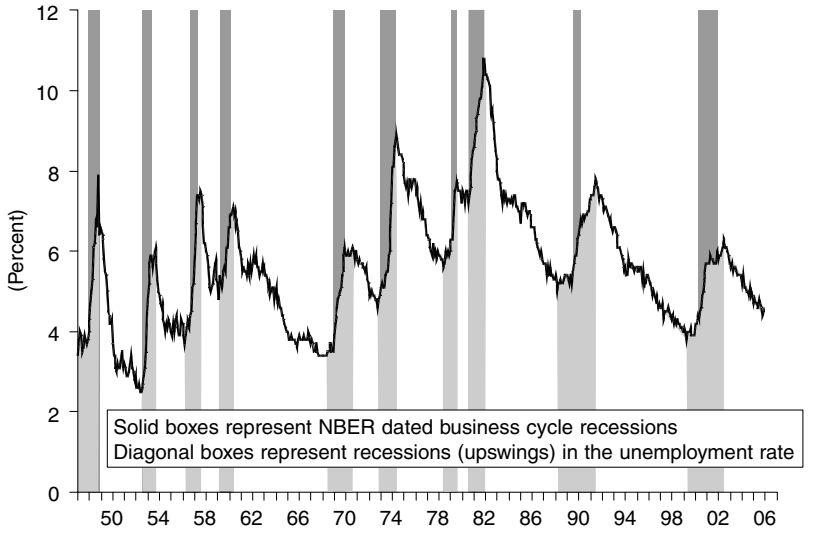

Figure 7.3 US civilian unemployment rate
Note: Unemployment data are from the US Bureau of Labor Statistics, and business cycle dates are from the National Bureau of Economic Research.

Table 7.1 Unemployment rate cycle dates: 1948–2006

Reference dates		*Duration in months*			
Peak	*Trough*	*Contraction*	*Expansion*	*Cycle*	
		Peak to trough	*Previous trough to this peak*	*Trough from previous trough*	*Peak from previous peak*
Oct 1949	June 1953	44	–	–	–
Sep 1954	Mar 1957	30	15	45	59
Jul 1958	Feb 1960	19	16	35	46
May 1961	May 1969	96	15	111	34
Aug 1971	Oct 1973	26	27	53	123
May 1975	May 1979	48	19	67	45
Jul 1980	Jul 1981	12	14	26	62
Dec 1982	Mar 1989	75	17	92	29
Jun 1992	Apr 2000	94	39	133	114
Jun 2003	Jun 2006	36	38	74	132
		Summary statistics			
	No. of phases	10 (9)	9 (10)		
	Average length	48.0 (59.1)	22.2 (10.4)		
	Standard deviation	30.3 (38.0)	10.0 (3.3)		

Note: NBER business cycle summary statistics are in parentheses. Unemployment contractions are paired with business cycle expansions, and unemployment expansions are paired with business cycle contractions.

−0.55, and the average amplitude of upswings is 0.55 with a coefficient of variation of 0.33. Since falls in unemployment appear about evenly matched with rises in unemployment, this lends some credence to the idea of a natural rate. The overall sample average unemployment rate is about 5.61%, although at times there were large deviations from the average. For example, in November 1982 the unemployment rate reached a high of 10.8%.

There are, however, significant differences between upswings and downswings. For downswings, the average cumulative movement is $\overline{F}_c = -18.43$, the average excess is $\overline{C} = -0.046$ and the coefficient of variation in the excess is −1.32. For upswings, the average cumulative movement is $\overline{F}_e = 6.40$, the average excess is $\overline{E} = 0.009$ and the coefficient of variation in the excess is 5.70. The average cumulative movement in downswings is well over twice the magnitude of the cumulative movement in upswings; this is consistent with the longer average duration of downswings. From the average excess $\overline{C}$, employment tends to fall at a decreasing rate during contractions, or downswings, and from $\overline{E}$, employment tends to rise at a decreasing rate during expansions, or upswings. The steep initial decline in unemployment during downswings is more prominent than the steep initial ascent in unemployment during upswings. In fact, from the coefficient of variation, there is much more relative variability in the excess for upswings than for downswings. Long durations in downswings, large cumulative movements, and stable excess across downswings all reflect favorably on current economic policy.

7.8.2 Synchronization with business cycles

From Figure 7.3, cycles in output and unemployment appear highly synchronized. However, even though there are about as many turning points in the unemployment cycle as there are in the business cycle (see the summary statistics in Table 7.1), the two binary series representing unemployment and output are not perfectly correlated. Let $S_{1t} = 1$ if output is rising and $S_{2t} = 1$ if unemployment is rising; also let $S_{1t} = 0$ if output is falling and $S_{2t} = 0$ if unemployment is falling. The coincidence indicator for the binary series is $\widehat{I} = 0.17$ and the correlation between them is $r_s = -0.61$. In other words, about 83% of the time rising output is associated with falling unemployment.

We can test the null hypothesis $H_0 : \rho_s = 0$ by using Harding and Pagan's (2006) method of moment test. With a bandwidth of either $m = 8$ or $m = 9$ we find that t_{SNS} is about −5.5, and thus we reject the null hypothesis that unemployment and output are statistically independent. Regression-based tests yield the same conclusion. Unemployment and output appear to be statistically dependent.

Separating upswings from downswings in unemployment provides an important insight. When measured at monthly intervals with our censoring rules, falling unemployment is coincident with rising output, though rising unemployment is not necessarily coincident with falling output. In fact, conditional on rising unemployment, output is falling only about half the time. In other words, unemployment is perfectly synchronized with output when unemployment is falling, but it is a coin toss when unemployment is rising.

7.8.3 Duration analysis

If expansions, or upswings, in the unemployment rate exhibit *positive duration dependence,* then upswings with longer maturities have a higher chance of terminating than those with shorter maturities. The hazard tends to rise with the duration of the event, and the average duration is greater than the standard deviation. In the opposite case, called *negative duration dependence,* the hazard tends to fall with the duration of the event, and the average duration is less than the standard deviation. *Duration independence* is characterized by neither of the above cases. For instance, the probability that unemployment exits an expansionary state and enters a contractionary state is constant regardless of how long the upswing has lasted.

The average duration of 22 months for upswings is more than twice the sample standard deviation of 10 months; this suggests that rises in unemployment exhibit positive duration dependence. Likewise, the average duration of 48 months for downswings is larger than the sample standard deviation of 30 months; this also suggests positive duration dependence, though such descriptive evidence is not as strong as it is for upswings. We can formally test for duration dependence by using the discrete-time SB and GMD tests from Ohn, Taylor and Pagan (2004). We subtract months from each of the observed durations to be consistent with our BBQ censoring rules.[16]

We analyze upswings and downswings separately. Under the null hypothesis of duration independence, the estimated termination probability for upswings is 0.076, but the estimated termination probability for downswings is only 0.025. However, neither SB nor GMD indicate duration dependence for either upswings or downswings. Finite-sample p-values are obtained through a parametric bootstrap algorithm, with the discrete-time geometric density corresponding to the null hypothesis of duration independence. Sensitivity analysis is performed by varying the termination probability to account for sampling variability in estimation. Since our calculated p-values are always considerably greater than 0.10, we cannot reject the null hypothesis that the probability of exiting a state of national unemployment is independent of its duration at the 10% significance level. As a further robustness check, we also employ the asymptotic LSB t-test and the continuous-time W-test from Shapiro and Wilk (1972). The distribution of W depends neither on the termination probability nor on the minimum phase, with finite-sample critical values tabulated by Shapiro and Wilk (1972). Consistent with SB and GMD, neither LSB nor W reject duration independence for either upswings or downswings in unemployment.

In comparision, Ohn, Taylor and Pagan (2004) find some evidence that post-war economic contractions exhibit positive duration dependence, though there is no such evidence for post-war expansions. However, such lack of evidence is not too surprising in light of the small number of completed cycles. For instance, post-war sample sizes are too small to employ the chi-square goodness-of-fit test for comparison with SB and GMD.

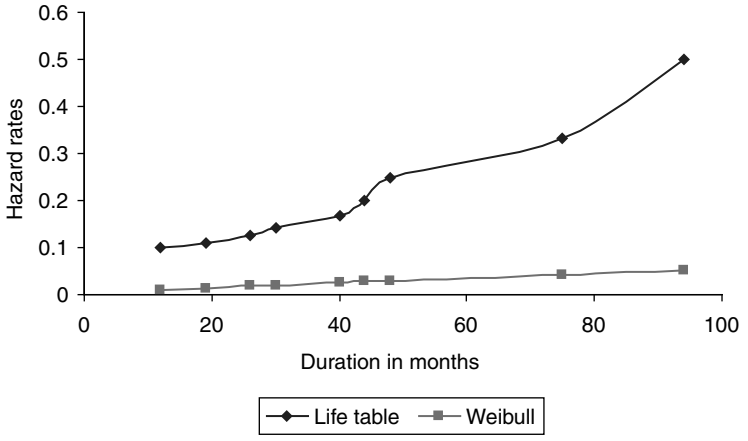

Figure 7.4 Downswings

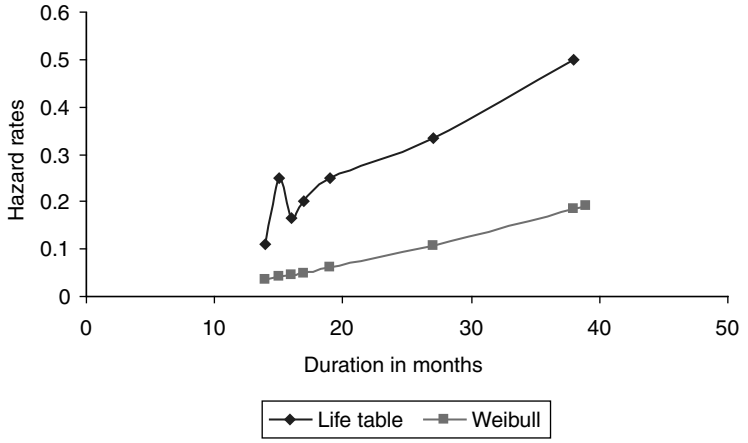

Figure 7.5 Upswings

Figures 7.4 and 7.5 present nonparametric plots of the hazard functions via the life table method of Cutler and Ederer (1958). The hazard functions for both downswings and (especially) upswings can be characterized as NBU, or perhaps even the more narrow classes, IFRA or IFR. The hazard function for upswings exhibits a local peak at 15 months, dropping at 16 months, and ascending thereafter. The rising hazard is consistent with the sharply rising hazard function for economic contractions observed by Ohn, Taylor and Pagan (2004). The hazard function for downswings exhibits strong IFR behavior with an upward trend, and this coincides well with the nonparametric hazard function for economic expansions from Ohn, Taylor and Pagan. For comparison, we also graph the parametric Weibull hazard

rates. In each case, the Weibull hazards indicate positive duration dependence. On the other hand, for upswings the parametric Weibull hazard fails to reflect the clustering of exits at 15–16 months.

We obtain further insights about the hazard functions through a regression analysis.[17] Our approach is most closely related to Estrella and Mishkin (1998) and especially that of Chin, Geweke and Miller (2000). For example, as did Chin, Geweke and Miller, we separate upswings from downswings to obtain separate estimates of the coefficients that control the hazard probabilities. As a point of contrast, our sample consists of monthly observations on unemployment from January 1948 through January 2007, whereas the sample of Chin, Geweke and Miller consists of monthly observations on unemployment from October 1949 through February 1998. We employ BBQ rules similar to those used for business cycles, whereas Chin, Geweke and Miller employ a three-month centered moving average rule subject to a threshold condition. Using either set of rules, the average upswing lasts roughly 23 months, and the average downswing lasts roughly 50 months; to be exact, for downswings we found an average of 48 months while Chin, Geweke and Miller found an average of 51 months.

Chin, Geweke and Miller employ probit estimation, closely related to our logit estimation. We favor logit estimation, however, since its use follows directly from the seminal work of Cox (1972). An additional difference is that, as is customary, we set our binary dependent variable to unity only in the month of a turning point, whereas they set the binary variable to unity in month t if a turning point occurs in months $t+1, \ldots, t+12$. Chin, Geweke and Miller construct artificial observations to control for overfitting of the model at highly leveraged values of the independent variables, but we employ a sensitivity analysis to determine whether our results are robust to dropping spells from the sample each in turn. For instance, we consider estimates from the full set of post-war contractions as well as contractions but for, say, the fourth one.

Unlike Estrella and Mishkin (1998) and Chin, Geweke and Miller (2000), we eliminate observations from the beginning of each spell to account for censoring. That is, we eliminate the first nine observations from each observed spell since the minimum phase duration allowed for either upswings or downswings is nine. As per the classical approach, we include dummy variables to allow for autonomous shifts in the hazard probabilities. In contrast, neither Estrella and Mishkin nor Chin, Geweke and Miller consider that duration dependence may be autonomous. That is, they do not allow hazard probabilities to change with the duration of the spell, independently of any change in time-varying covariates.

Harding and Pagan (2007) show that most binary time series constructed from the BBQ algorithm using NBER censoring rules are serially correlated with heteroskedastic disturbances. As is well known, either one of serial correlation or heteroskedasticity will typically lead to invalid inference. Furthermore, serial correlation in the binary time series, $\{S_t\}$, typically implies autonomous duration dependence in the spells of both contractions and expansions. Harding and Pagan account for autonomous duration dependence by directly modeling serial dependence in the state variable, S_t. Observe, however, that modeling the

serial dependence is infeasible once contractions are separated from expansions to eliminate heteroskedasticity in the disturbances. Suppose, for example, that S_t follows the second-order process:

$$S_t = \gamma_1 S_{t-1} + \gamma_2 S_{t-2} + \gamma_3 S_{t-1} S_{t-2} + u_t. \tag{7.32}$$

Having conditioned on either contractions or expansions, then $S_{t-1} = 0$ and $S_{t-2} = 0$, and it is thus infeasible to directly estimate equation 7.32. On the other hand, it is still possible to estimate the autonomous hazard function. Indeed, semi-parametric estimation of the autonomous hazard function is a very direct approach that addresses the same goal of accounting for the serially dependent nature of S_t. In other words, conditioning the constructed binary series on the states allows for estimation of the hazard function while eliminating the need to model potential serial dependence and heteroskedasticity in the state variable, S_t.

Consider first downswings with binary dependent variable S_t, such that $S_t = 1$ signifies a turning point towards rising unemployment. By considering only downswings, we eliminate one type of heteroskedasticity that occurs when upswings and downswings are considered together; see Hamilton (1989). Define the following autonomous-shift dummy variables: $D_1 = 1$ for months 1–20, inclusive, and $D_1 = 0$ otherwise; $D_2 = 1$ for months 21–30, inclusive, and $D_2 = 0$ otherwise; and $D_3 = 1$ for periods >30 and $D_3 = 0$ otherwise.[18]

Our first model is:

$$\log(P(t)/(1 - P(t)) = a_1 D_{1t} + a_2 D_{2t} + a_3 D_{3t}, \tag{7.33}$$

with estimates of the $a's$ reported in the second column of Table 7.2. Each of the coefficients is significant at the 5% level of significance. The hazard, or exit, probability is given by the formula:

$$P_i = 1/[1 + \exp(-a_i)]. \tag{7.34}$$

The estimated exit probability is about 0.019 in any month in the interval 10–20, about 0.013 in any month in the interval 21–30, and about 0.031 in any month

greater than 30. These values are very close to those obtained from the linear probability model – that is, by employing least squares with dependent variable S_t and interpreting the $a's$ from that model as probabilities. The implication is a U-shaped hazard for unemployment contractions. However, at the 5% significance level, the asymptotic likelihood ratio test from the logit model does not reject the null hypothesis of constant-hazard probabilities, $H_0 : a_1 = a_2 = a_3$.

Consider next expansions with binary dependent variable $1 - S_t$, such that $1 - S_t = 1$ signifies a turning point towards falling unemployment. For model (7.33), the estimates of the $a's$ are reported in the second column of Table 7.3. Each of the coefficients is significant at the 5% level. The estimated exit probability is about 0.074 in any month in the interval 10–20, about 0.036 in any month in the interval 21–30, and about 0.105 in any month greater than 30. Again, these values are very close to those estimated by the linear probability model. Consistent with our life table analysis, the estimated hazard function rises much more rapidly for upswings than for downswings in unemployment. However, we again fail to reject the null hypothesis of constant-hazard probabilities, $H_0 : a_1 = a_2 = a_3$, for upswings in unemployment.

Other variables may also influence the hazard probabilities. Our second equation in Table 7.2 augments the dummy variables with the duration of the immediately preceding (or lagged) upswing, and our second equation in Table 7.3 augments the dummy variables with the duration of the lagged downswing. Since neither lagged value is statistically significant, there is insufficient evidence from the logit model to conclude that the length of the current phase is influenced by the length of the preceding phase. In contrast, evidence from the linear probability model *does* suggest that the lag effect is important for upswings in unemployment. On average, the longer the preceding downswing, the shorter the current upswing.

Finally, we consider including the time-varying explanators examined by Chin, Geweke and Miller (2000). Let the symbol 0 signify the date of the last turning point prior to the date t. Then $(UR_t - UR_0)$, $(CU_t - CU_0)$, and $[(R-r)_t - (R-r)_0]$

are the respective differences in the values of unemployment (*UR*), the manufacturing capacity utilization rate (*CU*) and the spread between the monthly average of Moody's Aaa corporate bond rate and the monthly average of the 90-day treasury bill rate ($R - r$). The differences in these variables are measured from the start of the phase, t_0, up to time t. Logit or probit models can be adapted easily to incorporate such explanators that vary over time, and one purpose for including them is to account for non-stationarity of the turning points – or, in other words, duration dependence captured by covariates; see also Pesaran and Potter (1997). We also include in our regression equations the dummy variables D_1, D_2 and D_3 that account for autonomous shifts in the hazard probabilities, as well as the first differences in *UR*, *CU*, and $(R - r)$ that measure changes from time $t - 1$ to t.

Of the six time-varying explanators, only two were deemed important in our logit model: the change in the interest rate spread from time t_0 and the change in capacity utilization from time $t - 1$: $\Delta CU_t = CU_t - CU_{t-1}$. The interest rate spread typically increases about 2 percentage points over the life of an upswing, and decreases about 2 percentage points over the life of a downswing. We expect the hazard probability for downswings to be inversely related to the change in the spread from time t_0, and the hazard probability for upswings to be directly related to the change in the spread from time t_0. Inclusion of the interest rate spread corrects for drift in the hazard, though not in the same manner as do the autonomous-shift dummy variables.

From Tables 7.2 and 7.3, the *signs* on the spread coefficients are consistent with our prior reasoning. The coefficient on the spread is, however, statistically significant only for downswings. Thus, *ceteris paribus*, a large interest rate spread lowers the termination probability for a downswing in unemployment (a healthy labor market) but does not increase the termination probability for an upswing in unemployment. In other words, having controlled for autonomous shifts in the hazards, the interest rate spread has no discernable effect during unemployment upswings.

The economic interpretation of the change in capacity utilization is straightforward. An increase in utilization from time $t - 1$ should increase labor usage at time t, and a decrease in utilization should decrease labor usage. The signs on the coefficients in Tables 7.2 and 7.3 are again consistent with our prior reasoning. However, in this case the coefficient on utilization is statistically significant only for upswings in unemployment. Therefore, a decrease in capacity utilization has no discernable effects in good labor markets, but an increase marks a turnaround in bad labor markets. As a thought experiment, suppose that $D_1 = 1$ but that all other variables are set to zero in the equation for upswings. The termination probability for this relatively young upswing is only about 0.025 using the estimated coefficient for D_1 in the fourth column of Table 7.3. Consider increasing capacity utilization by 1 percentage point, say from 85% to 86%. With this change, the termination probability increases to about 0.18, a sevenfold increase in the hazard. Thus, as intuitively expected, labor fares substantially better when capital is reutilized.

At the 5% significance level, the above empirical results on the interest rate spread and capacity utilization are robust to whether we include either the

autonomous-shift dummy variables or lagged term. For with a single intercept, there is a constant hazard unless time-varying covariates actually change in value. A single-intercept probit model was chosen by Estrella and Mishkin (1998) to forecast turning points in US recessions, and by Chin, Geweke and Miller (2000) to forecast turning points in US unemployment.

Our empirical results also appear quite robust to dropping each spell, in turn, from the respective samples of either upswings or downswings. For example, we estimate the logit model with the full sample of ten downswings, as well as with the sample of nine downswings that excludes, say, the third spell. At the 5% significance level, our sensitivity analysis again indicates that the interest rate spread is statistically significant for downswings and that capacity utilization is statistically significant for upswings.

7.9 Conclusion

Duration analysis has many uses, both in academe and in industry. Consider that in a recent issue of *Business Week* (January 22, 2007) there were two duration applications in separate fields. Hugh Moore of Guerite Advisors (*Business Week*, p. 13) notes that the average amplitude in the fall of housing starts is 51% from peak to trough, and the average amplitude in the fall of housing expenditures as a percentage of GDP is 28% from peak to trough. Housing corrections, or recessions, last an average of 27 months. In the same issue (*Business Week*, p. 62), the global macro-group for Barclays Global Investors (BGI) reports devising a set of signals, or leading indicators, that predict turning points from recession to expansion in various countries. Profits are realized by buying stock and shorting bonds before the recovery is generally recognized. Using leading indicators is similar to using covariates in a duration analysis.

In this chapter we have emphasized classical, nonparametric methods in the duration analysis of unemployment cycles. The nonparametric turning point algorithm from Harding and Pagan (2002), or BBQ, is derived from the classical graphical approch of Burns and Mitchell (1946). The life table analysis follows directly from Cutler and Ederer (1958), and the logit model derives from the seminal work of Cox (1972). These classical techniques are just as relevant today as when first introduced, and have both micro- and macroeconometric applications.

Consider the many economic studies of individual job histories. Adamchik (1999), for example, uses the nonparametric Kaplan–Meier estimator and the semiparametric proportional-hazards model in her study of the effect of unemployment benefits on re-employment in Poland. In a related study, Bover, Arellano and Bentolila (2002) examine not only unemployment benefits, but also the relationship between the unemployment duration of Spanish men and the business cycle. In the latter study, they employ a logit model with autonomous shift dummies that is closely related to Cox's famous proportional-hazards model. The approach is very flexible since Cox's model is no longer proportional when explanators that vary with time are included in the model. Following the early frontier work of

Heckman and Singer (1984), Bover, Arellano and Bentolila (2002) then extend their logit model to account for unobserved heterogeneity.

In more recent macroeconometrics literature, Mudambi and Taylor (1995), Pagan (1998), and Ohn, Taylor and Pagan (2004) propose discrete-time tests for duration dependence and use bootstrap methods for finite-sample inference. Harding and Pagan (2002, 2006) propose new measures and tests for cycle asymmetries and synchronization. The practical importance of duration analysis for aggregate series is best illustrated by the March 28, 2007, testimony of Federal Reserve Chairman Ben Bernanke to the Joint Economic Committee of Congress. In response to his predecessor Alan Greenspan, who warned that the current expansion could be fizzling out, Bernanke responded:

> I would make a point, I think, which is important, which is there seems to be a sense that expansions die of old age, that after they reach a certain point, then they naturally begin to end. I don't think the evidence really supports that. If we look historically, we see that the periods of expansions have varied considerably. Some have been quite long.

Bernanke thus discounts the notion that expansions exhibit positive duration dependence. This view concurs with that of Ohn, Taylor and Pagan (2004), who fail to reject the constant-hazard assumption for post-World War II expansions but who do find statistically significant evidence of positive duration dependence in pre-World War II expansions. On the other hand, consider that the lack of support for positive duration dependence in the post-war period may be due to the small sample size. The mean duration of post-war expansions is about 50 months with a standard deviation of about 30 months. A mean larger than the standard deviation suggests positive duration dependence.

Finally, in this chapter we have stressed the advantage of a separate analysis of upswings and downswings in unemployment. Indeed, given a downswing in unemployment, aggregate output is always rising, but given an upswing in unemployment, the behavior of output is a coin toss. For a young spell of rising unemployment, an increase in capacity utilization of 1 percentage point increases by sevenfold the probability of a turning point from upswing to downswing. In contrast, for downswings the interest rate spread appears to affect the termination probability, and capacity utilization does not appear to matter.

Notes

1. For the reader interested in a concise discussion focused on measuring business cycles, see Harding and Pagan (2008).
2. The NBER URL is http://www.nber.org/cycles.html.
3. The Bry–Boschan (BB) program was originally designed for monthly data. James Engel, Don Harding and Mark Watson have each written or modified GAUSS programs that are similar to BB. The "Q" in the moniker BBQ stands for "quarterly" intervals even though BBQ easily accommodates either monthly or quarterly intervals. Our BBQ program is a derivative of the one written by Don Harding and is available upon request.

4. Teräsvirta (2006) provides an overview of MS and other types of univariate nonlinear time series models.
5. Our list of techniques to mark time is not exhaustive. Boldin (1994) reviews five techniques to mark time for business cycles: the NBER business cycle dating committee; GDP growth rules; the Commerce Department's Bureau of Economic Analysis (BEA) indicators; Stock and Watson's (1989, 1991) indicators; Stock and Watson's (1989, 1991) experimental business cycle indices; and a Markov-switching model for unemployment.
6. A nice introduction to continuous-time duration analysis is Greene (2006, pp. 710–12). Another good overview of duration techniques, discrete or continuous, is the chapter on transition data in the microeconometrics text by Cameron and Trivedi (2005, pp. 573–608).
7. If the length of an economic contraction is influenced by the length of the preceding expansion, *and* vice versa, the assumption of statistical independence is violated. Likewise, an economic contraction caused by an especially bad harvest could behave very differently from a contraction that occurs during the normal operation of modern market economies. These problems can be handled when modeling with covariates. Another way to help ensure homogeneity across spells of expansion and contraction is to segment the time line into distinct sampling periods with the same underlying probability distributions; see, for example, Diebold and Rudebusch (1990).
8. Watson's (1994) pre-war sampling period ranges from roughly 1860 through 1929, and his post-war sampling period ranges roughly from 1947 through 1990.
9. A realization from a so-called life distribution cannot be negative. The term "life distribution" is coined from the study of mortality, where many of these distributions were first employed.
10. Our notation for the time indices slightly abuses notation since there are gaps in the time line for a phase analysis of either contractions or expansions.
11. For instance, Chin, Geweke and Miller (2000) use covariates to capture drift in the hazard function. However, conditional on the x values, their hazard function is constant since it does not explicitly depend on the duration of the phase.
12. The transition probability for the latent state variable in the Durland and McCurdy (1994) Markov-switching model has a logit form. But $\{S_t\}$ is not the same as $\{S_t^*\}$, and there is no reason to consider the latter for the purpose of a duration analysis.
13. Vahid (2006) surveys both parametric and nonparametric methods of uncovering common cycles in multiple series. Our focus is on nonparametric methods that employ the binary variables S_1 and S_2. In contrast, to investigate synchronization in output across the G7 countries, Stock and Watson (2003) focus on the correlation between Δy_1 and Δy_2.
14. As shown by Hamilton (1989), a primary reason for the heteroskedasticity is heterogeneous transition probabilities across contractions and expansions.
15. The series ID is LNS14000000, and is available from the US Department of Labor, Bureau of Labor Statistics (http://stats.bls.gov).
16. Ohn, Taylor and Pagan (2004) refer to imposing a minimum phase jointly with the assumption of duration dependence as the *Markov hypothesis*. An alternative to subtracting the minimum phase is to incorporate the phase restriction into the econometric model. For instance, Harding and Pagan (2003) show that for a two-quarter minimum the base model that includes S_{t-1} is extended by including the variables S_{t-2} and $S_{t-1}S_{t-2}$.
17. Our LIMDEP program for the regression analysis is presented in the appendix (section 7.10).
18. Because of the limited number of post-war expansions in unemployment, it is not possible to include a dummy variable for each possible exit time. Further, the effective range for D_1 is 10–20 since it is not possible for the spell to terminate in the first nine months due to censoring.

The Long Swings Puzzle: What the Data Tell When Allowed to Speak Freely

Katarina Juselius

Abstract

The persistent movements away from long-run benchmark values in real exchange rates that are often observed in many real exchange rates during periods of currency float have been subject to much empirical and theoretical research without resolving the underlying puzzle. This chapter demonstrates how the cointegrated VAR approach of grouping together components of similar persistence can be used to uncover structures in the data that ultimately may help to explain theoretically the forces underlying such puzzling movements. The characterization of the data into components which are empirically $I(0)$, $I(1)$ and $I(2)$ is shown to be a powerful organizing principle, allowing us to structure the data into long-run, medium-run, and short-run behavior. Its main advantage is the ability to associate persistent movements away from fundamental benchmark values in one variable/relation with similar persistent movements somewhere else in the economy.

8.1 Introduction

International macroeconomics is known for a number of empirical puzzles, the most notable among them being the "PPP (purchasing power parity) puzzle," which is closely related to the "long swings puzzle" and the "exchange disconnect puzzle" (Rogoff, 1996). These puzzles are all related to the pronounced persistence away from equilibrium states that have been observed in many real exchange rates during periods of currency float. Among these, the Dmk–$ rate in the post-Bretton Woods period is one of the more extreme cases.

One important purpose of this chapter is to demonstrate how the cointegrated vector autoregressive (CVAR) approach (Johansen, 1995; Juselius, 2006) can be used to uncover structures in the data that ultimately may help to explain theoretically the forces underlying such persistent movements in the data. The CVAR approach starts from a general unrestricted VAR model that gives a good characterization of the raw data. It then tests down until a parsimonious representation of the data with as much economic content as possible has been achieved. When properly applied, the CVAR is able to extract valuable information about the dynamics of the pulling and pushing forces in the data without distorting this information. This entails the identification of stationary relationships between non-stationary variables, interpretable as long-run equilibrium states, and the dynamic adjustment of the system to deviations from these states. It also entails the identification of the transitory and permanent shocks that have affected the variables and the short- and long-run impacts of these shocks.

For the results to be reliable, the statistical properties of the model have, however, to be taken seriously. This implies adequately controlling for reforms, interventions, regime changes, etc., that are often part of the data-generating mechanism. The reunification of East and West Germany is an example of such an important event. The approach also entails the untying of any transformation of the variables, such as the real exchange rate transformation, imposed from the outset on the data. Such transformations, common in empirical economics, often seriously distort signals in the data that otherwise might help to uncover precisely those empirical regularities which give a clue to the underlying reasons for the puzzling behavior.

The weight of the empirical analysis is on characterizing data within the broad framework of a theory model. To facilitate the interpretation of the empirical results, the chapter argues that it is essential first to translate the underlying assumptions of the theoretical model into hypotheses on the pulling and pushing forces of the VAR model (Juselius and Johansen, 2006; Juselius, 2006; Juselius and Franchi, 2007). A careful formulation of such a scenario is indispensable for

being able to structure and interpret the empirical results so that empirical regularities either supporting or rejecting the theoretical assumptions become visible. In particular, the latter are valuable as they should ultimately lead to empirically more relevant theory models. Thus, to some extent, the CVAR approach switches the role of theory and statistical analysis in the sense of rejecting the privileging of *a priori* economic theory over empirical evidence. In the language of the CVAR approach, empirical evidence is the pushing force and economic theory is adjusting (Hoover, Johansen and Juselius, 2008).

The approach will be illustrated with an empirical analysis of the long swings in real exchange rates based on German and US prices and the Dmk–$ rate over the period 1975:09–1998:12. Using the above decomposition into pulling and pushing forces, the empirical analysis identifies a number of "structured" (rather than stylized) facts describing important empirical regularities underlying the long swings puzzle. These provide clues suggesting where to dig deeper (see Hoover, 2006) to gain an empirically more relevant understanding of the puzzling behavior in the goods and foreign exchange markets.

To structure the data as efficiently as possible, this chapter argues that the order of integration, rather than being regarded as a structural parameter, should be considered an empirical approximation, measuring the degree of persistent behavior in a variable or a relation. Organizing the data into directions where they are *empirically* $I(0)$, $I(1)$ or $I(2)$ is not the same as claiming they are *structurally* $I(0)$, $I(1)$ or $I(2)$. In the first case, some implications of the statistical theory of integrated processes are likely to work very well, such as inference on structures; others are likely to work less well, such as inference on the long-run values towards which the process converges when all the errors have been switched off. The focus of this chapter is on structure rather than long-run values (Johansen, 2005).

The statistical analysis suggested that the two prices (and possibly even the nominal exchange rate) were empirically $I(2)$. Thus another important aim of this chapter is to discuss the $I(2)$ model, how it relates to the $I(1)$ model, and what can be gained by interpreting the empirical reality within the rich structure of the $I(2)$ model. Because the $I(2)$ model is also more complex, the analysis is first done within the $I(1)$ model, emphasizing those signals in the results suggesting data are $I(2)$. Though most of the $I(1)$ results can be found in the $I(2)$ model, the chapter demonstrates that the $I(2)$ results are more precise and that the $I(2)$ structure allows for a far richer interpretation.

The exposition of the chapter is as follows. Section 8.2 defines the $I(1)$ and $I(2)$ models as parameter restrictions on the unrestricted VAR. Section 8.3 introduces the persistent features of the real exchange rate data for the German–US case and discusses how they can be formulated as the pulling and pushing forces of a CVAR model. Section 8.4 discusses under which conditions $I(2)$ data can be modeled with the $I(1)$ model, why it works, and how the interpretation of the results has to be modified. Section 8.5 presents the empirical $I(1)$ analysis of prices and nominal exchange rates inclusive of specification testing and estimation of the long-run structure. Section 8.6 gives a brief account of the $I(2)$ model and discusses at some

length the specification of the deterministic components. Section 8.7 discusses an estimation procedure based on maximum likelihood and shows how the $I(2)$ structure can be linked to the $I(1)$ model. Section 8.8 provides hypothetical scenarios for the real exchange rate data. Section 8.9 presents the empirical results of the pulling and pushing forces structured by the $I(2)$ model, summarizes the puzzling facts detected, and discusses what has been gained by this analysis compared to the $I(1)$ analysis. Section 8.10 concludes with a discussion of what the data were able to tell when allowed to speak freely.

8.2 The VAR model

The baseline VAR(2) model in its unrestricted form is given by:

$$\mathbf{x}_t = \mathbf{\Pi}_1 \mathbf{x}_{t-1} + \mathbf{\Pi}_2 \mathbf{x}_{t-2} + \mathbf{\Phi} \mathbf{D}_t + \boldsymbol{\varepsilon}_t, \tag{8.1}$$

with:

$$\boldsymbol{\varepsilon}_t \sim N_p(\mathbf{0}, \mathbf{\Omega}),\ t = 1, \ldots, T,$$

where $\mathbf{x}_t' = [x_{1,t}, x_{2,t}, \ldots x_{p,t}]$ is a vector of p stochastic variables and $\mathbf{D}_t$ is a vector of deterministic variables, such as a constant, trend and various dummy variables. As the subsequent empirical VAR model has lag two, all results are given for the VAR(2) model. A generalization to higher lags should be straightforward.

In terms of likelihood, an equivalent formulation of (8.1) is the vector equilibrium correction form:

$$\Delta \mathbf{x}_t = \mathbf{\Gamma}_1 \Delta \mathbf{x}_{t-1} + \mathbf{\Pi} \mathbf{x}_{t-1} + \mathbf{\Phi} \mathbf{D}_t + \boldsymbol{\varepsilon}_t, \tag{8.2}$$

where $\mathbf{\Gamma}_1 = -\mathbf{\Pi}_2$ and $\mathbf{\Pi} = -(\mathbf{I} - \mathbf{\Pi}_1 - \mathbf{\Pi}_2)$.

Alternatively, (8.1) can be formulated in acceleration rates, changes and levels:

$$\Delta^2 \mathbf{x}_t = \mathbf{\Gamma} \Delta \mathbf{x}_{t-1} + \mathbf{\Pi} \mathbf{x}_{t-1} + \mathbf{\Phi} \mathbf{D}_t + \boldsymbol{\varepsilon}_t, \tag{8.3}$$

where $\mathbf{\Gamma} = -(\mathbf{I} - \mathbf{\Gamma}_1)$. As long as all parameters are unrestricted, the VAR model is no more than a convenient summary of the covariances of the data. As a result, most VAR models are heavily overparameterized and insignificant parameters need to be set to zero. The idea of general-to-specific modeling is to reduce the number of parameters by significance testing, with the final aim of finding a parsimonious parameterization with interpretable economic contents. Provided that the simplification search is statistically valid, the final restricted model will reflect the full information of the data. Thus, given the broad framework of a theory model, a correct CVAR analysis allows the data to speak freely about the underlying mechanisms that have generated the data.

All three models are equivalent from a likelihood point of view, but (8.1) would generally be chosen when $\mathbf{x}_t$ is $I(0)$, (8.2) when $\mathbf{x}_t$ is $I(1)$, and (8.3) when $\boldsymbol{x}_t$ is $I(2)$.

The hypothesis that $\mathbf{x}_t$ is $I(1)$ is formulated as a reduced rank restriction on the matrix $\mathbf{\Pi}$:

$$\mathbf{\Pi} = \boldsymbol{\alpha}\boldsymbol{\beta}', \text{ where } \boldsymbol{\alpha}, \boldsymbol{\beta} \text{ are } p \times r, \tag{8.4}$$

and that $\mathbf{x}_t$ is $I(2)$ as an additional reduced rank restriction on the transformed matrix $\mathbf{\Gamma}$:

$$\boldsymbol{\alpha}_{\perp}'\mathbf{\Gamma}\boldsymbol{\beta}_{\perp} = \boldsymbol{\xi}\boldsymbol{\eta}', \text{ where } \boldsymbol{\xi}, \boldsymbol{\eta} \text{ are } (p-r) \times s_1, \tag{8.5}$$

where $\boldsymbol{\beta}_{\perp}, \boldsymbol{\alpha}_{\perp}$ are the orthogonal complements of $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$. The first reduced rank condition is formulated on the variables in levels, the second on the variables in differences. Condition (8.4) tells us that the variables contain stochastic trends (unit roots) that can be canceled by linear combinations. Condition (8.5) tells us that the differenced process also contains unit roots when data are $I(2)$. However, in this case the linear combinations that cancel these roots are more complicated. Thus, when $\mathbf{x}_t \sim I(2)$, and hence $\Delta\mathbf{x}_t \sim I(1)$, it is not sufficient to impose the reduced rank restriction on the matrix $\mathbf{\Pi}$ to get rid of all (near) unit roots in the model. This is because $\Delta\mathbf{x}_t$ is also a unit root process and lowering the value of r does not remove the unit roots belonging to $\mathbf{\Gamma} = -\left(\mathbf{I} - \mathbf{\Gamma}_1\right)$. Therefore, even though the rank of $\mathbf{\Pi} = \boldsymbol{\alpha}\boldsymbol{\beta}'$ has been correctly determined, there will remain additional unit roots in the VAR model when the data are $I(2)$. As will be demonstrated below, this provides a good diagnostic tool for detecting $I(2)$ problems in the VAR analysis.

Inverting the VAR model gives us the moving average (MA) form. Under the reduced rank of (8.4) and the full rank of (8.5), the MA form is given by:

$$\mathbf{x}_t = \mathbf{C}\sum_{i=1}^{t}(\boldsymbol{\varepsilon}_i + \mathbf{\Phi}\boldsymbol{D}_i) + \mathbf{C}^*(L)(\boldsymbol{\varepsilon}_t + \mathbf{\Phi}\mathbf{D}_t) + \mathbf{A}, \tag{8.6}$$

where $\mathbf{C}^*(L)$ is a lag polynomial describing the impulse response functions of the empirical shocks to the system, $\mathbf{A}$ is a function of the initial values $\mathbf{x}_0, \mathbf{x}_{-1}, \mathbf{x}_{-2}$, and $\mathbf{C}$ is of reduced rank $p-r$:

$$\mathbf{C} = \boldsymbol{\beta}_{\perp}(\boldsymbol{\alpha}_{\perp}'\mathbf{\Gamma}\boldsymbol{\beta}_{\perp})^{-1}\boldsymbol{\alpha}_{\perp}' = \tilde{\boldsymbol{\beta}}_{\perp}\alpha_{\perp}', \tag{8.7}$$

with $\tilde{\boldsymbol{\beta}}_{\perp} = \boldsymbol{\beta}_{\perp}(\boldsymbol{\alpha}_{\perp}'\boldsymbol{\beta}_{\perp})^{-1}$.

Inverting the VAR under the reduced rank of both (8.4) and (8.5) will be discussed in section 8.6.

8.3 The persistent movements in real exchange rate data

Parity conditions are central to international finance and, more specifically, to many open economy macro-models, such as the Dornbusch (1976) sticky-price overshooting model with rational expectations (RE). One important implication of this model and its modifications is that PPP should hold as an equilibrium cointegrating relationship (see Frydman *et al.*, 2008, and references therein). The idea here is to formulate the PPP condition under a currency float into testable hypotheses

on the pushing and pulling forces of the cointegrated VAR model. Comparing assumed with actual behavior is then likely to pinpoint the empirical mechanisms underlying the puzzling behavior. Since the VAR model is just a reformulation of the covariance information in the data, the end results should be a set of empirical features which a theory model should be able to replicate in order to claim empirical relevance.

8.3.1 The long swings puzzle

PPP is defined as:

$$p_1 = p_2 + s_{12}, \tag{8.8}$$

where p_1 is the log of the domestic price level (here German), p_2 is the log of the foreign price level (here US), and s_{12} denotes the log of the spot exchange rate (here Dmk–$). Thus, the departure at time t from (8.8) is given by:

$$ppp_t = p_{1,t} - p_{2,t} - s_{12,t}.^{1} \tag{8.9}$$

An ocular inspection gives a first impression of the development over time of prices and the nominal exchange rate and illustrates what the puzzle is all about. Figure 8.1 (upper panel) shows that US prices have grown more than German prices, resulting in a downward sloping stochastic trend in relative prices. According to purchasing power parity, the nominal exchange rate should reflect this downward sloping trend. The figure shows that this is also approximately the case over the very long run. However, what is striking are the long swings around that downward sloping trend.

How can we use econometrics to learn about the mechanisms underlying these swings? The subsequent VAR analyis will demonstrate that the joint modeling of prices and exchange rates allows us to formulate much richer hypotheses about the empirical mechanisms behind the puzzle.

8.3.2 Pulling and pushing forces in the cointegrated VAR model

To provide the intuition for the VAR approach and to show how the results can be interpreted in terms of pulling and pushing forces, a hypothetical VAR analysis of the German–US PPP data will be used as an illustration. For simplicity, the discussion will be restricted to a bivariate $I(1)$ model for relative prices and the nominal exchange rate. Because the period of interest defines a currency float, a prior hypothesis is that the nominal exchange rate has been adjusting and prices pushing. Provided that the stochastic trend in nominal exchange rates reflects the stochastic trend in relative prices, it is easy to show that $ppp = p_1 - p_2 - s_{12} \sim I(0)$. Thus the stationarity of PPP and its adjustment dynamics can be formulated as a composite hypothesis: $(p_1 - p_2) = pp \sim I(1)$, $s_{12} \sim I(1)$, $ppp \sim I(0)$, s_{12} is adjusting, and p_1, p_2 are pushing.

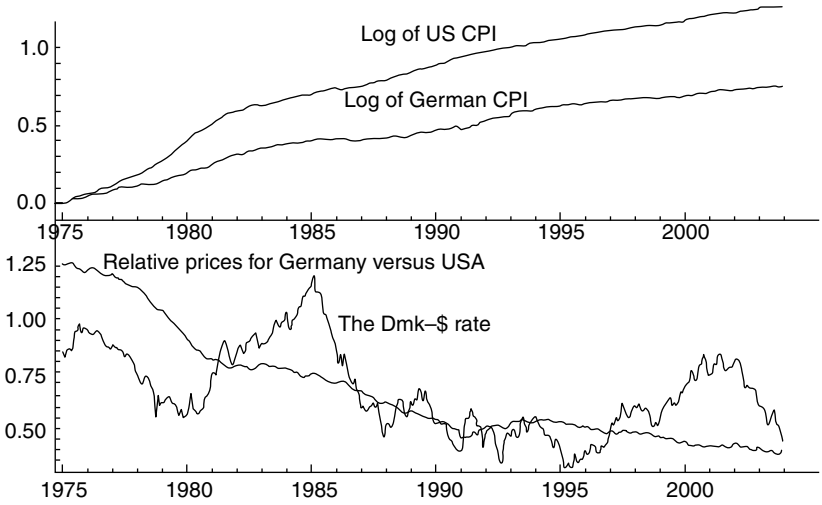

Figure 8.1 Time graphs of German and US prices (upper panel) and their relative prices and nominal exchange rate (lower panel)

The pulling forces are described by the vector equilibrium correction model:

$$\begin{bmatrix} \Delta pp_t \\ \Delta s_{12,t} \end{bmatrix} = \begin{bmatrix} \alpha_1 \\ \alpha_2 \end{bmatrix} (pp_{t-1} - s_{12,t-1} - \beta_0) + \begin{bmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \end{bmatrix},$$

where $(pp_t - s_{12,t} - \beta_0) = \boldsymbol{\beta}' \mathbf{x}_t$ is the cointegration relation with $E(ppp_t) = \beta_0$. Thus an equilibrium position, defined as $pp_t - s_{12,t} = \beta_0$, can be given an interpretation as a resting point towards which the process is drawn after it has been pushed away. In this sense, an equilibrium position exists at all time points, t, contrary to the long-run value of the process, which is the value of the process in the limit as $t \to \infty$ and all shocks have been switched off.

The pushing forces are described by the corresponding common trends model:

$$\begin{bmatrix} pp_t \\ s_{12,t} \end{bmatrix} = \begin{bmatrix} c \\ c \end{bmatrix} \boldsymbol{\alpha}'_{\perp} \sum_{i=1}^{t} \varepsilon_i + \mathbf{C}^*(L) \begin{bmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \end{bmatrix},$$

with $\boldsymbol{\alpha}'_{\perp} = \frac{1}{\alpha_1 - \alpha_2}[-\alpha_2, \alpha_1]$ and with $\boldsymbol{\alpha}'_{\perp} \sum_{i=1}^{t} \boldsymbol{\varepsilon}_i$ describing the common stochastic trend. Assume now that $\alpha' = [0, \alpha_2]$, i.e., only the nominal exchange rate is equilibrium correcting when $ppp_t - \beta_0 \neq 0$. In this case $\boldsymbol{\alpha}'_{\perp} = [1, 0]$ implies that the common stochastic trend originates from relative price shocks. This would conform to the theoretical prior for a period of floating exchange rates.

The question is now whether the empirical reality given by the observed variables in Figure 8.1 (lower panel) can be adequately represented by the above assumed pulling and pushing forces. Stationarity of ppp_t should imply that the nominal exchange rate would follow relative prices one-for-one apart from stationary noise. Figure 8.2 shows a cross-plot of the pp_t and $s_{12,t}$ variables. If the assumption that

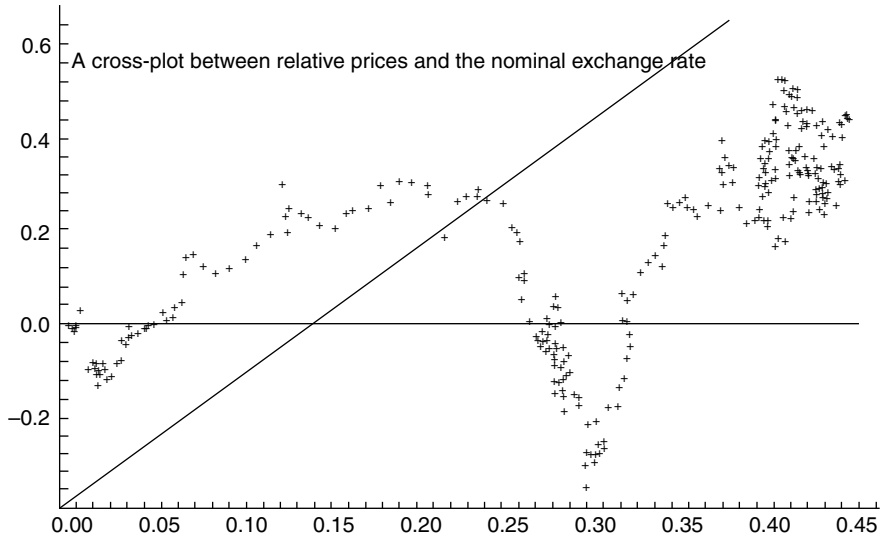

Figure 8.2 A cross-plot of US–German relative prices and the Dmk–$ rate for the period 1975:4–1998:12

$ppp_t \sim I(0)$ were correct, then the cross-plots should be randomly scattered around the 45° line defining the equilibrium position $pp_t = s_{12,t}$. Obviously, the cross-plots measuring the deviation from *ppp*, i.e., $\boldsymbol{\beta}'\mathbf{x}_t = pp_t - s_{12,t} - \beta_0$, are systematically scattered either above or below the 45° line. Thus the reality behind the observed real exchange rate looks very different from the assumed stationary PPP illustrating the puzzle. The non-stationarity of real exchange rates has been demonstrated in a number of studies (see Froot and Rogoff, 1995, and MacDonald, 1995, for surveys; Cheung and Lai, 1993; Juselius, 1995; Johansen and Juselius, 1992).

8.3.3 Approximating persistent behavior with $I(1)$ or $I(2)$

The above ocular analysis showed that the long swings puzzle is essentially a question of why nominal exchange rates have so persistently moved away from relative prices. The previous sub-section suggested that the cointegrated VAR model should be used to structure such data by the pulling and pushing forces. Section 8.3 defined the $I(1)$ and $I(2)$ models as reduced rank parameter restrictions on the $I(0)$ model, providing us with an empirically strong procedure for addressing behavioral macroeconomic problems. This is because the reduced rank parameterization of the CVAR allows us to group together components of similar persistence over the sample period. The characterization of the data into *empirically* $I(0)$, $I(1)$ and $I(2)$ components is a powerful organizing principle, allowing us to structure the data into long-run, medium-run and short-run behavior. An additional advantage is that inference is likely to become more robust than otherwise. For example, treating a near unit root as stationary tends to invalidate certain inferences based on the χ^2, F and t distributions unless we have a very long sample.[2]

This is a fairly pragmatic way of classifying data that allow a variable to be treated as $I(1)$ in one sample and $I(0)$ or even $I(2)$ in another. The idea is that, in a general equilibrium world, a persistent departure from a steady-state value of a variable or a relation should generate a similar persistent movement somewhere else in the economy. For example, if the Fisher parity holds as a stationary relation (stationary real interest rates) and we find that inflationary shocks have been very persistent, then we should expect interest rate shocks to have a similar persistence. Thus empirical persistence is a powerful property that can be used to investigate whether our prior hypothesis (the Fisher parity) is empirically relevant, and if not, which other variables have been co-moving in a similar manner, giving rise to new hypotheses.

From the outset, many economists would consider the idea that economic variables are $I(2)$ highly problematic. The argument is often that all inference on long-run values (the steady-state value a variable converges to when the errors are switched off) would lead to meaningless results. This is a valid argument provided one can argue that the order of integration is a structural parameter, which often seems doubtful. Nonetheless, there are cases when a structural interpretation is warranted. For example, Frydman *et al.* (2008) show that speculative behavior based on IKE is consistent with near $I(2)$ behavior; arbitrage theory suggests that a nominal market interest rate should be a martingale difference process, i.e., approximately a unit root process. Of course, in such cases a structural unit root should be invariant to the choice of sample period.

8.4 Modeling $I(2)$ data with the $I(1)$ model: does it work?

It often happens that $I(2)$ data are analyzed as if they were $I(1)$ because the $I(2)$ possibility was never checked, or one might have realized that the data exhibit $I(2)$ features but decided to ignore these signals in the data. For this reason, it is of some interest to ask whether the findings from such $I(1)$ analyses are totally useless, misleading, or can be trusted to some extent.

Before answering these questions, it is useful to examine the so-called **R**-model, in which short-run effects have been concentrated out. We consider first the simple VAR(2) model:

$$\begin{aligned}\Delta\mathbf{x}_t &= \boldsymbol{\Gamma}_1\Delta\mathbf{x}_{t-1} + \boldsymbol{\alpha}\boldsymbol{\beta}'\mathbf{x}_{t-1} + \boldsymbol{\mu}_0 + \boldsymbol{\varepsilon}_t \\ \boldsymbol{\varepsilon}_t &\sim N_p(\mathbf{0},\boldsymbol{\Omega}),\ t = 1,\ldots,T,\end{aligned} \tag{8.10}$$

and the corresponding **R**-model:

$$\mathbf{R}_{0t} = \boldsymbol{\alpha}\boldsymbol{\beta}'\mathbf{R}_{1t} + \boldsymbol{\varepsilon}_t, \tag{8.11}$$

where $\mathbf{R}_{0t}$ and $\mathbf{R}_{1t}$ are found by concentrating out the lagged short-run effects, $\Delta\mathbf{x}_{t-1}$:

$$\Delta\mathbf{x}_t = \hat{\boldsymbol{B}}_1\Delta\mathbf{x}_{t-1} + \hat{\boldsymbol{\mu}}_0 + \mathbf{R}_{0t}, \tag{8.12}$$

and:

$$\mathbf{x}_{t-1} = \hat{\boldsymbol{B}}_2\Delta\mathbf{x}_{t-1} + \hat{\boldsymbol{\mu}}_0 + \mathbf{R}_{1t}. \tag{8.13}$$

When $\mathbf{x}_t \sim I(2)$, both $\Delta\mathbf{x}_t$ and $\Delta\mathbf{x}_{t-1}$ contain a common $I(1)$ trend, which therefore cancels in the regression of one on the other, as in (8.12). Thus, $\mathbf{R}_{0t} \sim I(0)$ even if $\Delta\mathbf{x}_t \sim I(1)$. On the other hand, an $I(2)$ trend cannot be cancelled by regressing on an $I(1)$ trend and regressing $\mathbf{x}_{t-1}$ on $\Delta\mathbf{x}_{t-1}$ as in (8.13) does not cancel the $I(2)$ trend, so $\mathbf{R}_{1t} \sim I(2)$. Because $\mathbf{R}_{0t} \sim I(0)$ and $\boldsymbol{\varepsilon}_t \sim I(0)$, equation (8.11) can only hold if $\boldsymbol{\beta} = \mathbf{0}$ or, alternatively, if $\boldsymbol{\beta}'\mathbf{R}_{1t} \sim I(0)$. Thus, unless the rank is zero, the linear combination $\boldsymbol{\beta}'\mathbf{R}_{1t}$ transforms the process from $I(2)$ to $I(0)$.

The connection between $\boldsymbol{\beta}'\mathbf{x}_{t-1}$ and $\boldsymbol{\beta}'\mathbf{R}_{1t}$ can be seen by inserting (8.13) into (8.11):

$$\begin{aligned}
\underbrace{\mathbf{R}_{0t}}_{I(0)} &= \boldsymbol{\alpha}\boldsymbol{\beta}'(\underbrace{\mathbf{x}_{t-1}}_{I(2)} - \mathbf{B}_2\underbrace{\Delta\mathbf{x}_{t-1}}_{I(1)} - \hat{\boldsymbol{\mu}}_0) + \boldsymbol{\varepsilon}_t \\
&= \boldsymbol{\alpha}(\underbrace{\boldsymbol{\beta}'\mathbf{x}_{t-1}}_{I(1)} - \boldsymbol{\beta}'\underbrace{\mathbf{B}_2\Delta\mathbf{x}_{t-1}}_{I(1)} - \boldsymbol{\beta}'\hat{\boldsymbol{\mu}}_0) + \boldsymbol{\varepsilon}_t \\
&= \boldsymbol{\alpha}(\underbrace{\boldsymbol{\beta}'\mathbf{x}_{t-1} - \boldsymbol{\omega}'\Delta\mathbf{x}_{t-1}}_{I(0)} - \boldsymbol{\beta}'\hat{\boldsymbol{\mu}}_0) + \boldsymbol{\varepsilon}_t, \qquad (8.14)
\end{aligned}$$

where $\boldsymbol{\omega}' = \boldsymbol{\beta}'\mathbf{B}_2$. It is now easy to see that the stationary relations $\boldsymbol{\beta}'\mathbf{R}_{1t}$ consist of two components, $\boldsymbol{\beta}'\mathbf{x}_{t-1}$ and $\boldsymbol{\omega}'\Delta\mathbf{x}_{t-1}$. There are two possibilities:

1. $\boldsymbol{\beta}_i'\mathbf{x}_{t-1} \sim I(0)$ and $\boldsymbol{\omega}_i = \mathbf{0}$, where $\boldsymbol{\beta}_i$ and $\boldsymbol{\omega}_i$ denote the ith column of $\boldsymbol{\beta}$ and $\boldsymbol{\omega}$, or
2. $\boldsymbol{\beta}_i'\mathbf{x}_{t-1} \sim I(1)$ cointegrates with $\boldsymbol{\omega}_i'\Delta\mathbf{x}_{t-1} \sim I(1)$ to produce the stationary relation $\boldsymbol{\beta}'\mathbf{R}_{1t} \sim I(0)$.

In the first case, we talk about directly stationary relations; in the second case, about polynomially cointegrated relations. Here we shall consider $\boldsymbol{\beta}'\mathbf{x}_t \sim I(1)$ without distinguishing between the two cases, albeit recognizing that some of the cointegration relations $\boldsymbol{\beta}'\mathbf{x}_t$ may be stationary by themselves.

We have demonstrated above that $\mathbf{R}_{0t} \sim I(0)$ and $\boldsymbol{\beta}'\mathbf{R}_{1t} \sim I(0)$ in (8.11), which is the model on which all $I(1)$ estimation and test procedures are derived. This means that the $I(1)$ procedures can be used even though data are $I(2)$, albeit with the following reservations:

1. the $I(1)$ rank test cannot say anything about the reduced rank of the $\boldsymbol{\Gamma}$ matrix, i.e., about the number of $I(2)$ trends. The determination of the reduced rank of the $\boldsymbol{\Pi}$ matrix, though asymptotically unbiased, might have poor small sample properties (Nielsen and Rahbek, 2007)
2. the $\boldsymbol{\beta}$ coefficients relating $I(2)$ variables are T^2 consistent and thus are precisely estimated. We say that the estimate of $\boldsymbol{\beta}$ is super-super consistent
3. the tests of hypotheses on $\boldsymbol{\beta}$ are not tests of cointegration from $I(1)$ to $I(0)$, but instead from $I(2)$ to $I(1)$, as is evident from (8.14), and a cointegration relation should in general be considered $I(1)$, albeit noting that a cointegration relation $\boldsymbol{\beta}_i'\mathbf{x}_t$ can be CI(2,2), i.e., be cointegrating from $I(2)$ to $I(0)$
4. the MA representation is essentially useless, as the once cumulated residuals cannot satisfactorily explain variables containing $I(2)$ trends, i.e., twice cumulated residuals.

Thus, one can test a number of hypotheses based on the $I(1)$ procedure even if $\mathbf{x}_t$ is $I(2)$, but the interpretation of the results has to be modified accordingly.

8.5 An $I(1)$ analysis of prices and exchange rates

8.5.1 Specification

The VAR model is based on the assumption of multivariate normality which, if correct, implies linearity in parameters as well as constancy of parameters. However, multivariate normality is seldom satisfied in a first tentatively estimated VAR model. There are many reasons for this, e.g., omission of relevant variables, inadequate measurements, interventions, reforms, etc. All this may have changed the data-generating mechanisms, thus producing structural breaks or resulting in extraordinary effects on some of the variables. In the present case, the reunification of East and West Germany in 1991:1 was a particularly important institutional event which is likely to have changed some of the properties of the VAR model. For example, Figure 8.1 shows that the nominal exchange rate may have experienced a change in its trending behavior at the reunification, as well as a shift in its level. Therefore, a consequence of merging the less productive East with West Germany is likely to have been a change in relative productivity, which needs to be accounted for by a change in the slopes of the linear trends in the VAR model.

Thus, in order to achieve a well-specified VAR model one usually has to control for major institutional events. Section 8.6.2 will provide a more detailed account of how to specify deterministic components in the $I(2)$ model. For the specification of such events in the $I(1)$ model the reader is referred to Juselius (2006, Ch. 6). Here they will be modeled by a trend with a changing slope at 1991:1 ($t_{91.1}$) and various dummy variables, as explained below:

$$\Delta\mathbf{x}_t=\boldsymbol{\Gamma}_1\Delta\mathbf{x}_{t-1}+\boldsymbol{\alpha}\boldsymbol{\beta}'\mathbf{x}_{t-1}+\boldsymbol{\mu}_0+\boldsymbol{\mu}_{01}D_{s,91.1,t}+\boldsymbol{\mu}_1 t+\boldsymbol{\mu}_{11}t_{91.1}+\boldsymbol{\Phi}_p\mathbf{D}_{p,t}+\boldsymbol{\varepsilon}_t, \quad (8.15)$$

where the sample period is 1975:09–1998:12 and $\mathbf{x}_t' = [p_{1,t}, p_{2,t}, s_{12,t}]$ with:

$p_{1,t}$ = log of German CPI,[3]
$p_{2,t}$ = log of US CPI, and
$s_{12,t}$ = log of the nominal Dmk–$ exchange rate.

The linear terms in (8.15) are defined as:

$\boldsymbol{\mu}_0$ is a vector of constant terms,
$\boldsymbol{\mu}_{01}$ is a vector measuring a change in the constant term at 1991:1,
$\boldsymbol{\mu}_1$ is a vector of linear trend slopes,
$\boldsymbol{\mu}_{11}$ is a vector measuring a change in the trend slope at 1991:1.

The dummy variables are defined as:

$D_p tax = 1$ in 1991:7, 1991:9, and 1993:1, zero otherwise
$Ds91.1_t$ is 1 for $t \geq$ 1991:1, 0 otherwise,

$\mathbf{D}'_{p,t} = [Dp80.7, Dp91.1, D_p tax, D_p 97.7]$ with
$DpXX.y_t = 1$ in 19XX:y, zero otherwise.

The tax dummy is needed to account for a series of commodity tax increases to pay for reunification, and the three dummies are needed to account for a big drop in the US inflation rate in 1980:7, a large change in the nominal exchange rate in 1991:1, and a large change in the Dmk–$ rate in 1997:7.

As discussed in more detail in section 8.6, the two trend components, the constant, and the shift dummy need to be appropriately restricted in the VAR model to avoid quadratic and cubic trends. The dummy variables have been specified exclusively to control for the extraordinary shock at the time of the intervention, but to leave the information of the observation intact through its lagged impact. Thus the dummies do not *remove* the outlying observation as is usually the case in a static regression model. Table 8.1 reports the estimated effects.

Conditional on the dummies, the VAR model becomes reasonably well-specified. The tests for multivariate residual autocorrelation at one lag, $\chi^2(9) = 11.0[0.28]$, and two lags, $\chi^2(9) = 14.2[0.12]$, were acceptable, as were the tests of multivariate ARCH of order one, $\chi^2(36) = 45.9[0.12]$, and order two, $\chi^2(72) = 87.2[0.11]$. However, multivariate normality was rejected based on $\chi^2(6) = 27.1[0.00]$. To get some additional information, Table 8.1 reports the univariate Jarque–Bera tests, as well as skewness (third moment around the mean) and kurtosis (fourth moment around the mean). It appears that the non-normality problems are mostly due to excess kurtosis in the US inflation rate. Since the VAR estimates have been shown to be reasonably robust to moderate deviations from normality due to excess kurtosis (Gonzalo, 1994), the baseline VAR model is considered to be a reasonably adequate characterization of the data.

8.5.2 Rank determination and general model properties

The determination of the cointegration rank is a crucial step in the analysis, as it structures the data into its pulling and pushing components. The so-called trace test (Johansen, 1996) is a likelihood ratio test for the cointegration rank. However, the trace test is derived under the null of $p - r$ unit roots, which does not always correspond to the null of the theory model, as illustrated in section 8.8 (see also

Table 8.1 Estimated outlier effects and misspecification tests

	Estimated outlier effects				*Misspecification tests*		
	$D_p tax$	$Dp80.7$	$D_s 91.1$	$D_p 97.7$	*Norm.*	*Skew.*	*Kurt.*
$\Delta p_{1,t}$	**0.01** [11.36]	−0.00 [−1.40]	0.00 [1.77]	**0.01** [4.15]	7.22[0.03]	0.35	3.62
$\Delta p_{2,t}$	−0.00 [−0.15]	**−0.01** [−4.90]	0.00 [0.16]	0.00 [0.37]	15.4[0.00]	−0.20	4.20
$\Delta s_{12,t}$	−0.02 [−1.04]	0.01 [0.39]	**0.01** [2.57]	**0.06** [1.98]	6.31[0.04]	0.10	3.66

Note: t-ratios in [ ].

Table 8.2 Determination of rank in the $I(1)$ model

r	$p-r$	τ_{p-r}	*4 largest characteristic roots*			
0	3	80.06 [57.9]	1.0	1.0	1.0	0.75
1	2	**32.65** [36.6]	1.0	1.0	0.99	0.53
2	1	**6.72** [18.5]	1.0	0.99	0.99	0.52
3	0		0.99	0.99	0.98	0.53

Note: 95% quantiles in [].

Tests of pushing and pulling variables

	r	p_1	p_2	s_{12}
No levels feedback	1	7.52 [0.01]	16.17 [0.00]	7.58 [0.01]
	2	23.83 [0.00]	32.74 [0.00]	8.66 [0.01]
Pure adjustment	1	21.40 [0.00]	11.26 [0.00]	34.27 [0.00]
	2	**2.74** [0.10]	**1.31** [0.25]	18.74 [0.00]

Note: p-values in [].

Juselius, 2006, Ch. 8). Therefore, the choice of rank suggested by the trace test needs to be checked for its consistency with other information in the model, such as the characteristic roots.

The trace tests reported in Table 8.2 suggest a borderline acceptance of $r = 1$ cointegration relation, and hence $p - r = 2$ common stochastic trends or, alternatively, a strong acceptance of $r = 2$, and hence, $p - r = 1$ common stochastic trend. Thus, from a statistical point of view, both choices can be defended. Section 8.8 will argue that $r = 2$ is the theory consistent choice. To find out which choice is econometrically preferable, we shall check the consistency of $r = 1, 2$ with the characteristic roots in the model and with the mean reversion of the cointegration relations.

An inspection of the characteristic roots of the model shows that there are three large roots of magnitude 0.99 in the unrestricted model. These are generally indistinguishable from unit roots, so the model seems to contain three unit roots. The choice of $r = 1$ leaves one near unit root and the choice of $r = 2$ two near unit roots in the model. Section 8.4 showed that, when one or several large roots remain in the model for any reasonable choice of r, it is a sign of $I(2)$ behavior in at least one of the variables.[4]

To check the consistency of the results with the $I(2)$ model, it is useful to divide the total number of stochastic trends into $I(1)$ and $I(2)$ trends, i.e., $p - r = s_1 + s_2$, where s_1 denotes the number of $I(1)$ trends (unit root processes), and s_2 the number of $I(2)$ trends (double unit root processes). Three (near) unit roots in the model would be consistent with either $\{r = 0, p - r = 3\}$ or $\{r = 1, s_1 = 1, s_2 = 1\}$, whereas $\{r = 2, s_1 = 0, s_2 = 1\}$ corresponds to two unit roots. Since the latter is less than the three near unit roots in the model, the choice $r = 2$ would not be consistent with the empirical information in the data.

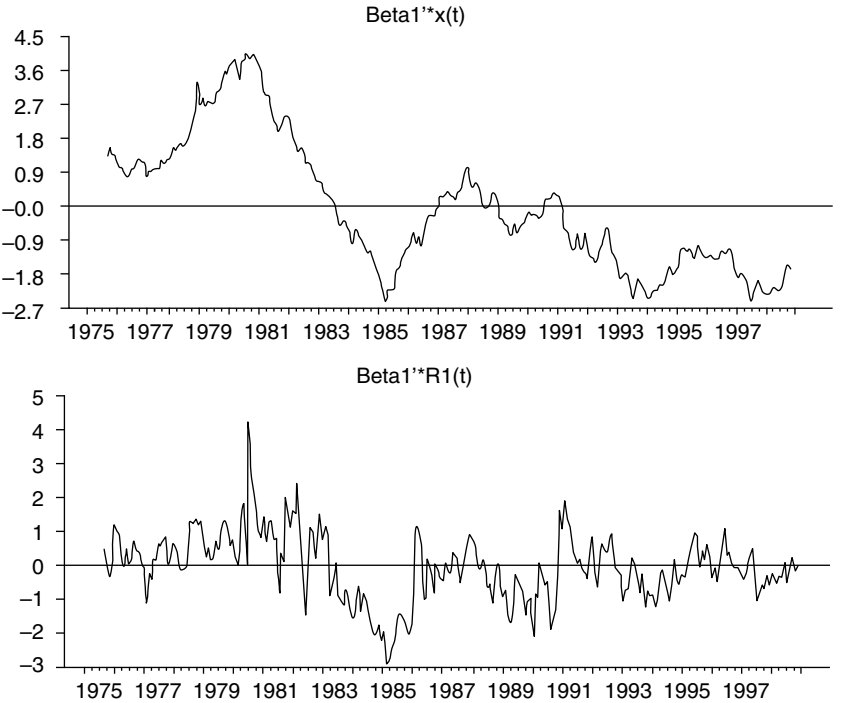

Figure 8.3 The graphs of the first cointegration relation ($\boldsymbol{\beta}'\mathbf{x}_t$ in the upper panel, $\boldsymbol{\beta}'\mathbf{R}_{1,t}$ in the lower panel)

Thus, by imposing $r = 1$, two of the big roots are restricted to unity, but the third would still be unrestricted in the $I(1)$ model, invalidating some of the interpretation of the empirical results discussed in section 8.4. The graphs of the first two cointegration relations, shown in Figures 8.3 and 8.4, illustrate the effect of a near unit root. Based on the graphs, it is difficult to argue that $\boldsymbol{\beta}_i'\mathbf{x}_t$, $i = 1, 2$, is mean-reverting as an equilibrium error should be. However, $\boldsymbol{\beta}_i'\mathbf{R}_{1,t}$ (in the lower panel) looks much more mean-reverting, at least for $r = 1$. This, of course, is exactly in accordance with (8.13). Thus, only $\{r = 1, s_1 = 1, s_2 = 1\}$ seems acceptable based on the characteristic roots of the model and the graphs of the cointegration relations.

It is also useful to investigate the general pulling and pushing properties of the model described by the test of a unit vector in $\boldsymbol{\alpha}$ and a zero row in $\boldsymbol{\alpha}$ (Juselius, 2006, Ch. 11) and how they would be affected by the choice of rank. In the lower part of Table 8.2 the tests of "no levels feedback" (a zero row in $\boldsymbol{\alpha}$) and "pure adjustment" (a unit vector in $\boldsymbol{\alpha}$) are reported for $r = 1$ and $r = 2$. For $r = 1$, none of the variables are found to purely pushing or pulling. For $r = 2$, there is some evidence that the two prices are exclusively adjusting (though the hypothesis that they are jointly adjusting is rejected). Altogether, the empirical evidence suggests that prices are

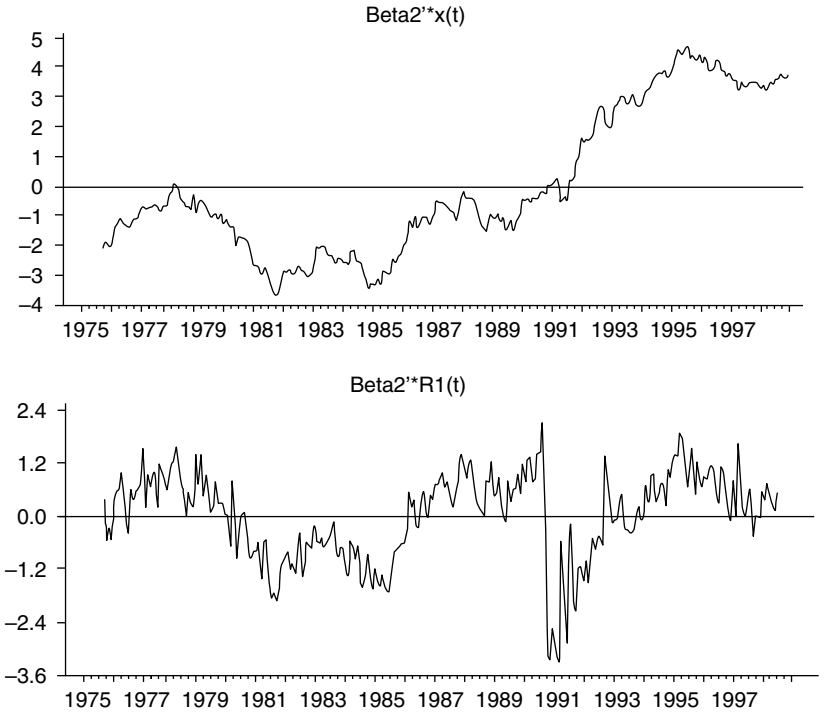

Figure 8.4 The graphs of the second cointegration relation ($\boldsymbol{\beta}'\mathbf{x}_t$ in the upper panel, $\boldsymbol{\beta}'\mathbf{R}_{1,t}$ in the lower panel)

"more" pulling than pushing, which is an interesting observation as one would expect the opposite during a currency float.

8.5.3 Estimating the long-run structure

Table 8.3 reports the estimates of $\boldsymbol{\alpha}, \boldsymbol{\beta}, \boldsymbol{\Gamma}_1$ and $\boldsymbol{\Phi}$ for the choice of $r = 1$. The estimated $\boldsymbol{\beta}$ relation suggests that $p_{1,t}$ and $p_{2,t}$ are almost homogeneously related. Testing the hypothesis gives a test statistic $\chi^2(1) = 0.56[0.46]$ and, thus, price homogeneity of $\boldsymbol{\beta}'\mathbf{x}_t$ seems acceptable[5] when allowing for a broken trend. The presence of a broken linear trend might seem difficult to interpret but is probably a proxy for omitted variables effects, such as the effect of productivity differentials on relative prices, the so-called Balassa–Samuelson effect (Balassa, 1964; Samuelson, 1964). The change in the trend slope at reunification supports this interpretation. What is more surprising, however, is that the sign of the nominal exchange rate is opposite to the expected one. Based on Figure 8.1, it is easy to see why: over the sample period, relative prices and nominal exchange rates have frequently moved in opposite directions for extended periods of time. For this reason, the data do not support the *ppp* restrictions $(1, -1, -1)$ on $\boldsymbol{\beta}$.

Table 8.3 The estimated short-run dynamic adjustment structure in the $I(1)$ model

$$\underbrace{\begin{bmatrix} \Delta p_{1t} \\ \Delta p_{2,t} \\ \Delta s_{12,t} \end{bmatrix}}_{I(1)} = \underbrace{\begin{bmatrix} \underset{[4.50]}{\mathbf{0.21}} & \underset{[2.31]}{\mathbf{0.12}} & \underset{[2.06]}{\mathbf{0.01}} \\ \underset{[2.21]}{\mathbf{0.10}} & \underset{[10.23]}{\mathbf{0.52}} & \underset{[0.38]}{0.00} \\ \underset{[1.15]}{0.92} & \underset{[-1.59]}{-1.44} & \underset{[-0.18]}{-0.01} \end{bmatrix}}_{\Gamma_1} \underbrace{\begin{bmatrix} \Delta p_{1t-1} \\ \Delta p_{2,t-1} \\ \Delta s_{12,t-1} \end{bmatrix}}_{I(1)}$$

$$+ \underbrace{\begin{bmatrix} \underset{[-3.92]}{\mathbf{-0.01}} \\ \underset{[-5.92]}{\mathbf{-0.02}} \\ \underset{[-3.05]}{\mathbf{-0.17}} \end{bmatrix}}_{\alpha} \underbrace{\begin{bmatrix} \boldsymbol{\beta}_1' \mathbf{x}_{t-1} \end{bmatrix}}_{I(1)} + \underbrace{\begin{bmatrix} \underset{[1.77]}{\mathbf{0.00}} & \underset{[4.09]}{\mathbf{0.02}} \\ \underset{[0.16]}{0.00} & \underset{[6.21]}{\mathbf{0.03}} \\ \underset{[2.57]}{\mathbf{0.01}} & \underset{[2.96]}{\mathbf{0.22}} \end{bmatrix}}_{\Phi} \begin{bmatrix} D_s 91.1 \\ \mu_0 \end{bmatrix} + \underbrace{\begin{bmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \\ \varepsilon_{3,t} \end{bmatrix}}_{I(0)}$$

where:

$$\boldsymbol{\beta}_1' x_t = \underset{}{\mathbf{1.0}} p_{1,t} \underset{[-7.76]}{-\mathbf{0.81}} p_{2,t} + \underset{[4.39]}{\mathbf{0.18}} s_{12,t} \underset{[-4.81]}{-\mathbf{0.0022}} t_{91.1} + \underset{[3.96]}{\mathbf{0.0022}} t,$$

and:

$$\Omega = \begin{bmatrix} 1.00 & & \\ 0.12 & 1.00 & \\ -0.58 & -0.07 & 1.00 \end{bmatrix}$$

The estimated $\boldsymbol{\alpha}$ coefficients show that German prices and nominal exchange rates have been equilibrium correcting to the estimated $\boldsymbol{\beta}$ relation whereas US prices have been increasing in the equilibrium errors. The overall behavior of the system is nevertheless stable as the other two variables compensate for the error-increasing behavior of US prices. The estimated coefficients of $\boldsymbol{\Gamma}_1$ show that lagged inflation rates are quite significant in the price equations, whereas the lagged depreciation/appreciation rate is only significant in the German price equation. As already demonstrated in section 8.4, the lagged changes of the $I(2)$ variables in $\boldsymbol{\Gamma}_1$ are needed to achieve stationarity of $\boldsymbol{\beta}_1' \mathbf{R}_{1,t}$.

The estimates of $\boldsymbol{\alpha}_{\perp 1}$, $\boldsymbol{\beta}_{\perp 1}$ and $\mathbf{C}$ in the MA representation of the $I(1)$ model are almost all insignificant and are not reported here. This is because the stochastic trends in the $I(1)$ model are measured by the once cumulated residuals, whereas the data are generated by second-order stochastic trends, measured by the twice cumulated residuals. Thus, when data are $I(2)$ the MA representation of the $I(1)$ model is completely uninformative.

Based on the above results, it would be hard to argue that the data are not empirically $I(2)$, and the next step is therefore to address the PPP puzzle in the correct framework of an $I(2)$ model.

8.6 Representing the $I(2)$ model

8.6.1 The basic structure

As discussed in section 8.2, formulation (8.3) is convenient when data are $I(2)$:

$$\Delta^2\mathbf{x}_t = \mathbf{\Gamma}\Delta\mathbf{x}_{t-1} + \mathbf{\Pi}\mathbf{x}_{t-1} + \boldsymbol{\mu}_0 + \boldsymbol{\mu}_{01}D_{s,91.1,t} + \boldsymbol{\mu}_1 t + \boldsymbol{\mu}_{11}t_{91.1} + \mathbf{\Phi}_p\mathbf{D}_{p,t} + \boldsymbol{\varepsilon}_t, \quad (8.16)$$

where the deterministic components are defined in section 8.5.1. Similar to the $I(1)$ model, we need to define the concentrated $I(2)$ model:[6]

$$\mathbf{R}_{0,t} = \mathbf{\Gamma}\mathbf{R}_{1,t} + \mathbf{\Pi}\mathbf{R}_{2,t} + \boldsymbol{\varepsilon}_t, \quad (8.17)$$

where $\mathbf{R}_{0,t}$, $\mathbf{R}_{1,t}$, and $\mathbf{R}_{2,t}$ are defined by:

$$\Delta^2\tilde{\mathbf{x}}_t = \hat{\mathbf{b}}_{10} + \hat{\mathbf{b}}_{11}t + \hat{\mathbf{B}}_{11}\mathbf{D}_{s,t} + \hat{\mathbf{B}}_{12}\mathbf{D}_{p,t} + \mathbf{R}_{0,t}, \quad (8.18)$$

$$\Delta\tilde{\mathbf{x}}_{t-1} = \hat{\mathbf{b}}_{20} + \hat{\mathbf{b}}_{21}t + \hat{\mathbf{B}}_{21}\mathbf{D}_{s,t} + \hat{\mathbf{B}}_{22}\mathbf{D}_{p,t} + \mathbf{R}_{1,t}, \quad (8.19)$$

$$\tilde{\mathbf{x}}_{t-1} = \hat{\mathbf{b}}_{30} + \hat{\mathbf{b}}_{31}t + \hat{\mathbf{B}}_{31}\mathbf{D}_{s,t} + \hat{\mathbf{B}}_{32}\mathbf{D}_{p,t} + \mathbf{R}_{2,t}, \quad (8.20)$$

and $\tilde{\mathbf{x}}_t$ indicates that $\mathbf{x}_t$ has been augmented with some deterministic components such as trend, constant, and shift dummy variables. The matrices $\mathbf{\Pi}$ and $\mathbf{\Gamma}$ are subject to the two reduced rank restrictions, $\mathbf{\Pi} = \boldsymbol{\alpha}'\boldsymbol{\beta}$, where $\boldsymbol{\alpha}, \boldsymbol{\beta}$ are $p \times r$, and $\boldsymbol{\alpha}_\perp'\mathbf{\Gamma}\boldsymbol{\beta}_\perp = \boldsymbol{\xi}\boldsymbol{\eta}'$, where $\boldsymbol{\xi}, \boldsymbol{\eta}$ are $(p-r)\times s_1$. The model in (8.16) contains an unrestricted constant with a shift, a broken trend and a few impulse dummies that will have to be adequately restricted to avoid undesirable effects, as discussed in section 8.6.2.

The moving average representation of the $I(2)$ model (Johansen, 1992, 1995, 1997) with unrestricted deterministic components is given by:

$$\begin{aligned}\mathbf{x}_t = {} & \mathbf{C}_2\sum_{j=1}^{t}\sum_{i=1}^{j}(\boldsymbol{\varepsilon}_i + \boldsymbol{\mu}_0 + \boldsymbol{\mu}_1 i + \boldsymbol{\mu}_{01}D_{s,91.1,i} + \mathbf{\Phi}_p\mathbf{D}_{p,i}) \\ & + \mathbf{C}_1\sum_{j=1}^{t}(\boldsymbol{\varepsilon}_j + \boldsymbol{\mu}_0 + \boldsymbol{\mu}_1 j + \boldsymbol{\mu}_{01}D_{s,91.1,j} + \mathbf{\Phi}_p\mathbf{D}_{p,j}) \\ & + \mathbf{C}^*(L)(\boldsymbol{\varepsilon}_t + \boldsymbol{\mu}_0 + \boldsymbol{\mu}_1 t + \boldsymbol{\mu}_{01}D_{s,91.1,t} + \mathbf{\Phi}_p\mathbf{D}_{p,t}) + \mathbf{A} + \mathbf{B}t,\end{aligned} \quad (8.21)$$

where $\mathbf{A}$ and $\mathbf{B}$ are functions of the initial values $\mathbf{x}_0, \mathbf{x}_{-1}, \mathbf{x}_{-2}$, and the coefficient matrices satisfy:

$$\begin{aligned}\mathbf{C}_2 &= \boldsymbol{\beta}_{\perp 2}(\boldsymbol{\alpha}_{\perp 2}'\mathbf{\Psi}\boldsymbol{\beta}_{\perp 2})^{-1}\boldsymbol{\alpha}_{\perp 2}', \\ \boldsymbol{\beta}'\mathbf{C}_1 &= -\overline{\boldsymbol{\alpha}}'\mathbf{\Gamma}\mathbf{C}_2, \quad \boldsymbol{\beta}_{\perp 1}'\mathbf{C}_1 = -\overline{\boldsymbol{\alpha}}_{\perp 1}'(\mathbf{I} - \mathbf{\Psi}\boldsymbol{C}_2), \\ \mathbf{\Psi} &= \mathbf{\Gamma}\overline{\boldsymbol{\beta}}\overline{\boldsymbol{\alpha}}'\mathbf{\Gamma} + \mathbf{I} - \mathbf{\Gamma}_1\end{aligned} \quad (8.22)$$

where the notation $\overline{\boldsymbol{\alpha}} = \boldsymbol{\alpha}(\boldsymbol{\alpha}'\boldsymbol{\alpha})^{-1}$ is used throughout the chapter. To facilitate the interpretation of the $I(2)$ stochastic trends and how they load into the variables, it is useful to let $\tilde{\boldsymbol{\beta}}_{\perp 2} = \boldsymbol{\beta}_{\perp 2}(\boldsymbol{\alpha}_{\perp 2}'\mathbf{\Psi}\boldsymbol{\beta}_{\perp 2})^{-1}$, so that:

$$\mathbf{C}_2 = \tilde{\boldsymbol{\beta}}_{\perp 2}\boldsymbol{\alpha}_{\perp 2}'. \quad (8.23)$$

It is now easy to see that the $\mathbf{C}_2$ matrix has a similar reduced rank representation to $\mathbf{C}_1$ in the $I(1)$ model, so it is straightforward to interpret $\boldsymbol{\alpha}'_{\perp 2}\sum\sum\boldsymbol{\varepsilon}_i$ as a measure of the s_2 second-order stochastic trends which load into the variables $\mathbf{x}_t$ with the weights $\tilde{\boldsymbol{\beta}}_{\perp 2}$.

From (8.22) we note that the $\mathbf{C}_1$ matrix in the $I(2)$ model cannot be given a simple decomposition as it depends on both the $\mathbf{C}_2$ matrix and the other model parameters in a complex way. Johansen (2008) derives an analytical expression for $\mathbf{C}_1$, essentially showing that:

$$\mathbf{C}_1 = \boldsymbol{\omega}_0\boldsymbol{\alpha}' + \boldsymbol{\omega}_1\boldsymbol{\alpha}'_{\perp 1} + \boldsymbol{\omega}_2\boldsymbol{\alpha}'_{\perp 2}, \tag{8.24}$$

where $\boldsymbol{\omega}_i$ are complicated functions of the parameters of the model (not reproduced here).

To summarize the basic structures of the $I(2)$ model, Table 8.4 decomposes the vector $\mathbf{x}_t$ into the directions of $(\boldsymbol{\beta}, \boldsymbol{\beta}_{\perp 1}, \boldsymbol{\beta}_{\perp 2})$ and the directions of $(\boldsymbol{\alpha}, \boldsymbol{\alpha}_{\perp 1}, \boldsymbol{\alpha}_{\perp 2})$. The left-hand side of the table illustrates the $\boldsymbol{\beta}, \boldsymbol{\beta}_{\perp}$ directions, where $\boldsymbol{\beta}'\mathbf{x}_t + \boldsymbol{\delta}'\Delta\mathbf{x}_t$ defines the stationary polynomially cointegrating relation, and $\boldsymbol{\beta}'_{\perp 1}\mathbf{x}_t$ the $CI(2,1)$ relation that can only become stationary by differencing. The $\boldsymbol{\beta}, \boldsymbol{\beta}_{\perp 1}$ relations define the two stationary cointegration relations between the differenced variables, $\boldsymbol{\tau}'\Delta\mathbf{x}_t$. Finally, $\boldsymbol{\beta}'_{\perp 2}\mathbf{x}_t \sim I(2)$ is a non-cointegrating relation, which can only become stationary by differencing twice. The right-hand side of the table illustrates the corresponding decomposition into the $\boldsymbol{\alpha}, \boldsymbol{\alpha}_{\perp}$ directions, where $\boldsymbol{\alpha}$ defines the dynamic adjustment coefficients to the polynomially cointegrating relation, whereas $\boldsymbol{\alpha}_{\perp 1}$ and $\boldsymbol{\alpha}_{\perp 2}$ define the first- and second-order stochastic trends as a linear function of the VAR residuals.

8.6.2 Deterministic components

A correct specification of the deterministic components, such as trends, constant and dummies, and how they enter the model, is mandatory for the $I(2)$ analysis. This is because the chosen specification is likely to strongly affect the reliability of the model estimates and to change the asymptotic distribution of the rank test. Because the typical smooth behavior of a stochastic $I(2)$ trend sometimes can be approximated with an $I(1)$ stochastic trend around a broken linear deterministic trend, one can in some cases avoid the $I(2)$ analysis altogether by allowing for sufficiently many breaks in the linear trend. Whether one specification is preferable

Table 8.4 Decomposing the data vector using the $I(2)$ model

	The $\boldsymbol{\beta}, \boldsymbol{\beta}_{\perp}$ *decomposition of* $\mathbf{x}_t$	*The* $\boldsymbol{\alpha}, \boldsymbol{\alpha}_{\perp}$ *decomposition*
$r = 1$	$[\underbrace{\boldsymbol{\beta}'_1\mathbf{x}_t}_{I(1)} + \underbrace{\boldsymbol{\delta}'_1\Delta\mathbf{x}_t}_{I(1)}] \sim I(0)$	$\boldsymbol{\alpha}_1$: short-run adjustment coefficients
$s_1 = 1$	$\boldsymbol{\beta}'_{\perp 1}\mathbf{x}_t \sim I(1)$	$\boldsymbol{\alpha}'_{\perp 1}\sum_{i=1}^{t}\boldsymbol{\varepsilon}_i$: $I(1)$ stochastic trend
$p - s_2 = 2$	$\boldsymbol{\tau}'\Delta\mathbf{x}_t = (\boldsymbol{\beta}, \boldsymbol{\beta}_{\perp 1})'\Delta\mathbf{x}_t \sim I(0)$	
$s_2 = 1$	$\boldsymbol{\beta}'_{\perp 2}\mathbf{x}_t = \boldsymbol{\tau}'_{\perp}\mathbf{x}_t \sim I(2)$	$\boldsymbol{\alpha}'_{\perp 2}\sum_{s=1}^{t}\sum_{i=1}^{s}\boldsymbol{\varepsilon}_i$: $I(2)$ stochastic trend

to the other is difficult to know, but we need to pay sufficient attention to this question, as the choice is likely to influence the empirical results significantly.

In the present data, the reunification of Germany is likely to have affected German prices significantly, but not US prices. The raw data exhibit an extraordinary large shock in $\Delta^2 p_{1,t}$ due to the reunification in 1991:1. A big impulse in $\Delta^2 p_{1,t}$ cumulates to a level shift in $\Delta p_{1,t}$, and double cumulates to a broken linear trend in $p_{1,t}$. Thus, accounting for the extraordinary large shock at 1991:1 with a blip dummy in $\Delta^2 p_{1,t}$, a shift dummy in $\Delta p_{1,t}$ is econometrically consistent with broken linear trends in prices. Because such a broken linear trend may or may not cancel in $\boldsymbol{\beta}'\mathbf{x}_t$, the model should be specified to allow for a (testable) broken linear trend in $\boldsymbol{\beta}'\mathbf{x}_t$. Likewise, the level shift may (or may not) cancel in $\boldsymbol{\delta}'\Delta\mathbf{x}_t$ or $\boldsymbol{\tau}'\Delta\mathbf{x}_t$. Thus the model specification should allow for this possibility. Inspecting the graphs in Figure 8.1 shows an increasing trend in both prices and a downward sloping trend in relative prices, and the question is whether the latter is canceled by cointegration with the nominal exchange rate.

Whatever the case, quadratic or cubic trends will be excluded from the outset and the model specification should account for this.

To understand the role of the deterministic terms in the $I(2)$ model, it is useful to specify the mean of the stationary parts of (8.16) allowing for the above effects (so that they can be tested), while at the same time excluding cubic or quadratic trend effects.

The mean of $\Delta^2\mathbf{x}_t$ should be allowed to contain the impulse dummies as these do not double cumulate to quadratic trends, i.e.:

$$E\Delta^2\mathbf{x}_t = \boldsymbol{\Phi}_p\mathbf{D}_{p,t}.$$

The mean of the polynomially cointegrated relations should be allowed to have a trend and a broken linear trend in $\boldsymbol{\beta}'\mathbf{x}_t$ and a constant and a shift dummy in $\boldsymbol{\delta}'\Delta\mathbf{x}_t$, i.e.:

$$E(\boldsymbol{\beta}'\mathbf{x}_t + \boldsymbol{\delta}'\Delta\mathbf{x}_t) = \boldsymbol{\rho}_0 t + \boldsymbol{\rho}_{01} t_{91.1} + \boldsymbol{\gamma}_0 + \boldsymbol{\gamma}_{01} D_s 91.1_t. \tag{8.25}$$

The mean of the difference stationary relations $\boldsymbol{\tau}'\Delta\mathbf{x}_t$ should be allowed to contain a shift dummy and a constant, i.e.:

$$E(\boldsymbol{\tau}'\Delta\mathbf{x}_t) = \boldsymbol{\omega}_0 + \boldsymbol{\omega}_{01} D_s 91.1_t.$$

The question is now how to restrict $\boldsymbol{\mu}_0, \boldsymbol{\mu}_{01}, \boldsymbol{\mu}_1$, and $\boldsymbol{\mu}_{11}$ in (8.16)[7] to allow for the deterministic components in the above mean values while suppressing any quadratic or cubic trend effects in the model. The general idea will only be demonstrated for the constant term $\boldsymbol{\mu}_0$ and the linear term $\boldsymbol{\mu}_1$, as the procedure is easily generalized to the step dummy and the broken trend. A more detailed discussion is given in Juselius (2006, Ch. 17).

First, the constant term $\boldsymbol{\mu}_0$ is decomposed into three components proportional to $\boldsymbol{\alpha}$, $\boldsymbol{\alpha}_{\perp 1}$ and $\boldsymbol{\alpha}_{\perp 2}$:

$$\boldsymbol{\mu}_0 = \boldsymbol{\alpha}\boldsymbol{\gamma}_0 + \boldsymbol{\alpha}_{\perp 1}\boldsymbol{\gamma}_1 + \boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_2. \tag{8.26}$$

The shift dummy $\boldsymbol{\mu}_{01}$ is similarly decomposed:

$$\boldsymbol{\mu}_{01} = \boldsymbol{\alpha}\boldsymbol{\gamma}_{01} + \boldsymbol{\alpha}_{\perp 1}\boldsymbol{\gamma}_{11} + \boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_{21}.$$

To investigate the effect of an unrestricted constant on $\mathbf{x}_t$, (8.26) is then inserted in (8.21) using (8.23) and (8.24). The effect of cumulating the constant twice is given by:

$$\begin{aligned}\mathbf{C}_2 \sum_{j=1}^{t}\sum_{i=1}^{j} \boldsymbol{\mu}_0 &= \sum_{j=1}^{t}\sum_{i=1}^{j} \tilde{\boldsymbol{\beta}}_{\perp 2}\boldsymbol{\alpha}'_{\perp 2}(\boldsymbol{\alpha}\boldsymbol{\gamma}_0 + \boldsymbol{\alpha}_{\perp 1}\boldsymbol{\gamma}_1 + \boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_2) \\ &= \tilde{\boldsymbol{\beta}}_{\perp 2}\boldsymbol{\alpha}'_{\perp 2}\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_2(t(t-1)/2), \end{aligned} \tag{8.27}$$

as $\boldsymbol{\alpha}'_{\perp 2}\boldsymbol{\alpha} = \mathbf{0}$ and $\boldsymbol{\alpha}'_{\perp 2}\boldsymbol{\alpha}_{1\perp} = \mathbf{0}$. Thus, an *unrestricted constant* term in the VAR model will allow for a quadratic trend in $\mathbf{x}_t$ so we need to restrict the $\boldsymbol{\alpha}_{\perp 2}$ component of $\boldsymbol{\mu}_0$ to avoid this. How to do this will be discussed below.

The effect of cumulating the constant term once is given by:

$$\begin{aligned}\mathbf{C}_1 \sum_{j=1}^{t} \boldsymbol{\mu}_0 &= (\boldsymbol{\omega}_0\boldsymbol{\alpha}' + \boldsymbol{\omega}_1\boldsymbol{\alpha}'_{\perp 1} + \boldsymbol{\omega}_2\boldsymbol{\alpha}'_{\perp 2}) \sum_{j=1}^{t} (\boldsymbol{\alpha}\boldsymbol{\gamma}_0 + \boldsymbol{\alpha}_{\perp 1}\boldsymbol{\gamma}_1 + \boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_2) \\ &= \left[(\boldsymbol{\omega}_0 \underbrace{\boldsymbol{\alpha}'\boldsymbol{\alpha}\boldsymbol{\gamma}_0}_{\widetilde{\boldsymbol{\gamma}}_0} + \boldsymbol{\omega}_1 \underbrace{\boldsymbol{\alpha}'_{\perp 1}\boldsymbol{\alpha}_{\perp 1}\boldsymbol{\gamma}_1}_{\widetilde{\boldsymbol{\gamma}}_1} + \boldsymbol{\omega}_2 \underbrace{\boldsymbol{\alpha}'_{\perp 2}\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_2}_{\widetilde{\boldsymbol{\gamma}}_2}) \right] t, \end{aligned} \tag{8.28}$$

as $\boldsymbol{\alpha}'\boldsymbol{\alpha}_{\perp 1} = \mathbf{0}$, $\boldsymbol{\alpha}'\boldsymbol{\alpha}_{\perp 2} = \mathbf{0}$ and $\boldsymbol{\alpha}'_{\perp 1}\boldsymbol{\alpha}_{\perp 2} = \mathbf{0}$. Thus, there are three different linear trends associated with the $\mathbf{C}_1$ components of the constant term.

Most applications of the $I(2)$ model are for nominal variables, implying that linear trends in the data are a natural starting hypothesis (as average nominal growth rates are generally non-zero). To achieve similarity in the rank test procedure (Nielsen and Rahbek, 2000), the model should allow for linear trends in all directions consistent with the specification of trend-stationarity as a starting hypothesis in (8.25). This means that $\boldsymbol{\mu}_1 t \neq \mathbf{0}$ and $\boldsymbol{\mu}_{11} t_{91.1} \neq \mathbf{0}$ in (8.16), so the vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_{11}$ need to be decomposed similarly to the constant term and the step dummy:

$$\boldsymbol{\mu}_1 = \boldsymbol{\alpha}\boldsymbol{\rho}_0 + \boldsymbol{\alpha}_{\perp 1}\boldsymbol{\rho}_1 + \boldsymbol{\alpha}_{\perp 2}\boldsymbol{\rho}_2,$$

and:

$$\boldsymbol{\mu}_{11} = \boldsymbol{\alpha}\boldsymbol{\rho}_{01} + \boldsymbol{\alpha}_{\perp 1}\boldsymbol{\rho}_{11} + \boldsymbol{\alpha}_{\perp 2}\boldsymbol{\rho}_{21}.$$

We now focus on the linear trend term. The effect of cumulating this term twice is given by:

$$\begin{aligned}\mathbf{C}_2 \sum_{j=1}^{t}\sum_{i=1}^{j} \boldsymbol{\mu}_1 i &= \sum_{j=1}^{t}\sum_{i=1}^{j} \boldsymbol{\beta}_{\perp 2}\boldsymbol{\alpha}'_{\perp 2}(\boldsymbol{\alpha}\boldsymbol{\rho}_0 + \boldsymbol{\alpha}_{\perp 1}\boldsymbol{\rho}_1 + \boldsymbol{\alpha}_{\perp 2}\boldsymbol{\rho}_2) i \\ &= \sum_{j=1}^{t}\sum_{i=1}^{j} \boldsymbol{\beta}_{\perp 2}\boldsymbol{\alpha}'_{\perp 2}\underbrace{\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\rho}_2}_{=0} i. \end{aligned} \tag{8.29}$$

Thus, unless we restrict $\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\rho}_2 = \mathbf{0}$ the model will allow for cubic trends in the data. The $I(2)$ procedure in CATS (Cointegration Analysis of Time Series) in RATS (Regression Analysis of Time Series) (Dennis, Johansen and Juselius, 2005) imposes this restriction. The effect of cumulating the linear trend term once is given by:

$$\begin{aligned}\mathbf{C}_1 \sum_{j=1}^{t} \boldsymbol{\mu}_1 j &= \sum_{j=1}^{t} (\boldsymbol{\omega}_0\boldsymbol{\alpha}' + \boldsymbol{\omega}_1\boldsymbol{\alpha}'_{\perp 1} + \boldsymbol{\omega}_2\boldsymbol{\alpha}'_{\perp 2})(\boldsymbol{\alpha}\boldsymbol{\rho}_0 + \boldsymbol{\alpha}_{\perp 1}\boldsymbol{\rho}_1 + \boldsymbol{\alpha}_{\perp 2}\boldsymbol{\rho}_2) j \\ &= \sum_{j=1}^{t} (\boldsymbol{\omega}_0\boldsymbol{\alpha}' \underbrace{\boldsymbol{\alpha}\boldsymbol{\rho}_0}_{\neq 0} + \boldsymbol{\omega}_1\boldsymbol{\alpha}'_{\perp 1}\underbrace{\boldsymbol{\alpha}_{\perp 1}\boldsymbol{\rho}_1}_{=0} + \boldsymbol{\omega}_2\boldsymbol{\alpha}'_{\perp 2}\underbrace{\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\rho}_2}_{=0}) j. \end{aligned} \tag{8.30}$$

It appears that all three $\mathbf{C}_1$ components of the linear trend will generate quadratic trends in the data. Based on (8.29), we already know that $\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\rho}_2 = \mathbf{0}$. Unless we are willing to accept linear trends in $\boldsymbol{\alpha}'_{\perp 1}\Delta\mathbf{x}_t$,[8] we should also restrict $\boldsymbol{\alpha}_{\perp 1}\boldsymbol{\rho}_1 = \mathbf{0}$. This leaves us with the $\boldsymbol{\alpha}$ component of $\mathbf{C}_1$, which cannot be set to zero, because $\boldsymbol{\alpha}\boldsymbol{\rho}_0 \neq \mathbf{0}$ is needed to allow for a linear trend in $\boldsymbol{\beta}'\mathbf{x}_t$. The problem is that a linear trend in a polynomially cointegrating relation, unless adequately restricted, generates a quadratic trend in $\mathbf{x}_t$. However, this can be solved by noticing that $\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_2 \neq \mathbf{0}$ in (8.27) also generates a quadratic trend in $\mathbf{x}_t$, so that by restricting $\boldsymbol{\omega}_0\boldsymbol{\alpha}'\alpha\rho_0 = -\boldsymbol{\beta}_{\perp 2}\boldsymbol{\alpha}'_{\perp 2}\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_2$, the two trend components cancel and there will be no quadratic trends in the data. The trend-stationary polynomially cointegrated relation in Kongsted, Rahbek and Jørgensen (1999) was estimated subject to this constraint.

To summarize: to avoid quadratic and cubic trends in the $I(2)$ model we need to impose the following restrictions: $\boldsymbol{\rho}_1 = \boldsymbol{\rho}_2 = \mathbf{0}$ and $\boldsymbol{\omega}_0\boldsymbol{\alpha}'\boldsymbol{\alpha}\boldsymbol{\rho}_0 = -\boldsymbol{\beta}_{\perp 2}\boldsymbol{\alpha}'_{\perp 2}\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_2$, as well as $\boldsymbol{\rho}_{11} = \boldsymbol{\rho}_{21} = \mathbf{0}$ and $\boldsymbol{\omega}_0\boldsymbol{\alpha}'\boldsymbol{\alpha}\boldsymbol{\rho}_{01} = -\boldsymbol{\beta}_{\perp 2}\boldsymbol{\alpha}'_{\perp 2}\boldsymbol{\alpha}_{\perp 2}\boldsymbol{\gamma}_{21}$ to avoid broken quadratic and cubic trends.

8.7 Estimation in the $I(2)$ model

Johansen (1995) provided the solution to the two-step estimator and Johansen (1997) to the full maximum likelihood (ML) estimator. Even though the two-stage procedure gives asymptotically efficient ML estimates (Paruolo, 2000), the small sample properties of the ML estimates are generally superior (Nielsen and Rahbek, 2007), and all subsequent results are based on the ML procedure.

8.7.1 The ML procedure

Section 8.2 showed that there is an important difference between the first- and second-rank conditions. The former is formulated as a reduced rank condition directly on $\boldsymbol{\Pi}$, whereas the latter is on a transformed $\boldsymbol{\Gamma}$. This is the basic reason why the ML estimation procedure needs a different parameterization than the one in (8.3).

The full ML procedure exploits the fact that the $I(2)$ model contains $p-s_2$ cointegration relations, $\boldsymbol{\tau}'\mathbf{x}_t$, where $\boldsymbol{\tau} = (\boldsymbol{\beta}, \boldsymbol{\beta}_{\perp 1})$ define $r+s_1 = p-s_2$ directions in which the process is cointegrated from $I(2)$ to $I(1)$. This means that $\boldsymbol{\tau}$ can be determined by solving just one reduced rank regression, after which the vector $\mathbf{x}_t$ is decomposed into the $p-s_2$ directions $\boldsymbol{\tau} = (\boldsymbol{\beta}, \boldsymbol{\beta}_{\perp 1})$ in which the process is $I(1)$, and the s_2 directions $\boldsymbol{\tau}_\perp = \boldsymbol{\beta}_{\perp 2}$ in which it is $I(2)$.

Johansen (1997) does not make a distinction between stationary and nonstationary components in $\Delta\mathbf{x}_t$. For example, when $\mathbf{x}_t$ contains variables which are $I(2)$, e.g., prices, as well as $I(1)$, e.g., nominal exchange rates, then some of the differenced variables will be $I(0)$. As the latter do not contain any stochastic $I(1)$ trends, they are by definition redundant in the polynomially cointegrated relations. The idea behind the parameterization in Paruolo and Rahbek (1999) was to express the polynomially cointegrated relations exclusively in terms of the differences of the $I(2)$ variables. The model given below is based on the Paruolo and Rahbek parameterization. As discussed in section 8.6, the (broken) trend has been restricted to be proportional to $\boldsymbol{\alpha}$, and the constant and the shift dummy to be proportional to $\boldsymbol{\zeta}$.

$$\begin{aligned}\underbrace{\Delta^2\mathbf{x}_t}_{I(0)} = \boldsymbol{\alpha}\Bigg\{\underbrace{\Big[\boldsymbol{\beta}', \boldsymbol{\rho}_0, \boldsymbol{\rho}_{01}\Big]\begin{bmatrix}\mathbf{x}_{t-1}\\ t\\ t_{91.1}\end{bmatrix}}_{I(1)} + \underbrace{\Big[\boldsymbol{\delta}', \boldsymbol{\gamma}_0, \boldsymbol{\gamma}_{01}\Big]\begin{bmatrix}\Delta\mathbf{x}_{t-1}\\ c\\ D_s 91.1_{t-1}\end{bmatrix}}_{I(1)}\Bigg\}_{I(0)} \\ + \underbrace{\boldsymbol{\zeta}\begin{bmatrix}\boldsymbol{\beta}', \boldsymbol{\rho}_0, \boldsymbol{\rho}_{01}\\ \underbrace{\boldsymbol{\beta}'_{\perp 1}, \tilde{\boldsymbol{\gamma}}_0, \tilde{\boldsymbol{\gamma}}_{01}}_{\boldsymbol{\tau}}\end{bmatrix}\begin{bmatrix}\Delta\mathbf{x}_{t-1}\\ c\\ D_s 91.1_{t-1}\end{bmatrix}}_{I(0)} + \boldsymbol{\Phi}_p\mathbf{D}_{p,t} + \boldsymbol{\varepsilon}_t,\end{aligned} \tag{8.31}$$

where $\boldsymbol{\varepsilon}_t \sim N_p(\mathbf{0}, \boldsymbol{\Omega})$, $t = 1, \ldots, T$, $\boldsymbol{\delta}' = \boldsymbol{\psi}'\boldsymbol{\tau}_\perp\boldsymbol{\tau}'_\perp$ with $\boldsymbol{\psi}' = -(\boldsymbol{\alpha}'\boldsymbol{\Omega}^{-1}\boldsymbol{\alpha})^{-1}\boldsymbol{\alpha}'\boldsymbol{\Omega}^{-1}\boldsymbol{\Gamma}$, $\boldsymbol{\zeta}' = \boldsymbol{\psi}'\boldsymbol{\tau} - \boldsymbol{\Omega}\boldsymbol{\alpha}_\perp(\boldsymbol{\alpha}'_\perp\boldsymbol{\Omega}\boldsymbol{\alpha}_\perp)^{-1}(\boldsymbol{\alpha}'_\perp\boldsymbol{\Gamma}\boldsymbol{\beta}, \boldsymbol{\xi})$ and $\boldsymbol{\xi}$ is defined in (8.5).

The relations $\boldsymbol{\beta}'\tilde{\mathbf{x}}_t + \tilde{\boldsymbol{\delta}}'\Delta\tilde{\mathbf{x}}_t$, with $\boldsymbol{\beta}' = [\boldsymbol{\beta}', \boldsymbol{\rho}_0, \boldsymbol{\rho}_{01}]$, $\tilde{\mathbf{x}}'_t = [\mathbf{x}'_t, t, t_{91.1}]$, $\tilde{\boldsymbol{\delta}}' = \Big[\boldsymbol{\delta}', \boldsymbol{\gamma}_0, \boldsymbol{\gamma}_{01}\Big]$, and $\Delta\tilde{\mathbf{x}}'_t = [\Delta\mathbf{x}'_t, 1, D_s 91.1]$, define r stationary polynomially cointegrating relations, whereas the relations $\boldsymbol{\tau}'\Delta\tilde{\mathbf{x}}_t$ define $p-s_2$ stationary relations between the growth rates.

8.7.2 Linking $I(1)$ with $I(2)$

It is useful to see how the formulation (8.31) relates to the usual VAR formulation (8.3). Relying on results in Johansen (1997), the levels and difference components

of the unrestricted VAR model (8.3) can be decomposed as:

$$\begin{aligned}\boldsymbol{\Gamma}\Delta\mathbf{x}_{t-1}+\boldsymbol{\Pi}\mathbf{x}_{t-1} = (\boldsymbol{\Gamma}\overline{\boldsymbol{\beta}})\underbrace{\boldsymbol{\beta}'\Delta\mathbf{x}_{t-1}}_{I(0)} \\ +(\boldsymbol{\alpha}\boldsymbol{\alpha}'\boldsymbol{\Gamma}\overline{\boldsymbol{\beta}}_{\perp 1}+\boldsymbol{\alpha}_{\perp 1})\underbrace{\boldsymbol{\beta}'_{\perp 1}\Delta\mathbf{x}_{t-1}}_{I(0)} \\ +(\boldsymbol{\alpha}\overline{\boldsymbol{\alpha}}'\boldsymbol{\Gamma}\overline{\boldsymbol{\beta}}_{\perp 2})\underbrace{\boldsymbol{\beta}'_{\perp 2}\Delta\mathbf{x}_{t-1}}_{I(1)} \\ +\boldsymbol{\alpha}\underbrace{\boldsymbol{\beta}'\mathbf{x}_{t-1}}_{I(1)},\end{aligned} \tag{8.32}$$

where $\overline{\boldsymbol{\beta}} = \boldsymbol{\beta}(\boldsymbol{\beta}'\boldsymbol{\beta})^{-1}$ and $\overline{\boldsymbol{\alpha}}$ is similarly defined. The decomposition describes three types of linear relations between the growth rates, $\boldsymbol{\beta}'\Delta\mathbf{x}_{t-1}, \boldsymbol{\beta}'_{\perp 1}\boldsymbol{\Delta}\mathbf{x}_{t-1}$ and $\boldsymbol{\beta}'_{\perp 2}\Delta\mathbf{x}_{t-1}$, of which the first two define $I(0)$ relations, and the third an $I(1)$ relation. The coefficients in soft brackets define the corresponding adjustment coefficients.

Since $\boldsymbol{\beta}'_{\perp 2}\Delta\mathbf{x}_{t-1}$ is $I(1)$, it needs to be combined with another $I(1)$ variable to become stationary. An obvious candidate for this is $\boldsymbol{\beta}'\mathbf{x}_{t-1}$. It is now easy to see how the parameterization in (8.3) relates to the one in (8.31):

$$\boldsymbol{\alpha}(\boldsymbol{\beta}'\mathbf{x}_{t-1}+(\overline{\boldsymbol{\alpha}}'\boldsymbol{\Gamma}\overline{\boldsymbol{\beta}}_{\perp 2})\,\boldsymbol{\beta}'_{\perp 2}\Delta\mathbf{x}_{t-1}) = \boldsymbol{\alpha}(\boldsymbol{\beta}'\mathbf{x}_{t-1}+\boldsymbol{\delta}'\Delta\mathbf{x}_{t-1}). \tag{8.33}$$

Finally, when $r > s_2$, the long-run matrix $\boldsymbol{\Pi}$ can be expressed as the sum of the two levels components:

$$\boldsymbol{\Pi} = \boldsymbol{\alpha}_0\boldsymbol{\beta}'_0 + \boldsymbol{\alpha}_1\boldsymbol{\beta}'_1,$$

where $\boldsymbol{\beta}'_0\mathbf{x}_{t-1}$ defines $r - s_2$ directly stationary $CI(2,2)$ relations, whereas $\boldsymbol{\beta}'_1\mathbf{x}_{t-1}$ defines s_2 non-stationary $CI(2,1)$ cointegrating relations, which needs to be combined with the differenced process to become stationary through polynomial cointegration.

Thus, the $I(2)$ model can distinguish between the $CI(2,1)$ relations between levels $\{\boldsymbol{\beta}'\mathbf{x}_t, \boldsymbol{\beta}'_{\perp 1}\mathbf{x}_t\}$, the $CI(1,1)$ relations between levels and differences $\{\boldsymbol{\beta}'\mathbf{x}_{t-1} + \boldsymbol{\delta}'\Delta\mathbf{x}_t\}$, and finally the $CI(1,1)$ relations between differences $\{\boldsymbol{\tau}'\Delta\mathbf{x}_t\}$. As a consequence, when discussing the economic interpretation of these components, the generic concept of a "long-run" equilibrium relation needs to be modified

accordingly. Juselius (2006, Ch. 17) proposed the following interpretation:

1. $\boldsymbol{\beta}'\mathbf{x}_t + \boldsymbol{\delta}'\Delta\mathbf{x}_t$ as r *dynamic long-run equilibrium relations*, or alternatively when $r > s_2$
   - $\boldsymbol{\beta}_0'\mathbf{x}_t$ as $r - s_2$ *static long-run equilibrium relations*, and
   - $\boldsymbol{\beta}_1'\mathbf{x}_t + \boldsymbol{\delta}_1\Delta\mathbf{x}_t$ as s_2 *dynamic long-run equilibrium relations,*
2. $\boldsymbol{\tau}'\Delta\mathbf{x}_t$ as *medium-run equilibrium relations*.

8.8 Two hypothetical scenarios

To be able to structure and interpret the empirical VAR results, it is useful to formulate a scenario for what we would expect to find in the VAR model, provided the reality is in accordance with the assumptions of the theoretical model. For example, the first scenario below is specified for the hypothesis: {$ppp_t \sim I(0)$, prices are pushing and the nominal exchange rate is pulling} under the assumption that $\mathbf{x}_t$ is empirically $I(2)$.

We shall discuss the following two cases: (1) $r = 2$, which corresponds to the theory consistent case, and (2) $r = 1$, which is what we find in the data. In both cases it will be assumed that long-run price homogeneity holds, i.e., $\boldsymbol{\beta}_{\perp 2}' = [c, c, 0]$.

Case 1 $\{r = 2, s_1 = 0, s_2 = 1\}$ is consistent with:

$$\begin{bmatrix} p_{1,t} \\ p_{2,t} \\ s_{12,t} \end{bmatrix} = \begin{bmatrix} c \\ c \\ 0 \end{bmatrix} \sum_{j=1}^{t}\sum_{i=1}^{j} u_{1,i} + \begin{bmatrix} b_1 \\ b_2 \\ b_3 \end{bmatrix} \sum_{i=1}^{j} u_{1,i} + \begin{bmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \\ \varepsilon_{3,t} \end{bmatrix}. \tag{8.34}$$

It is easy to see that $(p_{1,t} - p_{2,t}) \sim I(1)$ and $(p_{1,t} - p_{2,t} - s_{12,t}) \sim I(0)$ if $(b_1 - b_2) = b_3$. When the nominal exchange rate is adjusting (and price shocks are pushing), one would have it that $u_{1,t} = \boldsymbol{\alpha}_{\perp 1}'\boldsymbol{\varepsilon}_t$ with $\boldsymbol{\alpha}_{\perp 1}' = [a_1, a_2, 0]$. This scenario would imply two cointegrating relations, one of which is directly cointegrating, because $r - s_2 = 1$, and the other of which is polynomially cointegrating, because $s_2 = 1$. It is easy to show that the directly cointegrating relation is the *ppp* relation, i.e., $(p_{1,t} - p_{2,t} - s_{12,t}) \sim I(0)$. The polynomially cointegrated relation is more difficult to see and it is helpful to examine the system based on the nominal-to-real transformation (Kongsted, 2005):[9]

$$\begin{bmatrix} p_{1,t} - p_{2,t} \\ \Delta p_{1,t} \\ s_{12,t} \end{bmatrix} = \begin{bmatrix} b_1 - b_2 \\ c \\ b_3 \end{bmatrix} \sum_{i=1}^{j} u_{1,i} + \begin{bmatrix} \tilde{\varepsilon}_{1,t} \\ \tilde{\varepsilon}_{2,t} \\ \varepsilon_{3,t} \end{bmatrix}.$$

It is now straightforward to show that $\left\{p_{1,t} - p_{2,t} + \omega\Delta p_{1,t}\right\} \sim I(0)$, if $c = -(b_1 - b_2/\omega)$. Alternatively, if $c = -b_3/\omega$, then $\left\{s_{12,t} + \omega\Delta p_{1,t}\right\} \sim I(0)$. In both cases the polynomially cointegrating relation can be thought of as a dynamic equilibrium relation describing how the inflation rate adjusts when relative prices have been pushed apart, i.e., $\Delta p_{1,t} = -1/\omega\,(p_{1,t} - p_{2,t})$. It simply states the obvious, that the

inflation rates have to react in a non-homogeneous manner if relative prices move persistently apart.

Case 2 $\{r = 1, s_1 = 1, s_2 = 1\}$ is consistent with:

$$\begin{bmatrix} p_{1,t} \\ p_{2,t} \\ s_{12,t} \end{bmatrix} = \begin{bmatrix} c \\ c \\ 0 \end{bmatrix} \sum_{j=1}^{t} \sum_{i=1}^{j} u_{1,i} + \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \\ b_{31} & b_{32} \end{bmatrix} \begin{bmatrix} \sum_{i=1}^{j} u_{1,i} \\ \sum_{i=1}^{j} u_{2,i} \end{bmatrix} + \begin{bmatrix} \varepsilon_{1,t} \\ \varepsilon_{2,t} \\ \varepsilon_{3,t} \end{bmatrix}.$$

In this case one would not expect to find a directly cointegrating relation, as $r - s_2 = 0$. This result is easily seen from the nominal-to-real transformed system:

$$\begin{bmatrix} p_{1,t} - p_{2,t} \\ \Delta p_{1,t} \\ s_{12,t} \end{bmatrix} = \begin{bmatrix} b_{11} - b_{21} & b_{12} - b_{22} \\ c & 0 \\ b_{31} & b_{32} \end{bmatrix} \begin{bmatrix} \sum_{i=1}^{j} u_{1,i} \\ \sum_{i=1}^{j} u_{2,i} \end{bmatrix} + \begin{bmatrix} \tilde{\varepsilon}_{1,t} \\ \tilde{\varepsilon}_{2,t} \\ \varepsilon_{3,t} \end{bmatrix}.$$

It is now easy to see that stationarity of ppp_t can only be achieved in the special case when $b_{11} - b_{21} = b_{31}$ and $b_{12} - b_{22} = b_{32}$. But in general, empirical support for ppp_t can only be achieved by polynomial cointegration, i.e., in the form of a dynamic long-run adjustment relation. For example, if $b_{12} - b_{22} = b_{32}$ and $c = -(b_{11} - b_{21} - b_{31})/\omega$, then $\left\{p_{1,t} - p_{2,t} - s_{12,t} + \omega \Delta p_{1,t}\right\} \sim I(0)$. The latter can be interpreted as evidence of the following dynamic adjustment relation: $\Delta p_{1,t} = -1/\omega \left\{p_{1,t} - p_{2,t} - s_{12,t}\right\}$. In this case, either inflation rates or the currency depreciation/appreciation rate have to move in an offsetting direction when *ppp* has persistently deviated from its benchmark values.

Thus the outcome of testing rank indices in the $I(2)$ model has strong implications for whether support for a stationary relation can be found or not.

8.9 An $I(2)$ analysis of prices and exchange rates

8.9.1 Determining the two rank indices

The number of stationary multi-cointegrating relations, r, and the number of $I(1)$ trends, s_1, among the common stochastic trends, $p - r$, can be determined by the ML procedure in Nielsen and Rahbek (2007), where the trace test is calculated for all possible combinations of r and s_1 so that the joint hypothesis (r, s_1) can be tested, as explained below.

Table 8.5 reports the ML tests of the joint hypothesis of (r, s_1), which corresponds to the two reduced rank hypotheses in (8.4) and (8.5). The test procedure starts with the most restricted model $(r = 0, s_1 = 0, s_2 = 3)$ in the upper left-hand corner, continues to the end of the first row $(r = 0, s_1 = 3, s_2 = 0)$, and proceeds similarly row-wise from left to right until the first acceptance. Based on the tests, the first acceptance is at $(r = 1, s_1 = 1, s_2 = 1)$, which was also the preferred choice in section 8.4. The last column of the table correponds to the $I(1)$ trace test. When

Table 8.5 Determination of rank indices

r	p-r	$s_2 = 3$	$s_2 = 2$	$s_2 = 1$	$s_2 = 0$
0	3	527.6 [110.9]	293.9 [89.3]	118.10 [71.9]	80.06 [57.9]
1	2		96.88 [64.4]	**32.25** [48.5]	**32.65** [36.6]
2	1			**8.20** [28.7]	**6.72** [18.4]
The 4 largest characteristic roots, $r = 2$					
$s_1 = 0$	$s_2 = 1$		1.0	1.0	0.98 0.53
The 4 largest characteristic roots, $r = 1$					
$s_1 = 2$	$s_2 = 0$		1.0	1.0	0.99 0.53
$s_1 = 1$	$s_2 = 1$		1.0	1.0	1.0 0.53

Note: 95% quantiles in [].

the data are $I(2)$, determining the rank r exclusively by this test can often lead to incorrect results.

Our model has a broken linear trend restricted to the polynomially cointegrated relation and a shift dummy restricted to the differences. Because of this, the standard asymptotic trace test distributions (e.g., provided by CATS for RATS) are no longer correct. The critical values given in brackets below the test values have been kindly provided by Heino Nielsen using a simulation program described in Nielsen (2004) (see also Kurita, 2007). The inclusion of a broken linear trend in the cointegration relations shifts the distributions to the right, implying that the test will be undersized if one ignores the effect of the broken trend.

Table 8.5 also reports the characteristic roots in the VAR model for $r = 1$ and 2. For $\{r = 2, p - r = 1\}$ there is just one common stochastic trend, which has to be $I(2)$ if the data are $I(2)$. The choice of $\{r = 2, s_2 = 1\}$ will impose two unit root restrictions on the characteristic roots of the model. As already discussed in section 8.5.2 and confirmed in Table 8.5, this leaves one large unrestricted root, 0.98, in the model. Such a root is not statistically distinguishable from a unit root and would give problems if left unrestricted in the empirical model. When $r = 1$, the choice $\{r = 1, s_1 = 1, s_2 = 1\}$ accounts for all three near unit roots in the model with 0.53 as the largest unrestricted root, whereas the choice of $\{r = 1, s_1 = 0, s_2 = 2\}$ corresponds to four unit roots in the model and basically forces 0.53 to be a unit root. Altogether, the results strongly suggest that $\{r = 1, s_1 = 1, s_2 = 1\}$ is the correct choice.

That $r = 1$ is an important result, as the two scenarios in section 8.8 showed that a stationary ppp_t is inherently associated with *one* stochastic trend having generated prices and nominal exchange rates. Thus, the finding of $p - r = 2$ suggests that there exists another source of permanent shocks that have contributed to the persistent behavior in the data. A plausible explanation will be given in the concluding section.

8.9.2 The pulling forces

The scenarios above assume long-run price homogeneity. In section 8.6, this hypothesis was tested on $\boldsymbol{\beta}'\mathbf{x}_t$ and was accepted with high p-value. However, when

Table 8.6 The estimated short-run dynamic adjustment structure in the $I(2)$ model

$$\underbrace{\begin{bmatrix}\Delta^2 p_{1t}\\ \Delta^2 p_{2,t}\\ \Delta^2 s_{12,t}\end{bmatrix}}_{I(0)} = \underbrace{\begin{bmatrix}\mathbf{-0.01}\\ [-4.98]\\ \mathbf{-0.02}\\ [-8.66]\\ \mathbf{-0.13}\\ [-3.41]\end{bmatrix}}_{\boldsymbol{\alpha}} \underbrace{\begin{bmatrix}\boldsymbol{\beta}_1'\mathbf{x}_{t-1} + \boldsymbol{\delta}_1'\Delta\mathbf{x}_{t-1}\end{bmatrix}}_{I(0)}$$

$$+ \underbrace{\begin{bmatrix}\mathbf{-0.51} & \mathbf{-0.25}\\ [-11.97] & [-11.15]\\ \mathbf{0.29} & \mathbf{-0.14}\\ [7.25] & [-6.51]\\ 1.19 & 0.06\\ [1.66] & [0.15]\end{bmatrix}}_{\boldsymbol{\zeta}} \underbrace{\begin{bmatrix}\boldsymbol{\beta}_1'\Delta\mathbf{x}_{t-1}\\ \boldsymbol{\beta}_{\perp 1,1}'\Delta\mathbf{x}_{t-1}\end{bmatrix}}_{I(0)} + \underbrace{\begin{bmatrix}\varepsilon_{1,t}\\ \varepsilon_{2,t}\\ \varepsilon_{3,t}\end{bmatrix}}_{I(0)},$$

where:

$$\boldsymbol{\beta}_1'\mathbf{x}_t + \boldsymbol{\delta}_1'\Delta\mathbf{x}_t = \mathbf{1.0}p_{1,t} \underset{[-7.68]}{\mathbf{-0.85}}\, p_{2,t} + \underset{[15.08]}{\mathbf{0.19}}\, s_{12,t} - \underset{[-5.99]}{\mathbf{0.0025}}\, t_{91.1} + \underset{[8.34]}{\mathbf{0.0024}}t$$
$$+ \mathbf{2.61}\ \Delta p_{1,t} + \mathbf{5.21}\ \Delta p_{2,t} + \mathbf{9.31}\ \Delta s_{12,t} - \mathbf{0.10}\ D_s 91.1$$

$$\boldsymbol{\beta}_{\perp 1}'\Delta\mathbf{x}_{t-1} = \mathbf{1.01}\ \Delta p_{1,t} + \mathbf{1.0}\ \Delta p_{2,t} - \mathbf{0.84}\ \Delta s_{12,t} + \mathbf{0.01}\ \Delta t_{91.1} - \mathbf{0.01}\ \Delta t$$

Note: t-values in [].

$\mathbf{x}_t \sim I(2)$, long-run price homogeneity is defined on $\boldsymbol{\tau}'\mathbf{x}_t$, where $\boldsymbol{\tau}' = [\boldsymbol{\beta}, \boldsymbol{\beta}_{\perp 1}]$. Hence (see Johansen, 2006b), long-run homogeneity on $\boldsymbol{\beta}$ is a necessary but not sufficient condition. When tested, long-run price homogeneity of $\boldsymbol{\tau}'\mathbf{x}_t$ was strongly rejected based on $\chi^2(2) = 22.95[0.00]$ and $\boldsymbol{\beta}_{\perp 1}'\mathbf{x}_t$ cannot be considered homogeneous in prices. As Table 8.6 demonstrates, the coefficients to prices on $\boldsymbol{\beta}_{\perp 1}$ are proportional to (1, 1) rather than (1, −1). This, of course, is just another piece of evidence associated with the PPP puzzle.

Table 8.6 also reports the estimates of short-run adjustment dynamics towards the estimated long-run equilibrium relations. The $I(2)$ model is parameterized according to (8.31). We note that the $I(2)$ model allows the VAR variables to adjust to a medium-run equilibrium error, $\boldsymbol{\beta}_{\perp 1}'\boldsymbol{\Delta}\tilde{\mathbf{x}}_{t-1}$, to a change in the long-run "static equilibrium" error, $\boldsymbol{\beta}'\Delta\tilde{\mathbf{x}}_{t-1}$, and to the long-run "dynamic equilibrium" error, $\boldsymbol{\beta}'\tilde{\mathbf{x}}_{t-1} + \boldsymbol{\delta}\boldsymbol{\Delta}\tilde{\mathbf{x}}_{t-1}$. In this sense, the $I(2)$ model offers a much richer dynamic adjustment structure than the $I(1)$ model.

When discussing the adjustment dynamics with respect to the polynomially cointegrating relations, it is useful to interpret the adjustment coefficients $\boldsymbol{\alpha}$ and $\boldsymbol{\delta}$ as two levels of equilibrium correction. Consider, for example, the following model for the variable $x_{i,t}$:

$$\Delta^2 x_{i,t} = \cdots \sum_{j=1}^{r} \alpha_{ij}(\boldsymbol{\delta}_j'\Delta\mathbf{x}_{t-1} + \boldsymbol{\beta}_j'\mathbf{x}_{t-1}) + \cdots \tag{8.35}$$

If $\alpha_{ij}\delta_{ij} < 0$ for $j = 1, \ldots, r$, then the acceleration rates, $\Delta^2 x_{i,t}$ are equilibrium error correcting to the changes $\Delta x_{i,t}$, and if $\delta_{ij}\beta_{ij} > 0$ for $i = 1, \ldots, p$, then the changes $\Delta x_{i,t}$ are equilibrium error correcting to the levels $x_{i,t}$. In the interpretation below we shall pay special attention to whether a variable is equilibrium error correcting or increasing as defined above, as this is an important feature of the data.

Based on the estimates in Table 8.6, it appears that the acceleration rates of prices and nominal exchange rates are all equilibrium error correcting to their respective growth rates. When it comes to the relationship between growth rates and levels of variables, there is just one polynomial cointegration relation to check for equilibrium correction, but the check has to be done for all three growth rates. To make the equilibrium correction property more visible, the relation $\boldsymbol{\delta}'\Delta\mathbf{x}_{t-1} + \boldsymbol{\beta}'\mathbf{x}_{t-1}$ has been formulated in three alternative but equivalent ways:

$$\begin{aligned}
\Delta p_{1,t} &= -\mathbf{0.38}(p_{1,t} - \underset{[-7.68]}{\mathbf{0.85}}\, p_{2,t} + \underset{[15.08]}{\mathbf{0.19}}\, s_{12,t} - \underset{[-5.99]}{\mathbf{0.0025}}\, t_{91.1} + \underset{[8.34]}{\mathbf{0.0025}}t) \\
&\quad - \mathbf{2.0}\ \Delta p_{2,t} - \mathbf{3.5}\ \Delta s_{12,t} \\
\Delta p_{2,t} &= \mathbf{0.16}(p_{2,t} - \underset{[-7.68]}{\mathbf{1.15}}\, p_{1,t} - \underset{[15.08]}{\mathbf{0.25}}\, s_{12,t} + \underset{[-5.99]}{\mathbf{0.003}}\, t_{91.1} - \underset{[8.34]}{\mathbf{0.003}}t) \\
&\quad - \mathbf{0.50}\ \Delta p_{1,t} - \mathbf{1.8}\ \Delta s_{12,t} \\
\Delta s_{12,t} &= -\mathbf{0.02}(s_{12,t} - \mathbf{4.5}p_{2,t} + \underset{[7.68]}{\mathbf{5.5}}\, p_{1,t} + \underset{[-5.99]}{\mathbf{0.013}}\, t_{91.1} - \underset{[8.34]}{\mathbf{0.013}}t) \\
&\quad - \mathbf{0.28}\ \Delta p_{1,t} - \mathbf{0.56}\ \Delta p_{2,t}.
\end{aligned}$$

It appears that the polynomially cointegrated relation is consistent with equilibrium correction behavior in the German inflation rate and the Dmk–$ depreciation/appreciation rate, whereas the US inflation rate is error increasing. The lack of equilibrium error correction in US prices, already commented on in section 8.5.3, is an interesting empirical finding that is likely to be related to the PPP puzzle.

Ideally, one would like to interpret the above relations as dynamic adjustment of growth rates to a long-run static equilibrium relation, as described in the second scenario in section 8.8. In the present case, this is not straightforward because the nominal exchange rate has the wrong sign in $\boldsymbol{\beta}'\mathbf{x}_t$. Therefore, the latter cannot be given an approximate interpretation of a long-run *ppp* relation. Whatever the case, Figure 8.5 illustrates that the polynomially cointegrated relation is strongly mean-reverting.

Finally, the estimated adjustment coefficients, $\boldsymbol{\zeta} = [\boldsymbol{\zeta}_1, \boldsymbol{\zeta}_2]$, to the growth rate relations, $\boldsymbol{\beta}_1'\Delta\mathbf{x}_{t-1}$ and $\boldsymbol{\beta}_{\perp 1}'\Delta\mathbf{x}_{t-1}$, show that it is primarily the two prices that are adjusting. Both German and US prices are equilibrium adjusting to the first "growth rates" relation, $\boldsymbol{\beta}_1'\Delta\mathbf{x}_{t-1} = 1.0\Delta p_{1t} - 0.85\Delta p_{2t} + 0.20\Delta s_{12,t}$, but German prices more quickly so. The second "growth rates" relation, $\boldsymbol{\beta}_{\perp 1}'\Delta\mathbf{x}_{t-1} = 1.01\Delta p_{1,t} + 1.0\Delta p_{2,t} - 0.84\Delta s_{12,t}$, is more difficult to interpret. It essentially says that the change in the Dmk–$ rate has been proportional to the sum of German and US inflation rates, rather than to the inflation spread. As the coefficients of $\boldsymbol{\beta}_{\perp 1}$ are the

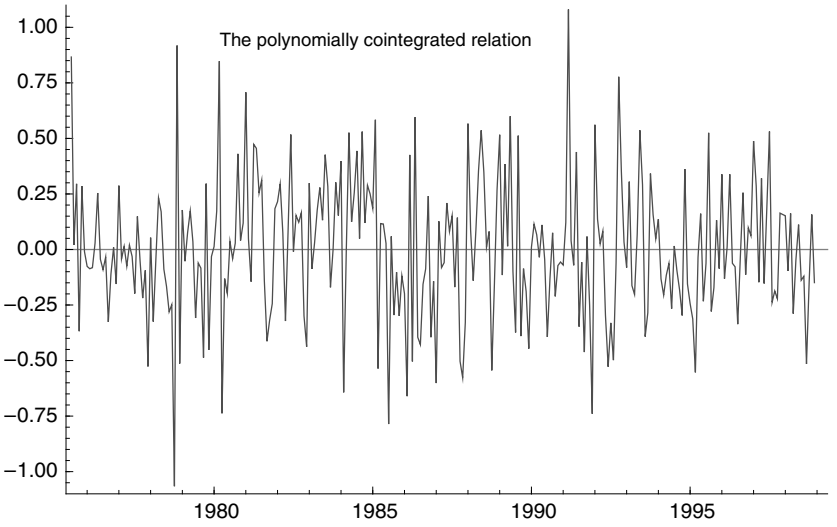

Figure 8.5 The graph of the polynomially cointegrated relation $\boldsymbol{\beta}'\mathbf{x}_t + \boldsymbol{\delta}'\Delta\mathbf{x}_t$

opposite of price homogeneity, the results explain why long-run price homogeneity in $\boldsymbol{\tau}$ was so strongly rejected.

That inflation rates are moving in opposite directions is a puzzling and even implausible result. Therefore, it is useful to check whether this result still holds for the combined estimates, $\boldsymbol{\zeta}\boldsymbol{\tau}'\Delta\mathbf{x}_t$, calculated below:

	$\Delta p_{1,t}$	$\Delta p_{2,t}$	$\Delta s_{12,t}$
$\Delta^2 p_{1t}$:	−0.75	0.18	0.10
$\Delta^2 p_{2,t}$:	0.44	−0.13	0.04
$\Delta^2 s_{12,t}$:	1.25	−1.00	0.17

Fortunately, the combined estimates are more plausible: German, as well as US, inflation rates are now equilibrium error-correcting to each other. The US inflation rate is equilibrium error-correcting to German price inflation with the correct sign, but to the Dmk–$ rate with an "incorrect" sign. However, the coefficient is very small and may not be significantly different from zero. Finally, the Dmk–$ rate is not equilibrium error correcting but even error increasing with the US–German inflation spread. Since the coefficients $\boldsymbol{\zeta}_{13}$ and $\boldsymbol{\zeta}_{23}$ were both insignificant, this is, however, not necessarily an empirically strong result.

To summarize, the VAR analysis has detected four puzzling results:

1. Nominal exchange rates tend to move in the opposite direction to relative prices for extended periods of time.
2. The US inflation rate is not equilibrium error correcting to $\boldsymbol{\beta}'\mathbf{x}_t$.

3. Changes in the nominal exchange rate either do not seem to have been significantly responding to movements in relative inflation rates or, if they have, in an equilibrium increasing manner.
4. The US inflation rate does not seem to have been responding to this "adverse" behavior of the change in the Dmk–$ rate.

8.9.3 The estimated driving forces

The scenario in section 8.8 can now be directly assessed based on the estimates of the MA representation in Table 8.7. The results clearly show that the empirical reality has deviated quite substantially from the assumed theoretical scenario. For example, the estimated loadings to the $I(2)$ trend, $\boldsymbol{\beta}_{\perp 2}$, show that the price coefficients are not even close to being equal, as assumed by the long-run homogeneity hypothesis. Given the previous rejection of long-run price homogeneity, this result should, of course, not come as a big surprise. However, what is more surprising is that the coefficient to the Dmk–$ rate is not even close to zero, suggesting that $s_{12,t}$ is empirically $I(2)$, rather than $I(1)$ as assumed in the scenario. Another surprising result is that, given the estimates of $\boldsymbol{\beta}_{\perp 2}$, the $I(2)$ trend does not seem to cancel in $ppp = p_1 - p_2 - s_{12}$. For this to be the case, the coefficients would need to be proportional to $\boldsymbol{\beta}'_{\perp 2} = [a, -a, 2a]$.

That the real exchange rate is empirically $I(2)$ would be hard to reconcile with standard theories. However, the theory of imperfect knowledge economics (Frydman and Goldberg, 2007) does in fact explain such a result. Frydman *et al.* (2008) demonstrate that, under highly plausible assumptions on agents' behavior, speculative transactions in the foreign exchange market are likely to generate pronounced persistence in nominal exchange rates that would be hard to distinguish from a near $I(2)$ process. Johansen *et al.* (2008) find strong evidence for this to be the case based on the same US–German (2008) data analyzed here, but extended with short- and long-term interest rates. They also find that the *ppp* transformed variable exhibits highly persistent behavior that can be considered either

Table 8.7 The common stochastic trends and their loadings

$$\begin{bmatrix} p_{1t} \\ p_{2,t} \\ s_{12,t} \end{bmatrix} = \begin{bmatrix} \mathbf{0.04} \\ \mathbf{0.09} \\ \mathbf{0.16} \end{bmatrix} \left[\boldsymbol{\alpha}'_{\perp 2,1} \sum \sum \hat{\boldsymbol{\varepsilon}} s \right]$$

$$+ \begin{bmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \\ c_{31} & c_{32} \end{bmatrix} \begin{bmatrix} \boldsymbol{\alpha}'_{\perp 2,1} \sum \hat{\boldsymbol{\varepsilon}}_i \\ \boldsymbol{\alpha}'_{\perp 1,1} \sum \hat{\boldsymbol{\varepsilon}}_i \end{bmatrix} + \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \\ b_{31} & b_{32} \end{bmatrix} \begin{bmatrix} t_{91.1} \\ t \end{bmatrix}$$

where:

$$\boldsymbol{\alpha}'_{\perp 2,1} \hat{\boldsymbol{\varepsilon}}_t = \underset{[-4.03]}{\mathbf{-0.57}} \hat{\varepsilon}_{p_1,t} + \mathbf{1.0} \hat{\varepsilon}_{p_2,t} \underset{[-2.32]}{\mathbf{-0.09}} \hat{\varepsilon}_{s_{12},t}$$
$$\boldsymbol{\alpha}'_{\perp 1,1} \hat{\boldsymbol{\varepsilon}}_t = \underset{[6.79]}{\mathbf{0.25}} \hat{\varepsilon}_{p_1,t} + \underset{[2.52]}{\mathbf{0.14}} \hat{\varepsilon}_{p_2,t} \underset{[-1.82]}{\mathbf{-0.04}} \hat{\varepsilon}_{s_{12},t}$$

empirically near $I(2)$ or $I(1)$, depending on whether the emphasis is on size or power.

The estimated $\boldsymbol{\alpha}_{\perp 2}$ shows that it is shocks to relative prices (but with a larger weight on US prices) and to nominal exchange rates that seem to have generated the stochastic $I(2)$ trend. Contrary to the scenario, the coefficient to the nominal exchange rate is significant and the sign is opposite to the expected one. The estimated $\boldsymbol{\alpha}_{\perp 1}$, describing the stochastic $I(1)$ trend, shows that a weighted average of inflationary shocks in Germany and the US have generated the medium-run movements in prices and exchange rates.

These results seem to strengthen the previous conclusions: standard theories of price determination in the goods market cannot explain the PPP puzzle. The overriding impression is that it is the nominal exchange rate that is behaving oddly, suggesting that the long swings puzzle needs to be solved together with another international macro-puzzle, the "forward premium puzzle." This will be discussed in the concluding section.

8.9.4 What did we gain from the $I(2)$ analysis?

Section 8.5 reported estimates and tests using the $I(1)$ model even though data were empirically $I(2)$. The question is whether the $I(2)$ analysis has changed some of the previous conclusions, or provided new insight that could not have been obtained from the $I(1)$ analysis.

To facilitate a comparison of the $I(1)$ and $I(2)$ models, it is useful first to subtract $\Delta \mathbf{x}_{t-1}$ from both sides of equation (8.15) estimated in section 8.5. The vector process would then be formulated in second differences $\Delta^2 \mathbf{x}_t$, and $\boldsymbol{\Gamma}_1$ would become $\boldsymbol{\Gamma} = \boldsymbol{\Gamma}_1 - \mathbf{I}$. In terms of likelihood, the two models differ only with respect to $\boldsymbol{\Gamma}$, which is unrestricted in the $I(1)$ model but subject to one nonlinear parameter restriction in the $I(2)$ model.

The estimates of the $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$ coefficients are very similar in the two models, but their standard errors are smaller in the $I(2)$ model, resulting in larger t-ratios. This is because in the $I(2)$ model the super-super consistency of $\boldsymbol{\beta}$ is adequately accounted for and because the $\boldsymbol{\beta}$ relation has been directly estimated as a polynomial cointegration relation. Also, the $\boldsymbol{\alpha}$ coefficients are not just measuring the adjustment to the levels relation, $\boldsymbol{\beta}' \mathbf{x}_{t-1}$, but to the levels and differences relation, $\boldsymbol{\beta}_1' \mathbf{x}_{t-1} + \boldsymbol{\delta}_1' \Delta \mathbf{x}_{t-1}$.

In the $I(1)$ model, the coefficient estimates of $\boldsymbol{\Gamma}_1$ are unrestricted, and there is not the same efficiency gain as in the $I(2)$ model, where the estimates are subject to the second reduced rank condition. In addition, the parameterization of the $I(1)$ model does not allow us to distinguish between $\boldsymbol{\beta}$ and $\boldsymbol{\tau} = (\boldsymbol{\beta}, \boldsymbol{\beta}_{\perp 1})$, and therefore not to decompose $\boldsymbol{\Gamma} = \boldsymbol{\Gamma}_1 - \mathbf{I}$ as in (8.32). So, even though we may have realized that the $\boldsymbol{\beta}$ relation is not mean-reverting by itself, and thus that it has to be combined with the differenced process $\boldsymbol{\delta}' \Delta \mathbf{x}_t$, we would not find the estimate of $\boldsymbol{\delta}$ without knowing the estimate of $\boldsymbol{\beta}_{\perp 1}$. Furthermore, the graphs of $\boldsymbol{\beta}_1' \mathbf{R}_{1,t}$ in Figure 8.3 and of $\boldsymbol{\beta}_1' \mathbf{x}_t + \boldsymbol{\delta}_1' \Delta \mathbf{x}_t$ in Figure 8.5 suggest that the latter relation is more precisely measured in terms of stationarity.

The hypothesis of long-run price homogeneity was adequately formulated as a test on $\boldsymbol{\tau}$ in the $I(2)$ model (and rejected), whereas in the $I(1)$ model it was formulated as a necessary but not sufficient test on $\boldsymbol{\beta}$ (and accepted). Thus, based on the $I(1)$ model, one might have been tempted to believe that long-run price homogeneity was acceptable even though it was strongly rejected. The rejection of homogeneity gave one of the clues as to why there are all these puzzles in international finance.

Finally, no useful results on the common driving trends could be obtained from the $I(1)$ model, whereas the MA analysis of the $I(2)$ model provided results on the $I(1)$ and $I(2)$ stochastic trends which suggested that we need to look closer at the determination of the nominal exchange rates.

To conclude, even though the $I(1)$ and $I(2)$ models are quite close in terms of likelihood, the $I(2)$ procedure is likely to insure against possible pitfalls in the statistical analysis when there is a double unit root in the data. Last, but not least, it also allows for a much richer structure and therefore more interesting interpretations of the information in the data.

8.10 Conclusions

The CVAR approach adopted in this chapter is based on general-to-specific modeling as a tool to uncover empirical regularities in the economy. Starting from a general unrestricted model representing the raw data and then testing down seems to be a useful way of extracting as much information as possible from the data without distorting them in a prespecified direction. In this vein, it is also important from the outset to untie any transformation of the variables, such as the real exchange rate transformation of prices and nominal exchange rates, assumed to hold rather than tested in the data. Such transformations, common in empirical economics, can often seriously distort signals in the data that otherwise might help to uncover important empirical regularities. This was also the case in this chapter, where the joint modeling of prices and exchange rates revealed empirical regularities in prices and the nominal exchange rate that were helpful in pinning down the underlying puzzling behavior in this period.

To effectively pull information from the data, this chapter has argued that the vector process should be classified into directions of similar persistence, dubbed empirically $I(0)$, $I(1)$ or $I(2)$. By following this route, one can achieve more precise inference and improve the interpretability of economic behavior in the short, medium and long run. However, the main advantage is the ability to associate persistent movements away from fundamental benchmark values in one variable/relation with similar persistent movements somewhere else in the economy. In a general equilibrium world, one would expect a persistent imbalance in one sector to generate a persistent departure in another. Thus, by characterizing the data according to the empirical order of integration, the CVAR approch offers a powerful tool with which to investigate the generating mechanisms underlying such puzzling behavior.

To distinguish between those empirical regularities which can be explained by the theory model and those which cannot, the chapter has demonstrated

the importance of first translating the basic assumptions of the theory model into testable assumptions on the CVAR model. As an illustration, the chapter showed how to translate the assumption of a stationary PPP and long-run price homogeneity, together with the assumption that prices are pushing and the exchange rate is pulling, into testable hypotheses in the CVAR model. This theory consistent scenario showed, among others, that a stationary real exchange rate is inherently associated with *one* stochastic trend having generated prices and nominal exchange rates. The finding of two (rather than one) stochastic trends was particularly important, as it suggested the existence of an additional source of permanent shocks that have contributed to the persistent behavior in the data. This additional shock seemed to be related to speculative behavior in the market for foreign exchange and pointed to the importance of addressing the long swings puzzle jointly with another puzzle in international finance, the "forward premium puzzle." Similar to the long swings puzzle, the forward premium puzzle also has to do with persistent movements in the data, now in the forward premium: $(R_{1,t} - R_{2,t} - E_t \Delta s_{12,t+m})$, where $R_{i,t}$ is an interest yield of maturity m.

Thus the two puzzles are connected, in that both stem from the determination of the nominal exchange rate in the foreign exchange market. Based on a cointegrated VAR analysis of German and US prices, the exchange rate, and interest rates, Juselius and MacDonald (2007) find that *ppp* and the real interest rate spread are cointegrating though individually $I(1)$, or even near $I(2)$. This is strong evidence against the implications of the Dornbusch (1976) sticky-price model with RE that PPP and real interest parity each should hold as equilibrium cointegrating relationships. A theoretical justification for this strong feature in the data is, however, provided by Frydman *et al*. (2008), who were able to show in a two-country monetary model with IKE that goods prices and exchange rates adjust to a long-run equilibrium relation, being a combination of the *ppp* and the real interest rate spreads.

Furthermore, Johansen *et al*. (2008) report results that point to the importance of inflationary expectations measured by the term spread which was found to be empirically $I(1)$. The latter finding again points to the importance of allowing for not just one, but at least two, stochastic trends in the term structure of interest rates (Giese, 2008), and thus to a reconsideration of the monetary policy interest rate channel.

This illustrates how the VAR approach can be used constructively. Starting with the basic information set, carefully structuring the information in the data, and adding more information if needed, might at an early stage suggest how to modify either the empirical or the economic model, or both.

The following passage from Hoover (2006) pinpoints the fundamental difference between an approach based on *a priori* theory and the general-to-specific approach to empirical economics:

> The Walrasian approach is totalizing. Theory comes first. Empirical reality must be theoretically articulated before it can be empirically observed. There is a sense that the Walrasian attitude is that to know anything, one must know everything.

> ... There is a fundamental problem: How do we come to our a priori knowledge? Most macroeconomists expect empirical evidence to be relevant to our understanding of the world. But if that evidence only can be viewed through totalizing *a priori* theory, then it cannot be used to revise the theory.
>
> ... The Marshallian approach is archaeological. We have some clues that a systematic structure lies behind the complexities of economic reality. The problem is how to lay this structure bare. To dig down to find the foundations, modifying and adapting our theoretical understanding as new facts accumulate, becoming ever more confident in our grasp of the super structure, but never quite sure that we have reached the lowest level of the structure.

For example, the significant finding of two shocks rather than one and the rejection of long-run price homogeneity are two examples of important information in the data, signaling the need to dig deeper in order to understand more. By taking this information in the data seriously instead of just ignoring it, we have been able to uncover more structure, and thus to improve our understanding, as demonstrated in Frydman *et al.* (2008) and Johansen *et al.* (2008). Needless to say, the need to dig deeper does not stop here.

Notes

1. Note that the *ppp* term is also the (logarithm) of the real exchange rate. We prefer to use the label *ppp* in this chapter because we are adopting a parity perspective and also because we do not model the real exchange rate in terms of so-called real fundamentals.
2. Johansen (2006a) demonstrated that valid inference on steady-state values requires more than 5,000 observations if the model contains a near unit root of 0.998.
3. German CPI has been additively mean corrected for the reunification in 1991:1 prior to the VAR analysis.
4. Note, however, that this diagnostic check is only reliable in a VAR model with a correct lag length. A VAR model with too many lags will often generate complex pairs of large (albeit insignificant) roots in the characteristic polynomial (Nielsen and Nielsen, 2006).
5. When the data are $I(2)$, price homogeneity of $\boldsymbol{\beta}'\mathbf{x}_t$ is a necessary but not sufficient condition, as will be discussed in section 8.8.
6. When the lag $k > 2$, there would also be lagged acceleration rates, $\Delta^2\mathbf{x}_{t-1}$, to concentrate out.
7. At this stage, $\boldsymbol{\Phi}_p$ will be left unrestricted in the model.
8. A linear trend in $\boldsymbol{\alpha}'_{\perp 1}\Delta\mathbf{x}_t$ would imply that the inflation rate, say, is allowed to grow with a linear trend, and thus prices with a quadratic trend. It would be hard to argue for such a specification, except possibly as a local approximation.
9. From a statistical point of view, an equivalent transformation would be achieved by replacing Δp_1 with Δp_2.

Structural Time Series Models for Business Cycle Analysis

Tommaso Proietti

Abstract

The chapter deals with parametric models for the measurement of the business cycle in economic time series. It presents univariate methods based on parametric trend-cycle decompositions and multivariate models featuring a Phillips-type relationship between the output gap and inflation and the estimation of the gap using mixed frequency data. We finally address the issue of assessing the accuracy of the output gap estimates.

9.1 Introduction

The term "structural time series" refers to a class of parametric models that are specified directly in terms of unobserved components which capture essential features of the series, such as trends, cycles and seasonality. The approach is suitable for the analysis of macroeconomic time series, where latent variables, such as trends and cycles, and more specialized notions, such as the output gap, core inflation and the natural rate of unemployment, need to be measured.

One of the key issues economists have faced in characterizing the dynamic behavior of macroeconomic variables, such as output, unemployment and inflation, is separating trends from cycles. The decomposition of economic time series has a long tradition, dating back to the nineteenth century (see the first chapter of Mills, 2003, for an historical perspective). Along with providing a description of the salient features of a series, the distinction between what is permanent and what is transitory in economic dynamics has important implications for monetary and fiscal policy. The underlying idea is that trends and cycles can be ascribed to different economic mechanisms and an understanding of their determinants helps to define policy targets and instruments.

This chapter focuses on structural time series modeling for business cycle analysis and, in particular, for output gap measurement. The *output gap* is the deviation of the economy's realized output from its potential. Potential output is defined as the noninflationary level of output, i.e., as the level that can be attained using the available technology and productive factors at a stable inflation rate. The gap measures the presence and the extent of real disequilibria and constitutes an indicator of inflationary pressure in the short run: a positive output gap testifies to excess demand, while a negative output gap implies excess supply.

The output gap plays a central role in the transmission mechanism of monetary policy, since short-term interest rates influence aggregate demand and the latter affects inflation via a Phillips curve relationship. The Phillips curve establishes a trade-off between output and inflation over the short run, and provides the rationale for using the short run component in output as an indicator of demand-driven inflationary pressure. For instance, the Taylor rule (Taylor, 1999) explicitly links the central bank's policy to the output gap. On the other hand, the growth rate of potential output is a reference value for broad money growth. Other important uses of the output gap are in fiscal analysis, where it is employed to assess the impact of cyclical factors on budget deficits, and in the adjustment of exchange rates. The output gap is also related to cyclical unemployment, which is the deviation of unemployment from its trend, known as the non-accelerating inflation rate of unemployment (NAIRU).

The signal extraction problems relating to latent variables, such as the output gap, core inflation and the NAIRU, can be consistently formulated within a model-based framework and, in particular, within the class of unobserved components time series models, so matching the fundamental economic relationships with observable macroeconomic aggregates.

The chapter is divided into three main parts: the first (section 9.2) deals with univariate methods for cycle measurement. One approach is to formalize a model of economic fluctuations such that the different components are driven by specific shocks that are propagated via a dynamic transmission mechanism. We start by introducing the traditional trend-cycle structural decomposition, discussing the parametric representation of both components (sections 9.2.1–4) and the correlation between the trend and cycle disturbances (section 9.2.5). Another approach is to consider the cycle as the bandpass component of output, i.e., as those economic fluctuations which have a periodicity greater then a year and smaller than, say, eight years. We review the relationship between popular signal extraction filters, such as the Hodrick–Prescott and the Baxter and King filters, and the model-based Wiener–Kolmogorov filter. Particular attention is devoted to the implementation of bandpass filtering in a model-based framework (section 9.2.6). The advantages of this strategy are twofold: the components can be computed in real time using standard principles of optimal signal extraction, so that efficient algorithms, such as the Kalman filter and smoother, can be applied. Second, the reliability of the estimated components can be thoroughly assessed.

The second part, starting with section 9.3, deals with multivariate models for the measurement of the output gap. The above definition of the output gap as an indicator of inflationary pressures suggests that the minimal measurement framework is of a bivariate model for output and inflation. After reviewing the work done in this area (section 9.3.1), we illustrate the estimation of a bivariate model for the US economy, under both the classical and the Bayesian approaches, and incorporating the feature known as the "Great Moderation" of the volatility of economic fluctuations (section 9.3.2). In section 9.3.3 we review the multivariate extensions of the basic bivariate model and we conclude this part with an application which serves to illustrate the flexibility of the state-space methodology in accommodating data features such as missing data, nonlinearities and temporal aggregation. In particular, section 9.3.4 presents the results of fitting a four-variate monthly time series model for the US economy with mixed frequency data, as gross domestic product (GDP) is available only quarterly, whereas industrial production, the unemployment rate and inflation are monthly. The model incorporates the temporal aggregation constraints (which are nonlinear since the model is formulated in terms of the logarithm of the variables) and produces as a byproduct monthly estimates of GDP, along with their reliability, that are consistent with the quarterly observed values.

The third part, section 9.4, deals with the reliability of the output gap estimates. The assessment of the quality of the latter is crucial for the decision maker. We discuss the various sources of uncertainty (model selection, parameter estimation, data revision, estimation of unboserved components,

statistical revision), and discuss ways of dealing with them using the state-space methodology.

One of the objectives of this chapter is to provide an overview of the main state-space methods and to illustrate their application and scope. The description of the algorithms is relegated to an appendix and we refer to Harvey (1989), West and Harrison (1997), Kitagawa and Gersch (1996), Durbin and Koopman (2001), and the selection of readings in Harvey and Proietti (2005), for a thorough presentation of the main ideas and methodological aspects concerning state-space methods and unobserved components models. For the class of state-space models with Markov-switching, see Kim and Nelson (1999b), Frühwirth-Schnatter (2006) and Cappé, Moulines and Ryden (2005). An essential and up-to-date monograph on modeling trends and cycles in economics is Mills (2003).

9.2 Univariate methods

In univariate analysis, the output gap can be identified as the stationary or transitory component in a measure of aggregate economic activity, such as GDP. Estimating the output gap thus amounts to *detrending* the series and a large literature has been devoted to this very controversial issue (see, e.g., Canova, 1998; Mills, 2003).

We shall confine our attention to the additive decomposition (after a logarithmic transformation) of real output, y_t, into potential output, μ_t, and the output gap, ψ_t: $y_t = \mu_t + \psi_t$. This basic representation is readily extended to handle a seasonal component and other calendar components such as those associated with trading days and moving festivals, which for certain output series, e.g., industrial production, play a relevant role.

In the structural approach a parametric representation for the components is needed; furthermore, the specification of the model is completed by assumptions on the covariances among the various components. The first identifying restriction that will be adopted throughout is that μ_t is fully responsible for the non-stationary behavior of the series, whereas ψ_t is a transitory component.

9.2.1 The random walk plus noise model

The random walk plus noise (RWpN) model provides the most basic trend-cycle decomposition of output, such that the trend is a random walk process with normal and independently distributed (NID) increments, and the cycle is a pure white noise (WN) component. The structural specification is the following:

$$\begin{aligned} y_t &= \mu_t + \psi_t, \qquad t = 1, \ldots, n, \qquad & \psi_t &\sim \text{NID}(0, \sigma_\psi^2), \\ \mu_t &= \mu_{t-1} + \beta + \eta_t, & \eta_t &\sim \text{NID}(0, \sigma_\eta^2). \end{aligned} \tag{9.1}$$

When the drift is absent, i.e., when $\beta = 0$, the model is also known as the *local level model* (see Harvey, 1989). We assume throughout that $\text{E}(\eta_t \psi_{t-j}) = 0$ for all t and j, so that the two components are orthogonal.

If $\sigma_\eta^2 = 0$, μ_t is a deterministic linear trend. The one-sided Lagrange multiplier test of the null hypothesis $H_0 : \sigma_\eta^2 = 0$ against the alternative $H_1 : \sigma_\eta^2 > 0$, is

known as a stationarity test and is discussed in Nyblom and Mäkeläinen (1983). The nonparametric extension to the case when ψ_t is any indeterministic stationary process is provided by Kwiatkowski, Phillips, Schmidt and Shin (KPSS) (1992) (see also Harvey, 2001, for a review and extensions).

The reduced-form representation of (9.1) is an integrated moving average model of orders (1,1), or IMA(1,1): $\Delta y_t = \beta + \xi_t + \theta\xi_{t-1}, \xi_t \sim \text{NID}(0, \sigma^2)$, where $\Delta y_t = y_t - y_{t-1}$. The difference operator can be defined in terms of the lag operator L, such that $L^d y_t = y_{t-d}$, for an integer d, as $\Delta = (1 - L)$.

The moving average (MA) parameter is subject to the restriction $-1 \leq \theta \leq 0$. Equating the autocovariance generating functions of Δy_t implied by the IMA(1,1) and by the structural representation (9.1), it is possible to establish that $\sigma_\eta^2 = (1+\theta)^2\sigma^2$ and $\sigma_\psi^2 = -\theta\sigma^2$. Hence it is required that $\theta \leq 0$, so that persistence, $(1+\theta)$, cannot be greater than unity. The variance ratio $\lambda = \sigma_\psi^2/\sigma_\eta^2$ depends uniquely on θ, as $\lambda = -\theta/(1+\theta)^2$. The ratio provides a measure of relative smoothness of the trend: if λ is large, then the trend varies little with respect to the noise component, and thus it can be regarded as "smooth."

The RWpN model has a long tradition and a well-established role in the analysis of economic time series, since it provides the model-based interpretation for the popular forecasting technique known as *exponential smoothing*, which is widely used in applied economic forecasting and fares remarkably well in forecast competitions (see Muth, 1960, and the comprehensive reviews by Gardner, 1985, 2006).

Assuming a doubly infinite sample, the one-step-ahead predictions, $\tilde{\mu}_{t+1|t}$, and the filtered and smoothed estimates of the trend component, denoted $\tilde{\mu}_{t|\infty}$, are given, respectively, by:

$$\tilde{\mu}_{t+1|t} = \tilde{\mu}_{t|t} = (1+\theta)\sum_{j=0}^{\infty}(-\theta)^j y_{t-j}, \quad \tilde{\mu}_{t|\infty} = \frac{1+\theta}{1-\theta}\sum_{j=-\infty}^{\infty}(-\theta)^{|j|}y_{t-j}.$$

Here, $\tilde{\mu}_{t+1|t}$ denotes the expectation of μ_{t+1} based on the information available at time t, whereas $\tilde{\mu}_{t|\infty}$ is the expectation based on all of the information in the doubly infinite data set. The filter $\text{w}(L) = (1+\theta)(1+\theta L)^{-1} = (1+\theta)\sum_{j=0}^{\infty}(-\theta)^j L^j$ is known as a one-sided exponentially weighted moving average (EWMA). These expressions follow from applying the Wiener–Kolmogorov prediction and signal extraction formulae (see Appendix B). In terms of the structural form parameters, $\tilde{\mu}_{t|\infty} = \frac{\sigma_\eta^2}{\sigma_\eta^2+\sigma_\psi^2|1-L|^2}y_t$, where $|1-L|^2 = (1-L)(1-L^{-1})$. The filter:

$$\text{w}_\mu(L) = \frac{\sigma_\eta^2}{\sigma_\eta^2 + \sigma_\psi^2|1-L|^2} = \frac{1+\theta}{1-\theta}\sum_{j=-\infty}^{\infty}(-\theta)^{|j|}L^j,$$

is known as a two-sided EWMA filter. In finite samples, the computations are performed by the Kalman filter and smoother (see Appendix C).

The parameter θ (or, equivalently, λ) is essential in determining the weights that are attached to the observations for signal extraction and prediction. When

$\theta = 0$, y_t is a pure random walk, and then the current observation provides the best estimate of the trend: $\tilde{\mu}_{t+1|t} = \tilde{\mu}_{t|t} = \tilde{\mu}_{t|\infty} = y_t$. When $\theta = -1$, the trend estimate, which is as smooth as possible, is a straight line passing through the observations.

The RWpN model provides a stripped to the bone separation of the transitory and permanent dynamics that depends on a single smoothness parameter, which determines the weights that are assigned to the available observations for forecasting and trend estimation. Its use as a misspecified model of economic fluctuations for out-of-sample forecasting, using multi-step (or adaptive) estimation, rather than maximum likelihood (ML) estimation, has been considered in the seminal paper by Cox (1961) and by Tiao and Xu (1993). Proietti (2005) discusses multi-step estimation of the RWpN model for the extraction of trends and cycles.

9.2.2 The local linear model and the Leser–HP filter

In the local linear trend model (LLTM) the trend μ_t is an integrated random walk:

$$\begin{array}{lllllll} y_t &=& \mu_t &+& \psi_t, & & \psi_t \sim \mathrm{NID}(0, \sigma_\psi^2), \quad t = 1, 2, \ldots, n, \\ \mu_t &=& \mu_{t-1} &+& \beta_{t-1} + \eta_t, & & \eta_t \sim \mathrm{NID}(0, \sigma_\eta^2), \\ \beta_t &=& & & \beta_{t-1} + \zeta_t, & & \zeta_t \sim \mathrm{NID}(0, \sigma_\zeta^2). \end{array} \tag{9.2}$$

It is assumed that ψ_t, η_t and ζ_t are mutually and serially uncorrelated. For $\sigma_\zeta^2 = 0$ the trend reduces to a random walk with constant drift, whereas for $\sigma_\eta^2 = 0$ the trend is an integrated random walk ($\Delta^2 \mu_t = \zeta_{t-1}$).

The above representation encompasses a deterministic linear trend, arising when both σ_η^2 and σ_ζ^2 are zero. Second, it is consistent with the notion that the real time estimate of the trend is coincident with the value of the eventual forecast function at the same time (see section 9.2.5 on the Beveridge–Nelson decomposition).

The LLTM is the model for which the Leser filter is optimal (see Leser, 1961). The latter is derived as the minimizer, with respect to $\mu_t, t = 1, \ldots, n$, of the penalized least squares (PLS) criterion:

$$PLS \;=\; \textstyle\sum_{t=1}^{n} (y_t - \mu_t)^2 + \lambda \sum_{t=3}^{n} (\Delta^2 \mu_t)^2.$$

The parameter λ governs the trade-off between fidelity and smoothness and it is referred to as the *smoothness* or *roughness penalty* parameter. The first addend of *PLS* measures the goodness-of-fit, whereas the second penalizes the departure from zero of the variance of the second differences (i.e., a measure of roughness). In matrix notation, if $\mathbf{y} = (y_1, \ldots, y_n)$, $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_n)$, and $\mathbf{D} = \{d_{ij}\}$ is the $n \times n$ matrix corresponding to a first difference filter, with $d_{ii} = 1$, $d_{i,i-1} = -1$ and zero otherwise, so that $\mathbf{D}\boldsymbol{\mu} = (\mu_2 - \mu_1, \ldots, \mu_n - \mu_{n-1})'$, we can write the criterion function as $PLS = (\mathbf{y} - \boldsymbol{\mu})'(\mathbf{y} - \boldsymbol{\mu}) + \lambda \boldsymbol{\mu}' \mathbf{D}^{2'} \mathbf{D}^2 \boldsymbol{\mu}$. Differentiating with respect to $\boldsymbol{\mu}$, the first-order conditions yield: $\tilde{\boldsymbol{\mu}} = (\mathbf{I}_n + \lambda \mathbf{D}^{2'} \mathbf{D}^2)^{-1} \mathbf{y}$. The rows of the matrix $(\mathbf{I}_n + \lambda \mathbf{D}^{2'} \mathbf{D}^2)^{-1}$ contain the filter weights for estimating the trend at a particular point in time. The solution arising for $\lambda = 1600$ is widely known in the analysis of quarterly macroeconomic time series as the Hodrick–Prescott filter (henceforth, HP; see Hodrick and Prescott, 1997); the choice of the smoothness parameter for

yearly and monthly time series is discussed in Ravn and Uhlig (2002) and Maravall and del Rio (2007).

We now show that the Leser filter is the optimal signal extraction filter for the LLTM (9.2) with $\sigma_\eta^2 = 0$ and $\lambda = \sigma_\psi^2/\sigma_\zeta^2$. In fact, apart from an additive term which does not depend on μ, *PLS* is proportional to $\ln f(\mathbf{y}, \boldsymbol{\mu}) = \ln f(\mathbf{y}|\boldsymbol{\mu}) + \ln f(\boldsymbol{\mu})$, where $f(\mathbf{y}, \boldsymbol{\mu})$, $f(\mathbf{y}|\boldsymbol{\mu})$ denote, respectively, the Gaussian joint density of the random vectors $\mathbf{y}$ and $\boldsymbol{\mu}$, and the conditional density of $\mathbf{y}$ given $\boldsymbol{\mu}$, whereas $f(\boldsymbol{\mu})$ is the joint density of $\boldsymbol{\mu}_t, t = 1, \ldots, n$. Now, $\ln f(\mathbf{y}|\boldsymbol{\mu})$ depends on $\boldsymbol{\mu}$ only via $(1/\sigma_\psi^2)\sum_{t=1}^n (y_t - \mu_t)^2$, whereas $\ln f(\boldsymbol{\mu}) = \ln f(\mu_3, \ldots, \mu_n|\mu_1, \mu_2) + \ln f(\mu_1, \mu_2)$. The first term depends on $\mu_t, t > 2$, only via $(1/\sigma_\zeta^2)\sum_{t=3}^n (\Delta^2 \mu_t)^2$. The contribution of the initial values vanishes under fixed initial conditions or diffuse initial conditions.[1] In conclusion, $\tilde{\boldsymbol{\mu}}$ maximizes, with respect to $\boldsymbol{\mu}$, the joint log-density $\ln f(\mathbf{y}, \boldsymbol{\mu})$ and thus the posterior log-density $\ln f(\boldsymbol{\mu}|\mathbf{y}) = \ln f(\mathbf{y}, \boldsymbol{\mu}) - \ln f(\mathbf{y})$. A consequence of this result is that the components can be efficiently computed using the Kalman filter and smoother (see Appendix C). The latter computes the mean of the conditional distribution $\boldsymbol{\mu}|\mathbf{y}$. As this distribution is Gaussian, the posterior mean is equal to the posterior mode. Hence, the smoother computes the mode of $f(\boldsymbol{\mu}|\mathbf{y})$, which is also the minimizer of the *PLS* criterion.

The equivalence $\lambda = \sigma_\psi^2/\sigma_\zeta^2$ makes clear that the roughness penalty measures the variability of the cyclical (noise) component relative to that of the trend disturbance, and regulates the smoothness of the long-term component. As σ_ζ^2 approaches zero, λ tends to infinity, and the limiting representation of the trend is a straight line. The Leser–HP detrended or cyclical component is the smoothed estimate of the component ψ_t in (9.2) and, although the maintained representation for the deviations from the trend is a WN component, the filter has been one of the most widely employed tools in macroeconomics to extract a measure of the business cycle. For the US GDP series (logarithms) this component is plotted in the top right-hand panel of Figure 9.4 (p. 404).

In terms of the reduced form of model (9.2), the IMA(2,2) model $\Delta^2 y_t = (1 + \theta_1 L + \theta_2 L^2)\xi_t$, $\xi_t \sim \text{NID}(0, \sigma^2)$, it can be shown that the restriction $\sigma_\eta^2 = 0$ implies $[(1 + \theta_2)\theta_2]/(1 - \theta_2)^2 = \lambda$ and $\theta_1 = -4\theta_2/(1 + \theta_2)$. Therefore, for $\lambda = 1600$, we have $\theta_1 = -1.778$ and $\theta_2 = 0.799$, so that $\theta(1) = 1 + \theta_1 + \theta_2 = 0.021$ and the MA polynomial is close to noninvertibility at the zero frequency.

The theoretical properties of the Leser–HP filter are better understood by assuming the availability of a doubly-infinite sample, $y_{t+j}, j = -\infty, \ldots, \infty$. In such a setting, the Wiener–Kolmogorov filter (see Whittle, 1983, and Appendix B) provides the minimum mean square linear estimator (MMSLE) of the trend, $\tilde{\mu}_{t|\infty} = \text{w}_\mu(L)y_t$, where:

$$\text{w}_\mu(L) = \frac{\sigma_\zeta^2}{\sigma_\zeta^2 + |1 - L|^4 \sigma_\psi^2} = \frac{1}{1 + \lambda|1 - L|^4}. \tag{9.3}$$

The frequency response function of the trend filter (see Appendix A) is:

$$\text{w}_\mu(e^{-\imath\omega}) = \frac{1}{1 + 4\lambda(1 - \cos\omega)^2}, \quad \omega \in [0, \pi];$$

notice that this is 1 at the zero frequency and decreases monotonically to zero as ω approaches π. This behavior enforces the interpretation of (9.3) as a lowpass filter, and the corresponding detrending filter, $1 - \mathrm{w}_\mu(L)$, is the highpass filter derived from it. We shall return to this issue in the next section.

9.2.3 Higher-order trends and lowpass filters

A *lowpass* filter is a filter that passes low-frequency fluctuations and reduces the amplitude of fluctuations with frequencies higher than a cut-off frequency ω_c (see, e.g., Percival and Walden, 1993). The frequency response function of an ideal lowpass filter takes the following form: for $\omega \in [0, \pi]$,

$$\mathrm{w}_{lp}(\omega) = \begin{cases} 1 & \text{if } \omega \leq \omega_c \\ 0 & \text{if } \omega_c < \omega \leq \pi. \end{cases}$$

The notion of a highpass filter is complementary, its frequency response function being $\mathrm{w}_{hp}(\omega) = 1 - \mathrm{w}_{lp}(\omega)$. The coefficients of the ideal lowpass filter are provided by the inverse Fourier transform of $\mathrm{w}_{lp}(\omega)$:

$$\mathrm{w}_{lp}(L) = \frac{\omega_c}{\pi} + \sum_{j=1}^{\infty} \frac{\sin(\omega_c j)}{\pi j}(L^j + L^{-j}).$$

A bandpass filter is a filter that passes fluctuations within a certain frequency range and attenuates those outside that range. Given lower and upper cut-off frequencies, $\omega_{1c} < \omega_{2c}$ in $(0, \pi)$, the ideal frequency response function is unity in the interval $[\omega_{1c}, \omega_{2c}]$ and zero outside. The notion of a bandpass filter is relevant to business cycle measurement: the traditional definition, ascribed to Burns and Mitchell (1946), considers all the fluctuations with a specified range of periodicities, namely those ranging from one and a half to eight years. Thus, if s is the number of observations in a year, fluctuations with periodicity between $1.5s$ and $8s$ are included. Baxter and King (1999; henceforth, BK) argue that the ideal filter for cycle measurement is a bandpass filter. Now, given the two business cycle frequencies, $\omega_{c1} = 2\pi/(8s)$ and $\omega_{c2} = 2\pi/(1.5s)$, the bandpass filter is:

$$\mathrm{w}_{bp}(L) = \frac{\omega_{c2} - \omega_{c1}}{\pi} + \sum_{j=1}^{\infty} \frac{\sin(\omega_{c2} j) - \sin(\omega_{c1} j)}{\pi j}(L^j + L^{-j}). \tag{9.4}$$

Notice that $w_{bp}(L)$ is the contrast between the two lowpass filters with cut-off frequencies ω_{c2} and ω_{c1}. The frequency response function of the ideal business cycle bandpass filter for quarterly observations ($s = 4$), which is equivalent to the gain function (see Appendix A), is plotted in Figure 9.3 (p. 403).

The ideal bandpass filter exists and is unique, but as it entails an infinite number of leads and lags, an approximation is required in practical applications. BK show that the K-terms approximation to the ideal filter (9.4), which is optimal in the sense of minimizing the integrated mean square approximation error, is obtained from (9.4) by truncating the lag distribution at a finite integer K. They propose

using a three-year window, i.e., $K = 3s$, as a valid rule of thumb for macroeconomic time series. They also constrain the weights to sum to zero, so that the resulting approximation is a detrending filter: denoting the truncated filter $\mathrm{w}_{bp,K}(L) = \mathrm{w}_0 + \sum_1^K \mathrm{w}_j(L^j + L^{-j})$, the weights of the adjusted filter will be $\mathrm{w}_j - \mathrm{w}_{bp,K}(1)/(2K+1)$. The gain of the resulting filter is displayed in Figure 9.3 (henceforth we shall refer to it as the BK filter). The ripples result from the truncation of the ideal filter and are referred to as the Gibbs phenomenon (see Percival and Walden, 1993, p. 177). BK do not entertain the problem of estimating the cycle at the extremes of the available sample; as a result the estimates for the first and last three years are unavailable. Christiano and Fitzgerald (2003) provide the optimal finite-sample approximations for the bandpass filter, including the real-time filter, using a model-based approach.

Within the class of parametric structural models, an important category of lowpass filter emerges from the application of Wiener–Kolmogorov optimal signal extraction theory to the following model:

$$\begin{array}{lcll} y_t & = & \mu_t + \psi_t, & t = 1, 2, \ldots, n, \\ \Delta^m \mu_t & = & (1+L)^r \zeta_t, \quad \zeta_t \sim \mathrm{NID}(0, \sigma_\zeta^2), & \\ \psi_t & \sim & \mathrm{NID}(0, \lambda\sigma_\zeta^2), \quad \mathrm{E}(\zeta_t, \psi_{t-j}) = 0, \forall j, & \end{array} \tag{9.5}$$

where μ_t is the signal or trend component, and ψ_t is the noise.

Assuming a doubly-infinite sample, the minimum mean square estimators of the components (see Appendix B) are, respectively, $\tilde{\mu}_t = \mathrm{w}_\mu(L) y_t$ and $\tilde{\psi}_t = y_t - \tilde{\mu}_t = [1 - \mathrm{w}_\mu(L)] y_t$, where:

$$\mathrm{w}_\mu(L) = \frac{|1+L|^{2r}}{|1+L|^{2r} + \lambda |1-L|^{2m}}. \tag{9.6}$$

The expression (9.6) defines a class of filters which depends on the order of integration of the trend (m, which regulates its flexibility), on the number of unit poles at the Nyquist frequency r, which *ceteris paribus* regulates the smoothness of $\Delta^m \mu_t$, and λ, which measures the relative variance of the noise component.

The Leser–HP filter arises for $m = 2, r = 0, \lambda = 1600$ (quarterly data). The two-sided EWMA filter arises for $m = 1, r = 0$. The filters arising for $m = r$ are Butterworth filters of the tangent version (see, e.g., Gómez, 2001). The analytical expression of the gain is:

$$\mathrm{w}_\mu(\omega) = \left\{ 1 + \left[\frac{\tan(\omega/2)}{\tan(\omega_c/2)} \right]^{2m} \right\}^{-1},$$

and depends solely on m and ω_c. As $m \to \infty$ the gain converges to the frequency response function of the ideal lowpass filter.

The previous discussion enforces the interpretation of the trend filter $\mathrm{w}_\mu(L)$ as a lowpass filter. Its cut-off frequency depends on the triple (m, r, λ). Frequency domain arguments can be advocated for designing these parameters so as to select the fluctuations that lie in a predetermined periodicity range. In particular, let us consider the Fourier transform of the trend filter (9.6), $\mathrm{w}_\mu(\omega) = \mathrm{w}_\mu(e^{-\imath\omega})$, $\omega \in [0, \pi]$,

which also expresses the gain of the filter. The latter is monotonically decreasing with λ; it takes the value 1 at the zero frequency and, if $r > 0$, it is zero at the Nyquist frequency. The trend filter will preserve to a great extent those fluctuations at frequencies for which the gain is greater than 1/2 and reduce to a given extent those for which the gain is below 1/2. This simple argument justifies the definition of a lowpass filter with cut-off frequency ω_c if the gain halves at that frequency; see Gómez (2001, sec. 1). Usually the investigator sets the cut-off frequency to a particular value, e.g., $\omega_c = 2\pi/(8s)$ and chooses the values of m and r (e.g., $m = 2, r = 0$ for the Leser–HP filter). Solving the equation $\mathrm{w}_\mu(\omega_c) = 1/2$, the parameter λ can be obtained in terms of the cut-off frequency and the orders m and r:

$$\lambda = 2^{r-m}\left[\frac{(1+\cos\,\omega_c)^r}{(1-\cos\,\omega_c)^m}\right]. \tag{9.7}$$

9.2.4 The cyclical component

In the previous section we considered some of the most popular decompositions of a time series into a trend and pure white noise component. Hence, the previous models are misspecified. In the analysis of economic time series it is more interesting to entertain a trend-cycle decomposition such that the trend is due to the accumulation of supply shocks that are permanent, whereas the cycle is ascribed to nominal or demand shocks that are propagated by a stable transmission mechanism. Clark (1987) and Harvey and Jaeger (1993), e.g., replace the irregular component by a stationary stochastic cycle, which is parameterized as an AR(2) or an ARMA(2,1) process, such that the roots of the AR polynomial are a pair of complex conjugates. The model for the cycle is a stationary process capable of reproducing widely acknowledged stylized facts, such as the presence of strong autocorrelation, determining the recurrence and alternation of phases, and the dampening of fluctuations, or zero long-run persistence.

In particular, the model adopted by Clark (1987) is:

$$\psi_t = \phi_1\psi_{t-1} + \phi_2\psi_{t-2} + \kappa_t, \quad \kappa_t \sim \mathrm{NID}(0, \sigma_\kappa^2),$$

where κ_t is independent of the trend disturbances. Harvey (1989) and Harvey and Jaeger (1993) use a different representation:

$$\begin{bmatrix} \psi_t \\ \psi_t^* \end{bmatrix} = \rho\begin{bmatrix} \cos\,\varpi & \sin\,\varpi \\ -\sin\,\varpi & \cos\,\varpi \end{bmatrix}\begin{bmatrix} \psi_{t-1} \\ \psi_{t-1}^* \end{bmatrix} + \begin{bmatrix} \kappa_t \\ \kappa_t^* \end{bmatrix}, \tag{9.8}$$

where $\kappa_t \sim \mathrm{NID}(0, \sigma_\kappa^2)$ and $\kappa_t^* \sim \mathrm{NID}(0, \sigma_\kappa^2)$ are mutually independent and independent of the trend disturbance, $\varpi \in [0, \pi]$ is the frequency of the cycle and $\rho \in [0, 1)$ is the damping factor. The reduced form of (9.8) is the ARMA(2,1) process:

$$(1 - 2\rho\cos\,\varpi L + \rho^2L^2)\psi_t = (1 - \rho\cos\,\varpi L)\kappa_t + \rho\sin\,\varpi\kappa_{t-1}^*.$$

When ρ is strictly less than one the cycle is stationary with $\mathrm{E}(\psi_t) = 0$ and $\sigma_\psi^2 = \mathrm{Var}(\psi_t) = \sigma_\kappa^2/(1-\rho^2)$; the autocorrelation at lag j is $\rho^j\cos\,\varpi j$. For $\varpi \in (0, \pi)$ the

roots of the AR polynomial are a pair of complex conjugates with modulus ρ^{-1} and phase ϖ; correspondingly, the spectral density displays a peak around ϖ.

Harvey and Trimbur (2003) further extend the model specification by proposing a general class of model-based filters for extracting trend and cycles in macroeconomic time series, showing that the design of lowpass and bandpass filters can be considered as a signal extraction problem in an unobserved components framework. In particular, they consider the decomposition $y_t = \mu_{mt} + \psi_{kt} + \epsilon_t$, where $\epsilon_t \sim \text{NID}(0, \sigma_\epsilon^2)$. The trend is specified as an mth-order stochastic trend:

$$\begin{array}{rcl} \mu_{1t} &=& \mu_{1,t-1} + \zeta_t \\ \mu_{it} &=& \mu_{i,t-1} + \mu_{i-1,t}, \quad i = 2, \ldots, m. \end{array} \tag{9.9}$$

This is the recursive definition of an $m-1$-fold integrated random walk, such that $\Delta^m \mu_{mt} = \zeta_t$. The component ψ_{kt} is a kth-order stochastic cycle, defined as:

$$\begin{bmatrix} \psi_{1t} \\ \psi_{1t}^* \end{bmatrix} = \rho \begin{bmatrix} \cos\varpi & \sin\varpi \\ -\sin\varpi & \cos\varpi \end{bmatrix} \begin{bmatrix} \psi_{1,t-1} \\ \psi_{1,t-1}^* \end{bmatrix} + \begin{bmatrix} \kappa_t \\ 0 \end{bmatrix},$$

$$\begin{bmatrix} \psi_{it} \\ \psi_{it}^* \end{bmatrix} = \rho \begin{bmatrix} \cos\varpi & \sin\varpi \\ -\sin\varpi & \cos\varpi \end{bmatrix} \begin{bmatrix} \psi_{i,t-1} \\ \psi_{i,t-1}^* \end{bmatrix} + \begin{bmatrix} \psi_{i-1,t} \\ 0 \end{bmatrix}. \tag{9.10}$$

The reduced form representation for the cycle is:

$$(1 - 2\rho\cos\varpi L + \rho^2 L^2)^k \psi_{kt} = (1 - \rho\cos\varpi L)^k \kappa_t.$$

Harvey and Trimbur show that, as m and k increase, the optimal estimators of the trend and the cycle approach the ideal lowpass and bandpass filter, respectively.

9.2.5 Models with correlated components

Morley, Nelson and Zivot (2003; henceforth, MNZ) consider the following unobserved components model for US quarterly GDP:

$$\begin{array}{rcll} y_t &=& \mu_t + \psi_t & t = 1, 2, \ldots, n, \\ \mu_t &=& \mu_{t-1} + \beta + \eta_t, & \\ \psi_t &=& \phi_1\psi_{t-1} + \phi_2\psi_{t-2} + \kappa_t, & \\ \begin{pmatrix} \eta_t \\ \kappa_t \end{pmatrix} &\sim& \text{NID}\left[\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma_\eta^2 & \sigma_{\eta\kappa} \\ \sigma_{\eta\kappa} & \sigma_\kappa^2 \end{pmatrix}\right], & \sigma_{\eta\kappa} = r\sigma_\eta\sigma_\kappa. \end{array} \tag{9.11}$$

It should be noticed that the trend and cycle disturbances are allowed to be contemporaneously correlated, with r being the correlation coefficient. The reduced form of model (9.11) is the ARIMA(2,1,2) model: $\Delta y_t = \beta + \frac{\theta(L)}{\phi(L)}\xi_t, \quad \xi_t \sim \text{NID}(0, \sigma^2)$, where $\theta(L) = 1 + \theta_1 L + \theta_2 L^2$ and $\phi(L) = 1 - \phi_1 L - \phi_2 L^2$. The structural form is exactly identified, both it and the reduced form have six parameters. The orthogonal trend-cycle decomposition considered by Clark (1987) imposes the overidentifying restriction $r = 0$.

We estimate this model for the US GDP series using the sample period 1947:1–2006:4. For comparison we also fit an unrestricted ARIMA(2,1,2) model and the restricted version imposing $r = 0$, which will be referred to henceforth as the Clark model. Estimation of the unknown parameters is carried out by frequency domain ML estimation (see Nerlove, Grether and Carvalho, 1995; Harvey, 1989, sec. 4.3, for the derivation of the likelihood function and a discussion on the nature of the approximation involved). Given the availability of the differenced observations $\Delta y_t, t = 1, 2, \ldots, n$, and denoting by $\omega_j = 2\pi j/n$, $j = 0, 1, \ldots, (n-1)$, the Fourier frequencies, the Whittle likelihood is defined as follows:

$$\text{loglik} = -\frac{n}{2}\ln 2\pi - \frac{1}{2}\sum_{j=0}^{n-1}\left[\log f(\omega_j) + \frac{I(\omega_j)}{f(\omega_j)}\right], \tag{9.12}$$

where $I(\omega_j)$ is the sample spectrum:

$$I(\omega_j) = \frac{1}{2\pi}\left[c_0 + 2\sum_{k=1}^{n-1} c_k \cos(\omega_j k)\right],$$

c_k is the sample autocovariance of Δy_t at lag k, and $f(\omega_j)$ is the parametric spectrum of the implied stationary representation of the MNZ model, $\Delta y_t = \beta + \eta_t + \Delta\psi_t, t = 1, \ldots, n$, evaluated at the Fourier frequency ω_j. In particular:

$$f(\omega) = f_{\Delta\mu}(\omega) + f_{\Delta\psi}(\omega) + f_{\Delta\mu,\Delta\psi}(\omega),$$

with:

$$f_{\Delta\mu}(\omega) = \frac{\sigma_\eta^2}{2\pi}, \quad f_{\Delta\psi}(\omega) = \frac{1}{2\pi}\frac{2(1-\cos\omega)\sigma_\kappa^2}{\phi(e^{-\imath\omega})\phi(e^{\imath\omega})},$$

$$f_{\Delta\mu,\Delta\psi}(\omega) = \frac{(1-e^{-\imath\omega})\phi(e^{\imath\omega}) + (1-e^{\imath\omega})\phi(e^{-\imath\omega})}{2\pi\phi(e^{-\imath\omega})\phi(e^{\imath\omega})} r\sigma_\eta\sigma_\kappa,$$

$e^{-\imath\omega} = \cos\omega - \imath\sin\omega$, where $\imath$ is the imaginary unit, is the complex exponential, and $\phi(e^{-\imath\omega}) = 1 - \phi_1 e^{-\imath\omega} - \phi_2 e^{-2\imath\omega}$. The last term is the cross-spectrum of $(\Delta\psi_t, \Delta\mu_t)$ and, of course, it vanishes if $r = 0$. For the Clark model the parametric spectrum is given by the above expression with $f_{\Delta\mu,\Delta\psi}(\omega) = 0$, whereas for the unrestricted ARIMA(2,1,2) it is given by $f(\omega) = \sigma^2\theta(e^{-\imath\omega})\theta(e^{\imath\omega})[\phi(e^{-\imath\omega})\phi(e^{\imath\omega})]^{-1}$.

Figure 9.1 displays the quarterly growth rates, Δy_t, of US GDP in the first panel. The next panel plots the profile likelihood for the correlation parameter against the value of r in $[-1,1]$ and shows the presence of two modes, the first around $-.9$ and the second around zero. The parameter estimates, along with their estimated standard errors, and the value of the maximized likelihood, are reported in Table 9.1.[2] It should be noticed that the unrestricted ARIMA(2,1,2) is exactly coincident with the reduced form of the MNZ model, as the two models yield the same likelihood and the AR and MA parameters are the mapping of the structural parameters. Second,

Table 9.1 Frequency domain ML estimation results for quarterly US real GDP, 1947:1–2006:4

	ARIMA	*MNZ*	*Clark*
ϕ_1	1.34 (0.07)	1.34 (0.07)	1.49 (0.05)
ϕ_2	−0.76 (0.16)	−0.76 (0.16)	−0.56 (0.11)
θ_1	−1.08 (0.11)		
θ_2	0.59 (0.20)		
σ^2	0.8224 (0.08)		
r		−0.93 (0.28)	0(r)
σ^2_η		1.2626 (0.08)	0.3478 (0.15)
σ^2_κ		0.3556 (0.33)	0.4120 (0.16)
loglik	−315.76	−315.76	−317.14

the estimated correlation coefficient is high and negative (−0.93) and the likelihood ratio test of the hypothesis $r = 0$ has a p-value equal to 0.097. MNZ interpret the negative disturbance correlation as strengthening the case for the importance of real shocks in the macroeconomy: real shocks tend to shift the long run path of output, so short-term fluctuations will largely reflect adjustments toward a shifting trend if real shocks play a dominant role.

The bottom left panel of Figure 9.1 displays the sample spectrum $I(\omega_j)$ of Δy_t along with the estimated parametric spectral densities for the MNZ model (which is, of course, coincident with that of the ARIMA(2,1,2) model) and the Clark restricted model ($r = 0$). For the ARIMA(2,1,2) and the MNZ models the roots of the AR polynomial are a pair of complex conjugates that imply a spectral peak for Δy_t at the frequency 0.68, corresponding to a period of nine quarters. As a matter of fact, a dominant feature of Δy_t is the presence of a cyclical component with a period of roughly two years. On the other hand, the spectral density implied by the Clark model peaks at the frequency 0.09, corresponding to a period of 68 quarters (i.e., a medium-run cycle).

A closer inspection of the sample spectrum reveals the presence of two consecutive periodogram ordinates, corresponding to a cycle of roughly two years, that are highly influential on the estimation results (they are circled in Figure 9.1). It is indeed remarkable that when these are not used in the estimation, the correlation coefficient turns positive ($\hat{r} = 0.35$). The last panel of the figure presents the leave-two-out cross-validation estimates of the correlation coefficient, which are obtained by maximizing Whittle's likelihood after deleting two consecutive periodogram ordinates at the frequencies ω_j and ω_{j+1}. This is a special case of weighted likelihood estimation, where each summand in (9.12) receives a weight equal to 1 if the frequency ω_j is retained and 0 if it is deleted.

The real-time and the smoothed estimates of the cyclical component arising from the MNZ model, $\tilde{\psi}_{t|t} = \mathrm{E}(\psi_t|Y_t)$ and $\tilde{\psi}_{t|n} = \mathrm{E}(\psi_t|Y_n)$, respectively, are reported in Figure 9.2, along with the 95% interval estimates; here Y_t denotes the information available up to and including time t. The bottom panels display the weights $\mathrm{w}_{\psi,j}$

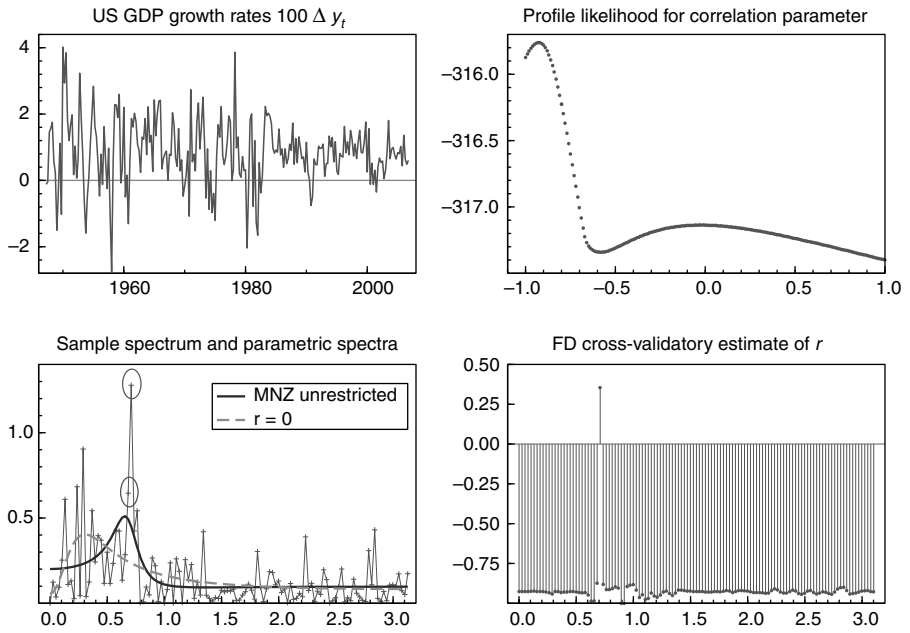

Figure 9.1 Quarterly US real growth, 1947:2–2006:4. Sample spectrum and parametric spectral fit of trend-cycle model with correlated components

of the signal extraction filters $\sum_j w_{\psi,j} L^j y_t$ that yield the cycle estimates in the two cases.

The real-time estimates support the view that most of the variation in GDP is permanent, i.e., it should be ascribed to changes in the trend component, whereas little variance is attributed to the transitory component. In fact, the amplitude of $\tilde{\psi}_{t|t}$ is small and the interval estimates of ψ_t in real time are never significantly different from zero. When we analyze the smoothed estimates the picture changes quite radically: the cycle estimates are much more variable and there is a dramatic reduction in the estimation error variance, so that the contribution of the transitory component to the variation in GDP is no longer negligible. The real-time estimates provide a gross underestimation of the cyclical component and are heavily revised as the future missing observations become available. As a matter of fact, the final estimates depend heavily on future observations, as can be seen from the pattern of the weights in the last panel of Figure 9.2. That this behavior is typical of the MNZ model when $\hat{r}$ is high and negative is documented in Proietti (2006a).

The real-time estimates of the trend and cyclical components are coincident with the Beveridge and Nelson (1981; henceforth, BN) components defined for the ARIMA(2,1,2) reduced form. The BN decomposition defines the trend component at time t as the value of the eventual forecast function at that time, or, equivalently, the value that the series would take if it were on its long-run path (see also Brewer, 1979). For an ARIMA$(p, 1, q)$ process, this argument defines the

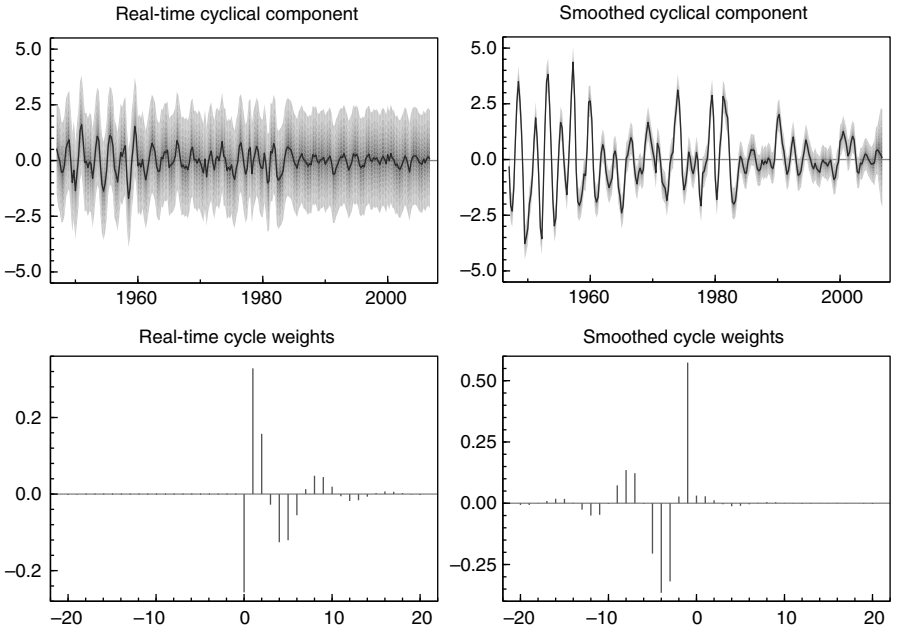

Figure 9.2 Trend-cycle decomposition with correlated disturbances. Real-time and smoothed estimates of the cyclical components

trend as a random walk driven by the innovations $\xi_t = y_t - \mathrm{E}(y_t|Y_{t-1})$. Writing the ARIMA representation for y_t as $\Delta y_t = \beta + \psi(L)\xi_t$, $\psi(L) = \theta(L)/\phi(L)$, where $\phi(L)$ is a stationary AR polynomial of order p and $\theta(L)$ an invertible MA polynomial of order q, the BN decomposition can be written as: $y_t = m_t + c_t, t = 1, \ldots, n$, where m_t is the BN trend, and c_t is the cyclical component.

The trend is defined as $\lim_{l\to\infty}[\tilde{y}_{t+l|t} - l\beta]$, with $\tilde{y}_{t+l|t} = \mathrm{E}(y_{t+l}|Y_t)$. Writing $y_{t+l} = y_{t+l-1} + \beta + \psi(L)\xi_t$, taking the conditional expectation and rearranging, it is easily shown to give $m_t = m_{t-1} + \beta + \psi(1)\xi_t$, where $\psi(1) = \theta(1)/\phi(1)$ is the persistence parameter, as it measures the fraction of the innovation at time t that is retained in the trend. In terms of the observations, $m_t = \mathrm{w}_m(L)y_t$, where $\mathrm{w}_m(L)$ is the one-sided filter:

$$w_m(L) = \frac{\psi(1)}{\psi(L)} = \frac{\theta(1)}{\phi(1)}\frac{\phi(L)}{\theta(L)}.$$

The sum of the weights is one, i.e., $w_m(1) = 1$.

The *transitory component* is defined residually as $c_t = y_t - m_t = \psi^*(L)\xi_t$, where $\Delta\psi^*(L) = \psi(L) - \psi(1)$. Alternative representations in terms of the observations y_t and of the innovations ξ_t are, respectively:

$$c_t = \frac{\phi(1)\theta(L) - \theta(1)\phi(L)}{\phi(1)\theta(L)}y_t, \qquad c_t = \frac{\phi(1)\theta(L) - \theta(1)\phi(L)}{\phi(1)\phi(L)\Delta}\xi_t. \tag{9.13}$$

The first expression shows that the weights for the extraction of the cycle sum to zero. Since $\phi(1)\theta(L) - \theta(1)\phi(L)$ must have a unit root, we can write $\phi(1)\theta(L) - \theta(1)\phi(L) = \Delta\vartheta(L)$, and substituting this into (9.13), the ARMA representation for this component can be established as $\phi(L)c_t = \vartheta(L)[\phi(1)]^{-1}\xi_t$. As the order of $\vartheta(L)$ is $\max(p,q) - 1$, the cyclical component has a stationary ARMA$(p, \max(p,q) - 1)$ representation. For the ARIMA(2,1,2) model fitted to US GDP, the cycle has the ARMA(2,1) representation:

$$\phi(L)c_t = (1 + \vartheta L)\left[1 - \frac{\theta(1)}{\phi(1)}\right]\xi_t, \quad \vartheta = -\frac{\phi_2\theta(1) + \theta_2\phi(1)}{\phi(1) - \theta(1)}. \tag{9.14}$$

It is apparent that the two components are driven by the innovations, ξ_t; the fraction $\theta(1)/\phi(1)$, known as *persistence*, is integrated in the trend, and its complement to 1 drives the cycle. The sign of the correlation between the trend and the cycle disturbances is provided by the sign of $\phi(1) - \theta(1)$; when persistence is less (greater) than one then the trend and cycle disturbances are positively (negatively) and perfectly correlated.

9.2.6 Model-based bandpass filters

As we said before, macroeconomic time series such as GDP do not usually admit the decomposition $y_t = \mu_t + \psi_t$, with ψ_t being a purely irregular component; nevertheless, applications of the class of filters (9.6) is widespread, as the popularity of the Hodrick–Prescott filter testifies. However, when the available series y_t cannot be modeled as (9.2), it is not immediately clear how the components should be defined and how inferences about them should be made. In particular, the Kalman filter and the associated smoothing algorithms no longer provide the minimum mean square estimators of the components nor their mean square error. The discussion of model-based bandpass filtering in a more general setting will be the theme of this section.

The trend-cycle decompositions dealt with in the two previous sections are models of economic fluctuations, such that the components are driven by random disturbances which are propagated according to a transmission mechanism. In this section we start from a reduced form model (as in the case of the BN decomposition) and define parametric trend-cycle decompositions that are less loaded with structural interpretation, since they just represent the lowpass and highpass components in the series. The aim is to motivate and extend the use of signal extraction filters of the class (9.6) to a more general and realistic setting than (9.5). For this approach to the definition of bandpass filters see Gómez (2001) and Kaiser and Maravall (2005). The following treatment is based on Proietti (2004).

Let y_t denote a univariate time series with ARIMA(p,d,q) representation, which we write as:

$$\phi(L)(\Delta^d y_t - \beta) = \theta(L)\xi_t, \quad \xi_t \sim \text{NID}(0, \sigma^2),$$

where β is a constant, $\phi(L) = 1 - \phi_1 L - \cdots - \phi_p L^p$ is the AR polynomial with stationary roots, and $\theta(L) = 1 + \theta_1 L + \cdots + \theta_q L^q$ is invertible. We are going to exploit the fundamental idea that we can uniquely decompose the WN disturbance ξ_t into

two orthogonal stationary processes as follows:

$$\xi_t = \frac{(1+L)^r \zeta_t + (1-L)^m \kappa_t}{\varphi(L)}, \tag{9.15}$$

where ζ_t and κ_t are two mutually and serially independent Gaussian disturbances, $\zeta_t \sim \text{NID}(0, \sigma^2)$, $\kappa_t \sim \text{NID}(0, \lambda\sigma^2)$, and:

$$|\varphi(L)|^2 = \varphi(L)\varphi(L^{-1}) = |1+L|^{2r} + \lambda|1-L|^{2m}. \tag{9.16}$$

We assume that λ is known. Equation (9.16) is the spectral factorization of the lag polynomial on the right-hand side of (9.15); the existence of the polynomial $\varphi(L) = \varphi_0 + \varphi_1 L + \cdots + \varphi_{q^*} L^{q^*}$, of degree $q^* = \max(m, r)$, is guaranteed by the fact that the Fourier transform of the right-hand side is never zero over the entire frequency range (see Sayed and Kailath, 2001, for details).

According to (9.15), for given values of λ, m and r, the innovation ξ_t is decomposed into two ARMA(2,2) processes, characterized by the same AR polynomial, but by different MA components. The first component will drive the lowpass component of y_t and its spectral density is proportional to $\sigma^2 \text{w}_\mu(\omega)$, where $\text{w}_\mu(\omega)$ is the gain of the filter (9.6). If $r > 0$ the MA representation is noninvertible at the π frequency. Notice that, as m and r increase, the transition from the pass band to the stop band is sharper.

Substituting (9.15)–(9.16) into the ARIMA representation, the series can be decomposed into two orthogonal components:

$$\begin{aligned} y_t &= \mu_t + \psi_t, \\ \phi(L)\varphi(L)(\Delta^d \mu_t - \beta) &= (1+L)^r \theta(L)\zeta_t, \quad \zeta_t \sim \text{NID}(0, \sigma^2) \\ \phi(L)\varphi(L)\psi_t &= \Delta^{m-d}\theta(L)\kappa_t, \quad \kappa_t \sim \text{NID}(0, \lambda\sigma^2). \end{aligned} \tag{9.17}$$

The trend or lowpass component has the same order of integration as the series (regardless of m), whereas the cycle or highpass component is stationary provided that $m \geq d$, which will be assumed throughout.

Given the availability of a doubly infinite sample, the Wiener–Kolmogorov estimators of the components are $\tilde{\mu}_t = \text{w}_\mu(L) y_t$ and $\tilde{\psi}_t = [1 - \text{w}_\mu(L)] y_t$, where the impulse response function of the optimal filters is given by (9.6). Hence, the signal extraction filter for the central data points will continue to be represented by (9.6), regardless of the properties of y_t, but this is the only feature that is invariant to the nature of the time series and its ARIMA representation. The mean square error of the smoothed components, as a matter of fact, depends on the ARIMA model for y_t. In finite samples, the estimators and their mean square errors will be provided by the Kalman filter and smoother associated with the model (9.17), and thus will depend on the ARIMA model for y_t.

Bandpass filters can also be constructed from the principle of decomposing the lowpass component in (9.17). Let us consider fixed values of m and r and two cut-off frequencies, ω_{c1} and $\omega_{c2} > \omega_{c1}$, with corresponding values of the smoothness

parameter λ_1 and λ_2, determined according to (9.7). Obviously $\lambda_1 > \lambda_2$. The trend-cycle decomposition corresponding to the triple m, r, λ_2 (or, equivalently, m, r, ω_{c2}), is as in (9.17):

$$\begin{aligned} y_t &= \mu_{2t} + \epsilon_t, \\ \Delta^d \mu_{2t} &= \beta + \frac{(1+L)^r}{\varphi_2(L)} \frac{\theta(L)}{\phi(L)} \zeta_{2t}, \quad \zeta_{2t} \sim \text{NID}(0, \sigma^2) \\ \epsilon_t &= \frac{(1-L)^m}{\varphi_2(L)} \frac{\theta(L)}{\Delta^d \phi(L)} \kappa_{2t}, \quad \kappa_{2t} \sim \text{NID}(0, \lambda_2 \sigma^2), \end{aligned} \tag{9.18}$$

with $|\varphi_2(L)|^2 = |1+L|^{2r} + \lambda_2 |1-L|^{2m}$.

We can similarly define the trend-cycle decomposition corresponding to the triple m, r, λ_1 (or, equivalently, m, r, ω_{c1}), $y_t = \mu_{1t} + \psi_t$. As $\lambda_1 > \lambda_2$ this decomposition features a lower cut-off frequency, ω_{c1}, thereby yielding a smoother trend. The components μ_{1t} and ψ_t are defined as in (9.18), with $\varphi_1(L)$, $\zeta_{1t} \sim \text{NID}(0, \sigma^2)$ and $\kappa_{1t} \sim \text{NID}(0, \lambda_1 \sigma^2)$ replacing, respectively, $\varphi_2(L)$, ζ_{2t} and κ_{2t}. The polynomial $\varphi_1(L)$ is such that $|\varphi_1(L)|^2 = |1+L|^{2r} + \lambda_1 |1-L|^{2m}$.

The lowpass component, μ_{2t}, can, in turn, be decomposed using the orthogonal decomposition of the disturbance ζ_{2t}:

$$\zeta_{2t} = \frac{\varphi_2(L)}{\varphi_1(L)} \zeta_{1t} + \frac{(1-L)^m}{\varphi_1(L)} \kappa_{1t}, \tag{9.19}$$

with:

$$\zeta_{1t} \sim \text{NID}(0, \sigma^2), \quad \kappa_{1t} \sim \text{NID}\left(0, (\lambda_1 - \lambda_2)\sigma^2\right), \quad \text{E}(\zeta_{1j} \kappa_{1t}) = 0, \quad \forall j, t.$$

Under this setting, the spectrum of both sides of (9.19) is constant and equal to $\sigma^2/2\pi$.

Substituting (9.19) into (9.18), and writing $\mu_{2t} = \mu_{1t} + \psi_t$, enables y_t to be decomposed into three components, representing the lowpass (μ_{1t}), bandpass (ψ_t) and highpass (ϵ_t) components, respectively.

$$\begin{aligned} y_t &= \mu_{1t} + \psi_t + \epsilon_t, \\ \Delta^d \mu_{1t} &= c + \tfrac{(1+L)^r}{\varphi_1(L)} \tfrac{\theta(L)}{\phi(L)} \zeta_{1t}, \qquad \zeta_{1t} \sim \text{NID}(0, \sigma^2) \\ \psi_t &= \tfrac{(1+L)^n (1-L)^m}{\varphi_1(L)\varphi_2(L)} \tfrac{\theta(L)}{\Delta^d \phi(L)} \kappa_{1t}, \quad \kappa_{1t} \sim \text{NID}\left(0, (\lambda_1 - \lambda_2)\sigma^2\right), \end{aligned} \tag{9.20}$$

and ϵ_t, given in (9.18), is the highpass component of the decomposition (9.20). The model can be cast in state-space form and the Kalman filter and smoother (see Appendix C) will provide the optimal estimates of the components and their standard errors.

Figure 9.3 shows the gain of an ideal bandpass filter and the BK filter. The dashed line is the gain of the model-based bandpass filter which is optimal for ψ_t in (9.20)

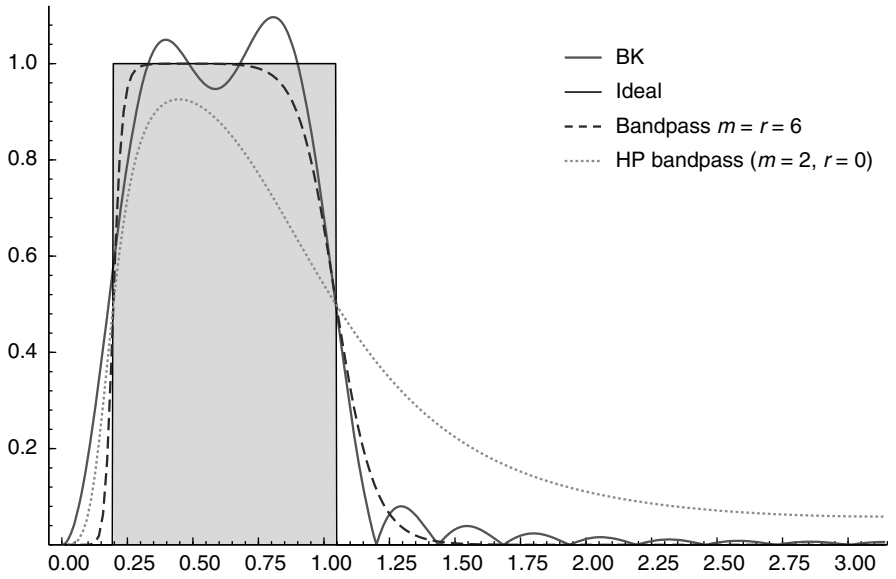

Figure 9.3 Gain function of the ideal business cycle bandpass filter, the BK filter and two model-based filters

using $m = r = 6$ and the two cut-off frequencies $\omega_{c1} = 2\pi/32$ (corresponding to a period of eight years for quarterly data) and $\omega_{c2} = 2\pi/6$ (one and a half years); such large values of the parameters yield a gain which is close to the ideal boxcar function. The HP bandpass curve is the gain of the Wiener–Kolmogorov filter for extracting the component ψ_t in (9.20) with $m = 2, r = 0$, and ω_{c1}, ω_{c2} given above. In this case the leakage is larger but, as shown in Proietti (2004), taking large values of m and r is detrimental to the reliability of the end of sample estimates.

9.2.7 Applications of model-based filtering: bandpass cycles and the estimation of recession probabilities

We present two applications of the model-based filtering approach outlined in the previous section. Our first illustration deals with the estimation and the assessment of the reliability of the deviation cycle in US GDP. The cycle is defined as the highpass component extracting the fluctuations in the level of log GDP that have a periodicity smaller than ten years (40 quarters). To evaluate model uncertainty, we fit three models to the logarithm of GDP, namely a simple random walk, or ARIMA(0,1,0) model ($\hat{\sigma}^2 = 0.8570$), an ARIMA(1,1,0) model (the estimated first-order autoregressive coefficient is $\hat{\phi} = 0.33$ and $\hat{\sigma}^2 = 0.8652$), and finally, we consider the ARIMA(2,1,2) model fitted in section 9.2.5, whose parameter estimates were reported in Table 9.1.

The estimates of the lowpass component corresponding to the three models obtained by setting $m = 2, r = 0$ (and thus $\lambda = 1600$ and $\omega_c = 0.158279$) are displayed in the top right-hand panel of Figure 9.4, along with the Leser–HP cycle.

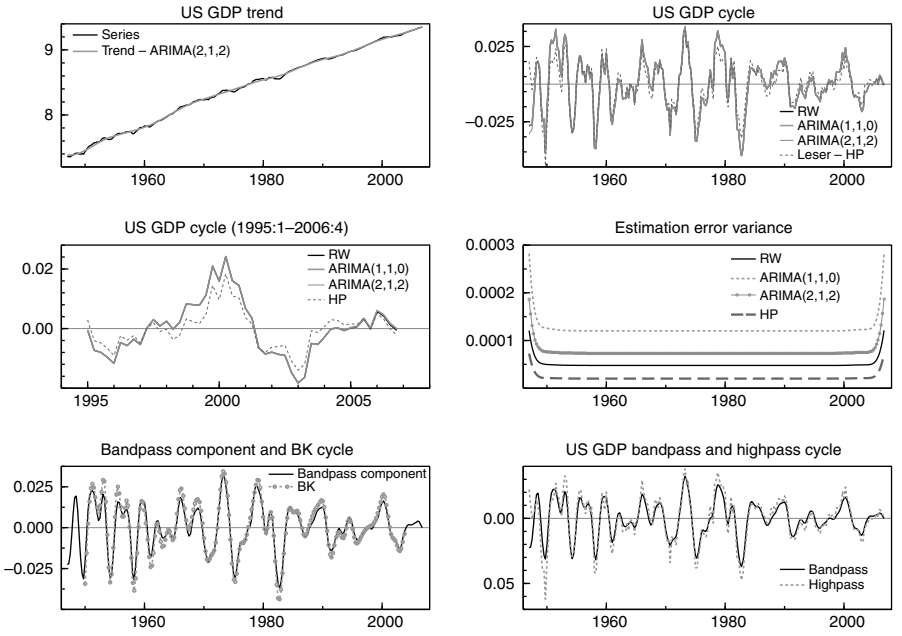

Figure 9.4 Model-based filtering. Estimates of the lowpass component (using the ARIMA(2,1,2) model) and of the highpass and bandpass components in US GDP, and their comparison with the Leser–HP and BK cycles

The estimates for the three models are obtained as the conditional mean of ψ_t given the observations by applying the Kalman filter and smoother to the representation (9.17); the algorithm also provides their estimation error variance. It must be stressed that the Leser–HP filter is optimal for a restricted IMA(2,2) process and thus it does not yield the minimum mean square estimator of the cycle, nor its standard error. In general, also looking at the middle panel, which displays the estimated cycles for the last 12 years, the model-based estimates are almost indistinguishable, and are quite close to the Leser–HP cycle estimates in the middle of the sample. Large differences with the latter arise at the beginning, where the lowpass component had greater amplitude, and at the end of the sample period.

The particular model that is chosen matters little as far as the point estimates of ψ_t are concerned. Nevertheless, it is relevant for the assessment of the accuracy of the estimates, as can be argued from the right middle panel of the figure, which shows the estimation error variance, $\mathrm{Var}(\psi_t|Y_n)$, for the three models of US GDP. It is also evident that the standard errors obtained for the Leser–HP filter would underestimate the uncertainty of the estimates.

We conclude this first illustration by estimating the deviation cycle as a bandpass component, assuming that the true model is the ARIMA(2,1,2) and using the cut-off frequencies $\omega_{c1} = 2\pi/32$, $\omega_{c2} = 2\pi/6$, and the values $m = 2, r = 0$; as a consequence, the component ψ_t in (9.20) selects all the fluctuations in a range

of periodicity that goes from one and a half years (6 quarters) to eight years (32 quarters). The gain of the filter is displayed in Figure 9.3. The estimates of ψ_t are compared to the BK cycle in the bottom left panel of Figure 9.4 and to the corresponding highpass estimates ($\psi_t + \epsilon_t$). With respect to the BK cycle, the estimates are available also in real time.

The conclusion is that model-based filtering improves the quality of the estimated lowpass component, providing estimates at the boundary of the sample period that are automatically adapted to the series under investigation, and enables the investigator to assess the reliability of the estimates (conditional on a particular reduced form).

The second application deals with assessing the uncertainty in estimating the business cycle chronology. According to the classical definition, the business cycle is a recurrent sequence of expansions and contractions in the aggregate level of economic activity (see Burns and Mitchell, 1946, p. 3). Dating the business cycle amounts to establishing a set of reference dates that mark the phases or states of the economy. Usually two phases, recessions and expansions, are considered, that are delimited by peaks and troughs in economic activity. Dating is carried out by an algorithm, such as that due to Bry and Boschan (1971), or that proposed by Artis, Marcellino and Proietti (2004), which aims at estimating the location of turning points, enforcing the alternation of peaks and troughs and minimum duration ties for the phases and the full cycle. Downturns and upturns have to be persistent to qualify as cycle phases; thus, they need to fulfill minimum duration constraints, such as at least two quarters for each phase; moreover, to separate it from seasonality, a complete sequence, recession-expansion or expansion-recession, i.e., a full cycle, has to last longer than one year. Depth restrictions, motivated by the fact that only major fluctuations qualify for the phases, should also be enforced.

An integral part of the dating algorithm is prefiltering, which is necessary in order to isolate fluctuations in the series with period greater than the minimum cycle duration. For instance, in the quarterly case we need to abstract from all the fluctuations with periodicity less than five quarters, i.e., from high-frequency fluctuations that do not satisfy the minimum cycle duration. In lieu of the *ad hoc* and old-fashioned moving averages adopted by Bry and Boschan, one can use model-based lowpass signal extraction filters.

The advantages are twofold: first, it is possible to select the cut-off frequency so as to match the minimum cycle duration; e.g., in our case $\omega_c = 2\pi/5$. Second, the uncertainty in dating arising from prefiltering can be assessed by Monte Carlo simulation, by means of an algorithm known as the simulation smoother (see de Jong and Shephard, 1995; Durbin and Koopman, 2002; and Appendix C, section 9.7.4). This repeatedly draws simulated samples from the posterior distribution of the lowpass component with a cut-off frequency corresponding to five quarters, $\tilde{\mu}_t^{(i)} \sim \mu_t | Y_n$, so that by repeating the draws a sufficient number of times we can get Monte Carlo estimates of different aspects of the marginal and joint distribution of the lowpass component, intended here as the level of output devoid of all fluctuations with a periodicity smaller that five quarters.

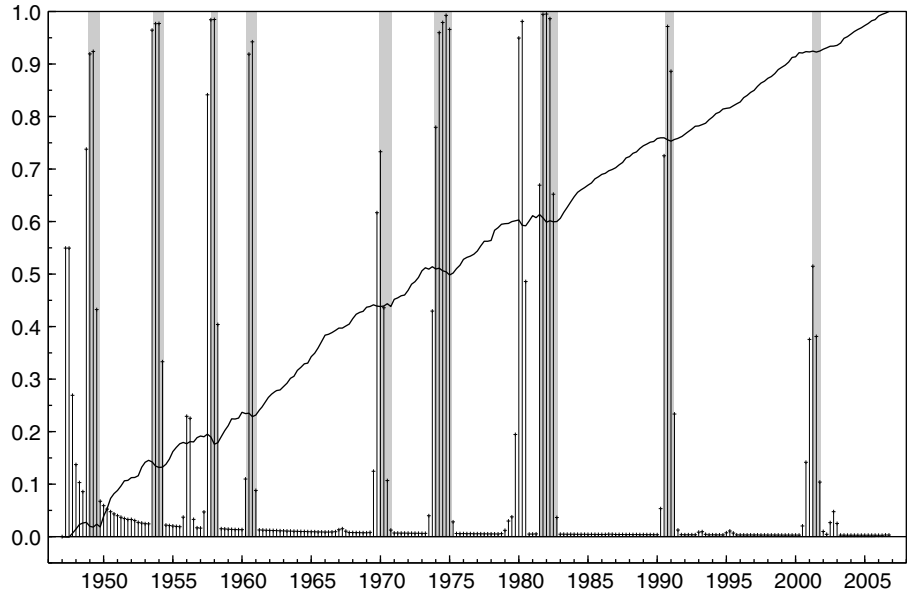

Figure 9.5 Relative number of times each quarter is classified as a recessionary period, using 5,000 simulated samples. The shaded areas represent NBER-classified recessions

Figure 9.5 plots the recession frequencies, i.e., the relative number of times each quarter was classified as a recessionary period. For this purpose 5,000 draws from the conditional distribution of $\boldsymbol{\mu}|\mathbf{y}$ were extracted; each quarter was classified as recession or expansion according to the Artis, Marcellino and Proietti (2004) Markov chain dating algorithm. There is a close agreement with the NBER chronology, which is not based on GDP alone, and the last recession, which started in March 2001 and ended in October 2001, was really mild in terms of GDP; in fact, the recession frequency is only in one quarter greater than 0.5.

9.2.8 *Ad hoc* filtering and the Slutsky–Yule effect

A filter is *ad hoc* when it is invariant to the properties of the time series under investigation. An instance is provided by the Leser–HP filter with a fixed smoothing parameter, and another example is the BK filter. The potential danger associated with an *ad hoc* cycle extraction filter is that the filtered series displays cyclical features that are absent from the original series. The risk of extracting spurious cycles is known in the time series literature as the Slutsky–Yule effect.

The distortionary effects of the Leser–HP filter have been discussed by King and Rebelo (1993), Harvey and Jaeger (1993), and Cogley and Nason (1995). These authors document that, when the series to which the filter is applied is difference stationary (e.g., a random walk, or an integrated random walk), the detrended series can display spurious cyclical behavior. As a matter of fact, the transfer function will display a distinctive peak at business cycle frequencies, which is only due to the

leakage from the non-stationary component. Moreover, the filter seriously distorts the evidence for the comovements among detrended series.

The issue of spuriousness is problematic, at least, if not tautological. The main difficulty stems from the fact that it ties in with a more fundamental question concerning what is indeed the cycle in economic time series. If we adhere to the bandpass paradigm of viewing the cycle as consisting of those fluctuations within a give range of periodicity, than the case for spuriousness is much less compelling.

Another source of concern among practitioners, especially for the conduct of monetary policy, relates to the end-of-sample behavior of the Leser–HP filter: the real-time estimates would be subject to "end-of-sample bias," since they result from the application of a one-sided filter and will suffer from both phase shifts and amplitude distortions. One has to separate two issues: as we hinted before, the IMA(2,2), for which the Leser–HP filter is optimal, is usually misspecified for macroeconomic time series. As a result, the cycle estimates have no optimality properties. Model-based bandpass filtering is aimed at overcoming this limitation. Having said that, it is a fact of life that, for a correctly specified model, the optimal real time signal extraction filter will be one-sided and thus will produce phase shifts and amplitude distortions.

9.3 Multivariate models

Information on the output gap is contained in macroeconomic variables other than aggregate output, either because those variables provide alternative measures of production, or because they are functionally related to the output gap. In this section we start from the consideration of a bivariate model that, along with an output decomposition, includes an inflation equation. We then extend the model to include other variables, such as the unemployment rate and industrial production, and consider the estimation of a monthly model using quarterly observations on real GDP.

9.3.1 Bivariate models of real output and inflation

Price inflation carries relevant information for the output gap. The definition of the latter as an indicator of inflationary pressure and, correspondingly, of potential output as the level of output consistent with stable inflation, makes clear that a rigorous measurement can be made within a bivariate model of output and inflation, embodying a Phillips curve relationship. The Phillips curve establishes a relation between the nominal price, or wage, inflation rate, Δp_t, where, e.g., p_t is the logarithm of the consumer price index (CPI), and an indicator of excess demand, typically the output gap (ψ_t).

A general specification is the following:

$$\delta(L)\Delta p_t = c + \theta_\psi(L)\psi_t + \boldsymbol{\gamma}(L)'\mathbf{x}_t + \xi_{pt}, \tag{9.21}$$

where c is a constant, $\mathbf{x}_t$ denotes a set of exogenous supply shocks, such as changes in energy prices and terms of trade, and ξ_{pt} is WN. Often the restriction is imposed

that the sum of the AR coefficients on lagged inflation is unity, $\delta(L) = \Delta\delta^*(L)$, where $\delta^*(L)$ is a stationary AR polynomial; the gap enters the equation with more than one lag to capture the change in demand, since we can rewrite $\theta_\psi(L) = \theta_\psi(1) + \Delta\theta^*_\psi(L)$. This is known as Gordon's "triangle" model of inflation (see Gordon, 1997), since it features the three main driving forces: inertia (or inflation persistence, via $\delta(L)$), endogenous demand shocks (via ψ_t), and exogenous supply shocks (via $\mathbf{x}_t$). If $\delta(L)$ has a unit root and $\theta_\psi(1) \neq 0$ the output gap has permanent effects on the inflation rate. If, instead, $\theta_\psi(1) = 0$, then the output gap is neutral in the long run and the inflation rate shares a common cycle in the levels with output. Harvey, Trimbur and Van Dijk (2007) consider the Bayesian estimation of a bivariate model of output and inflation, where the cycle in inflation is driven by the output gap plus an idiosyncratic cycle.

Kuttner (1994) estimated potential output and the output gap for the US using a bivariate model of real GDP and CPI inflation. The output equation was specified as in the Clark (1987) model, i.e., $y_t = \mu_t + \psi_t$, such that potential output is a random walk with drift and the output gap is an AR(2) process driven by orthogonal disturbances. The equation for the inflation rate is a variant of Gordon's triangle model:

$$\Delta p_t = c + \gamma\Delta y_{t-1} + \theta_\psi\psi_{t-1} + \nu(L)\xi_{pt},$$

according to which the inflation rate is linearly related to the lagged output gap and to lagged GDP growth; inflation persistence is captured by the MA feature, $\nu(L)\xi_{pt}$, where the disturbance ξ_{pt} is allowed to be correlated with the output gap disturbance, κ_t. The inclusion of lagged real growth is not formally justified by Kuttner, and the correlation between ξ_{pt} and κ_t makes the dynamic relationship between the output gap and inflation more elaborate than it appears at first sight (e.g., inflation depends on the contemporaneous value of the gap). Moreover, permanent shocks are allowed to drive inflation via the term $\Delta y_{t-1} = \beta + \eta_{t-1} + \Delta\psi_{t-1}$, so that it cannot be maintained that μ_t is the noninflationary level of output. Planas, Rossi and Fiorentini (2007) consider the Bayesian estimation of Kuttner's bivariate model, with the only variant being that the MA feature is replaced by an autoregressive feature: $\delta(L)\Delta p_t = c + \gamma\Delta y_{t-1} + \theta_\psi\psi_{t-1} + \xi_{pt}$.

Gerlach and Smets (1999) again use a bivariate model of output and inflation, but the output gap generating equation takes the form of an aggregate demand equation featuring the lagged real interest rate as an explanatory variable. The inflation equation is specified as in (9.21) with $\delta(L) = \Delta$.

The Gordon triangle model may be interpreted as a reduced form of a structural model of inflation that embodies expectations; the presence of lagged inflation in the specification reflects backward looking inflation expectations. In the New Keynesian approach the Phillips curve is forward-looking, as inflation depends on expected future inflation. Doménech and Gómez (2006) estimate a multivariate model of output fluctuations including a forward-looking Phillips curve specified as follows:

$$\Delta p_t = c + \delta\mathrm{E}(\Delta p_{t+1}|\mathcal{F}_t) + \theta_\psi(L)\psi_t + \xi_{pt},$$

where $\mathcal{F}_t$ is the information set at time t. Basistha and Nelson (2007) estimate a bivariate model of output and inflation where the output equation features the MNZ decomposition with correlated components, and in the inflation equation, survey-based expectations replace $\mathrm{E}(\Delta p_{t+1}|\mathcal{F}_t)$.

9.3.2 A bivariate quarterly model of output and inflation for the US

This section is devoted to the estimation of a bivariate model for US quarterly real GDP and the quarterly rate of inflation Δp_t, where p_t is the logarithm of quarterly CPI for the US, using data from the first quarter of 1950 to the fourth quarter of 2006. The KPSS test conducted on the inflation series leads to the rejection of the null of stationarity against a random walk for all values of the lag truncation parameter up to 5; if a linear trend is considered and stationarity is tested against a random walk with drift, then the null is also rejected for much higher values of the lag truncation parameter. In the sequel, inflation will be taken to be integrated of order one. The model has the following specification:

$$\begin{array}{lcll} y_t & = & \mu_t + \psi_t, & t = 1, \ldots, n, \\ \mu_t & = & \mu_{t-1} + \beta_t + \eta_t, & \eta_t \sim \mathrm{NID}(0, \sigma^2_\eta) \\ \psi_t & = & \phi_1 \psi_{t-1} + \phi_2 \psi_{t-2} + \kappa_t, & \kappa_t \sim \mathrm{NID}(0, \sigma^2_\kappa) \\ & & & \\ \Delta p_t & = & \tau_t + \varepsilon_{pt} & \varepsilon_{pt} \sim \mathrm{NID}(0, \sigma^2_{p\varepsilon}) \\ \tau_t & = & \tau_{t-1} + \theta_\psi(L)\psi_t + \eta_{\tau t} & \eta_{\tau t} \sim \mathrm{NID}(0, \sigma^2_{\tau\eta}), \end{array} \tag{9.22}$$

where η_t, κ_t, ε_{pt}, and η_{pt} are mutually independent.

The output equation is the usual decomposition into orthogonal components; the inflation equation is a decomposition into a core component, τ_t, and a transitory one. The changes in the core component are driven by the output gap and by the idiosyncratic disturbances $\eta_{\tau t}$. The lag polynomial $\theta_\psi(L) = \theta_{\psi 0} + \theta_{\psi 1} L$ can be rewritten as $\theta_\psi(1) - \theta_{\psi 1}\Delta$, which enables us to isolate the level effect of the gap from the change effect, which we expect to be positive, that is we expect $\theta_{\psi 1} < 0$. If $\theta_\psi(1) = 0$, the inflation equation can be rewritten as $\Delta p_t = \tau^*_t - \theta_{\psi 1}\psi_t + \varepsilon_t$, with $\Delta\tau^*_t = \eta_{\tau t}$, so that output and inflation would share a common cycle.

We also extend the specification of model (9.22) to take into account an important stylized fact, known as the "Great Moderation" of the business cycle, and which consists of a substantive reduction in the volatility of GDP growth. This feature is visible from the plot of Δy_t in Figure 9.1. The date when the structural break in volatility occurred is identified as the first quarter of 1984 (see Kim and Nelson, 1999a; McConnell and Perez Quiros, 2000; Stock and Watson, 2003).

Let S_t denote an indicator variable which takes the value 1 in the high volatility state (which we label regime *a*) and 0 in the low volatility state (regime *b*). The trend and cycle disturbance variances are time varying and the model will be specified as in (9.22) with:

$$\eta_t \sim \mathrm{N}\left(0, S_t\sigma^2_{\eta a} + (1 - S_t)\sigma^2_{\eta b}\right), \quad \kappa_t \sim \mathrm{N}\left(0, S_t\sigma^2_{\kappa a} + (1 - S_t)\sigma^2_{\kappa b}\right).$$

This will be referred to as the GM specification. We shall consider two cases: (i) the sequence S_t is deterministic, taking the value 1 before 1984:1, and 0 thereafter; (ii) S_t is a random process, which we model as a first-order Markov chain with initial probability $p(S_0 = 1) = 1$, i.e., we know for certain that the process started in a high variance state, and transition probabilities $P(S_t = j|S_{t-1} = i) = \mathcal{T}_{ij}, i = 0, 1$, with $\mathcal{T}_{ij} = 1 - \mathcal{T}_{ii}$ for $j \neq i$.

9.3.2.1 ML estimation

The bivariate model and its GM extension under assumption (i) were estimated by ML in the time domain. The likelihood is evaluated by the Kalman filter (see Appendix C for details). The parameter estimates and the associated standard errors are reported in Table 9.2. The estimated trend and cycle disturbance variances are smaller after 1984:1 (regime b), as expected, and the likelihood ratio test of the homogeneity hypothesis, $H_0 : \sigma^2_{\eta a} = \sigma^2_{\eta b}, \sigma^2_{\kappa a} = \sigma^2_{\kappa b}$, clearly leads to a rejection. The roots of the AR polynomial for the output gap are complex and the loadings of core inflation on the output gap are significantly different from zero at the 5% level. The table also reports the Wald test for the null of long-run neutrality of the output gap, $H_0 : \theta_\psi(1) = 0$, which is accepted under both specifications, with p-values equal to 0.16 and 0.19. The evidence is thus that the output gap has only transitory effects on the level of inflation.

Figure 9.6 displays the point and 95% interval estimates of the output gap and the core component of inflation for both specifications. It is interesting that the explicit consideration of the Great Moderation of volatility makes the estimates of the output gap after the 1984 break more precise. In interpreting this result, we must stress that the interval estimates make no allowance for parameter uncertainty and for the uncertainty in dating the transition from the high volatility state to the low volatility one.

9.3.2.2 Bayesian estimation

Let us focus on the standard bivariate model (9.22) first and denote by $\mathbf{y}$ the stack of the observations $(y_t, \Delta p_t)$ for $t = 1, \ldots, n$, $\boldsymbol{\alpha} = (\boldsymbol{\alpha}_0', \ldots, \boldsymbol{\alpha}_n')'$, where the state vector at time t is $\boldsymbol{\alpha}_t = (\mu_t, \beta_t, \psi_t, \psi_{t-1}, \tau_t)$. Also, let $\boldsymbol{\mu}, \boldsymbol{\psi}, \boldsymbol{\eta}, \boldsymbol{\kappa}$ denote, respectively, the stack of potential output, the output gap, the disturbances η_t, and the cycle disturbances, where, e.g., $\boldsymbol{\psi} = (\psi_1, \ldots, \psi_n)$, and let $\Xi = [\phi_1, \phi_2, \sigma^2_\eta, \sigma^2_\kappa, \sigma^2_{p\varepsilon}, \sigma^2_{\tau\eta}, \theta_{\psi 0}, \theta_{\psi 1}]$ denote the vector of hyperparameters.[3] Notice that knowledge of $\boldsymbol{\alpha}$ implies knowledge of both the individual state components and the disturbances. Our main interest lies in aspects of the posterior marginal densities of the states given the observations, e.g., $f(\boldsymbol{\psi}|\mathbf{y})$ and $f(\Xi|\mathbf{y})$: e.g., $\mathrm{E}[h(\boldsymbol{\psi})] = \int h(\boldsymbol{\psi}) f(\boldsymbol{\psi}|\mathbf{y}) d\boldsymbol{\psi}$, for some function $h(\cdot)$ such as $h(\boldsymbol{\psi}) = \psi_t$. The computation of the integral is carried out by stochastic simulation: given a sample $\psi_t^{(i)}, i = 1, \ldots, M$, drawn from the posterior $f(\boldsymbol{\psi}|\mathbf{y})$, $\mathrm{E}[h(\boldsymbol{\psi})]$ is approximated by $M^{-1} \sum_i h\left(\psi_t^{(i)}\right)$. The required sample is obtained by Monte Carlo Markov chain methods and, in particular, by a Gibbs sampling (GS) scheme that we now discuss in detail. This scheme produces correlated random draws from the joint posterior density $f(\boldsymbol{\alpha}, \Xi|\mathbf{y})$, and thus from $f(\boldsymbol{\psi}|\mathbf{y})$, by repeatedly sampling an

ergodic Markov chain whose invariant distribution is the target density (see Chib, 2001, and the references therein).

This is achieved by the following iterative scheme. Specify an initial value $\boldsymbol{\alpha}^{(1)}, \Xi^{(1)}$. For $i = 1, 2, \ldots, M$:

1. Generate $\boldsymbol{\alpha}^{(i)} \sim f(\boldsymbol{\alpha}|\Xi^{(i-1)}, \mathbf{y})$ using the simulation smoother (see Appendix C, section 9.7.4)
2. Generate $\Xi^{(i)} \sim f(\Xi^{(i)}|\boldsymbol{\alpha}^{(i)}, \mathbf{y})$. This block is divided into smaller components, whose full conditional distribution is available for sampling. In particular:
   (a) Generate $(\phi_1^{(i)}, \phi_2^{(i)})'$ from the full conditional $(\phi_1, \phi_2)'|\boldsymbol{\psi}, \sigma_\kappa^{2(i-1)}$ (this distribution is conditionally independent of $\mathbf{y}$, given $\boldsymbol{\psi}$). Assuming a Gaussian prior distribution, $\mathrm{N}(\mathbf{m}_{\phi 0}, \Sigma_{\phi 0})$, $(\phi_1, \phi_2)'|\boldsymbol{\psi}, \sigma_\kappa^{2(i-1)} \sim \mathrm{N}(\mathbf{m}_{\phi 1}, \Sigma_{\phi 1})$ where, denoting $\boldsymbol{\chi}_{t-1} = (\psi_{t-1}^{(i-1)}, \psi_{t-2}^{(i-1)})'$,

$$\Sigma_{\phi 1} = \left(\Sigma_{\phi 0}^{-1} + \frac{1}{\sigma_\kappa^{2(i-1)}} \sum_t \boldsymbol{\chi}_{t-1} \boldsymbol{\chi}_{t-1}' \right)^{-1},$$

$$\mathbf{m}_{\phi 1} = \Sigma_{\phi 1} \left(\Sigma_{\phi 0}^{-1} \mathbf{m}_{\phi 0} + \frac{1}{\sigma_\kappa^{2(i-1)}} \sum_t \boldsymbol{\chi}_{t-1} \psi_t \right).$$

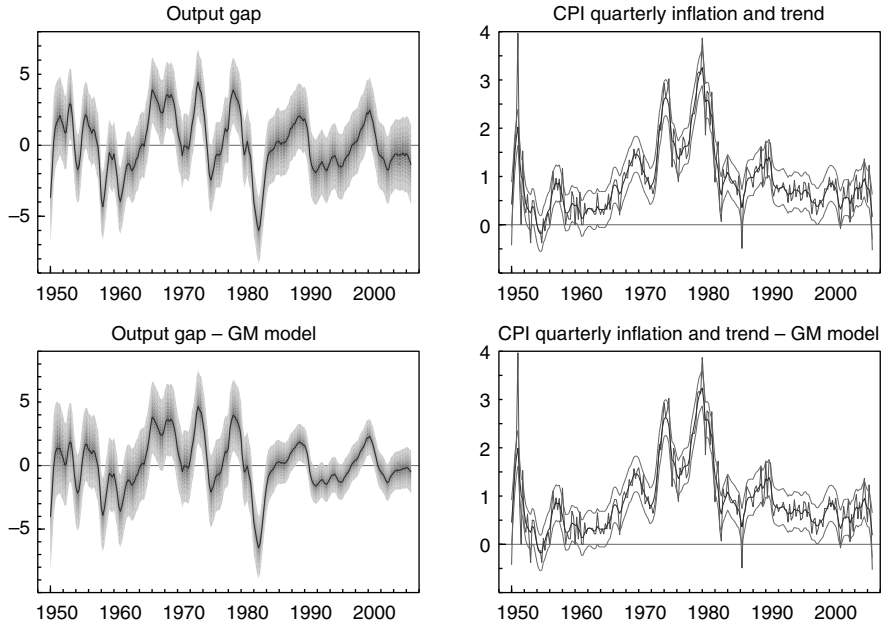

Figure 9.6 Estimates of the output gap and core inflation using the ML estimates of the parameters of the bivariate models of output and inflation under two specifications

The generations are repeated until a draw falls inside the stationarity region.

(b) Generate $\sigma_\eta^{2(i)}$ from the full conditional inverse gamma (IG) distribution:

$$\sigma_\eta^2 | \boldsymbol{\eta}^{(i-1)} \sim IG\left(\frac{\nu_\eta + n}{2}, \frac{\delta_\eta + \sum_t \eta_t^{(i-1)^2}}{2}\right).$$

This assumes that the prior distribution is $\sigma_\eta^2 \sim IG(\nu_\eta/2, \delta_\eta/2)$.

(c) Generate $\sigma_\kappa^{2(i)}$ from the full conditional IG distribution:

$$\sigma_\kappa^2 | \boldsymbol{\kappa}^{(i-1)} \sim IG\left(\frac{\nu_\kappa + n}{2}, \frac{\delta_\kappa + \sum_t \kappa_t^{(i-1)^2}}{2}\right).$$

This assumes that the prior distribution is $\sigma_\kappa^2 \sim IG(\nu_\kappa/2, \delta_k/2)$.

(d) Generate $(\theta_{\psi 0}^{(i)}, \theta_{\psi 1}^{(i)})'$. Assuming the Gaussian prior $(\theta_{\psi 0}, \theta_{\psi 1})' \sim \mathrm{N}(\mathbf{m}_{\theta 0}, \Sigma_{\theta 0})$, the full posterior is $(\theta_{\psi 0}, \theta_{\psi 1})' | \boldsymbol{\tau}, \sigma_{\tau\eta}^{2(i-1)} \sim \mathrm{N}(\mathbf{m}_{\theta 1}, \Sigma_{\theta 1})$, where

$\boldsymbol{\tau} = (\tau_1, \ldots, \tau_n)$, and:

$$\Sigma_{\theta 1} = \left(\Sigma_{\theta 0}^{-1} + \frac{1}{\sigma_{\tau\eta}^{2(i-1)}} \sum_t \boldsymbol{\chi}_t \boldsymbol{\chi}_t' \right)^{-1},$$

$$\mathbf{m}_{\phi 1} = \Sigma_{\phi 1} \left(\Sigma_{\theta 0}^{-1} \mathbf{m}_{\phi 0} + \frac{1}{\sigma_{\tau\eta}^{2(i-1)}} \sum_t \boldsymbol{\chi}_t \Delta\tau_t \right).$$

(e) Generate $\sigma_{p\varepsilon}^{2(i)}$ from the full conditional IG distribution:

$$\sigma_{p\varepsilon}^2 | \boldsymbol{\varepsilon}_p^{(i-1)} \sim IG\left(\frac{\nu_\varepsilon + n}{2}, \frac{\delta_\varepsilon + \sum_t (\varepsilon_t^{(i-1)})^2}{2} \right).$$

Here $\boldsymbol{\varepsilon}_p$ is the stack of the inflation equation measurement disturbances, and we assume the prior $\sigma_{p\varepsilon}^2 \sim IG(\nu_\varepsilon/2, \delta_\varepsilon/2)$.

(f) Generate $\sigma_{\tau\eta}^{2(i)}$ from the full conditional IG distribution:

$$\sigma_{\tau\eta}^2 | \boldsymbol{\eta}_\tau^{(i-1)} \sim IG\left(\frac{\nu_\tau + n}{2}, \frac{\delta_\tau + \sum_t \eta_{\tau t}^{(i-1)^2}}{2} \right),$$

where $\boldsymbol{\eta}_\tau$ is the stack of the inflation equation core level disturbances, and we assume the prior $\sigma_{\eta\tau}^2 \sim IG(\nu_\tau/2, \delta_\tau/2)$.

The above GS scheme defines a homogeneous Markov chain such that the transition kernel is formed by the full conditional distributions and the invariant distribution is the unavailable target density.

The IG prior for the variance parameter is centered around the ML estimate and is not very informative ($\nu_\eta = \nu_\kappa = \nu_\varepsilon = \nu_\tau = 4$, and $n = 426$); for the AR parameters and the loadings impose a standard normal prior. The number of samples is $M = 2{,}000$ after a burn-in sample of size 1,000. Figure 9.7 displays the posterior means and the 95% interval estimates of the output gap (first panel), along with a nonparametric estimate of the posterior density of the variance parameters σ_η^2 and σ_κ^2 (top right panel); the modes are not far from the ML estimates. The bottom left panel shows the M draws $(\phi_1^{(i)}, \phi_2^{(i)})$ from the posterior of the AR parameter distribution. The triangle delimits the stationary region of the parameter space; the posterior means are 1.48 for ϕ_1 and -0.57 for ϕ_2. Finally, the last panel shows the posterior distribution of the change effect, $-\theta_{\psi 1}$, and the level effect $\theta_\psi(1)$. The 95% confidence interval for the latter is $(-0.01, 0.05)$, which confirms that the output gap has only transitory effects on inflation. The posterior mean of ψ_t does not differ from the point estimates arising from the classical analysis. However, the classical confidence intervals in Figure 9.6 are constructed by replacing Ξ with the ML estimates and thus do not take into account parameter uncertainty (see also section 9.4.2). It cannot be maintained that the classical estimates are more reliable.

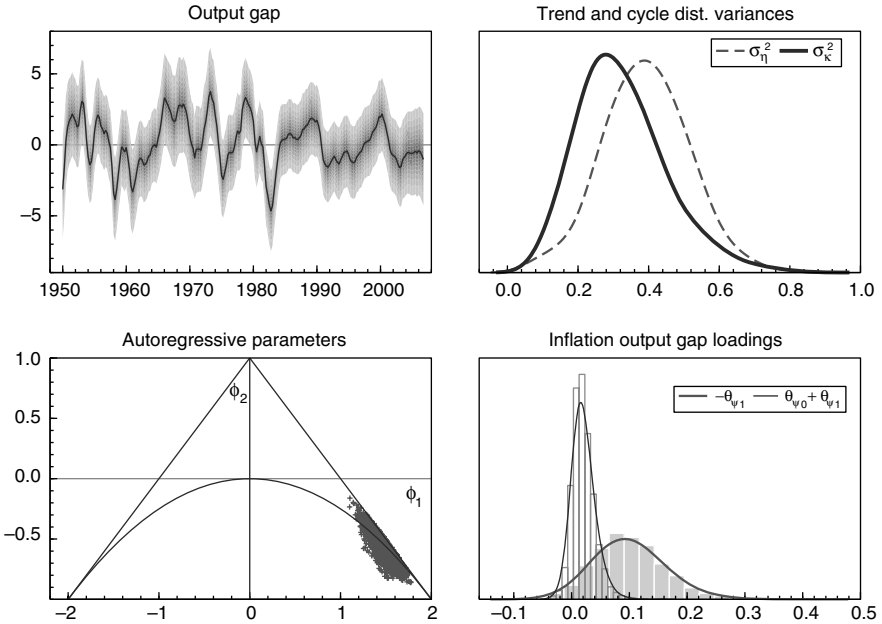

Figure 9.7 Bayesian estimation of the standard bivariate output gap model. Point and 95% interval estimates of the output gap; posterior densities of variance and loadings parameters; draws from the posterior of the AR parameters

For the GM model, the parameter set Ξ is such that the trend and cycle disturbance variances are replaced by the variances in the two regimes, $\sigma^2_{\eta a}, \sigma^2_{\eta b}, \sigma^2_{\kappa a}, \sigma^2_{\kappa b}$, and under the Markov switching specification (ii), according to which S_t is a first-order Markov chain, includes the transition probabilities $\mathcal{T}_{11}, \mathcal{T}_{00}$.

The steps of the GS algorithm need to be amended. An additional step is necessary to draw a sample from the distribution of $\mathbf{S} = (S_0, \ldots, S_n)$ conditional on $\boldsymbol{\alpha}$ and Ξ. Notice that this distribution depends on these random vectors only via $\boldsymbol{\eta}, \boldsymbol{\kappa}$, and the elements of Ξ, $\sigma^2_{\eta a}, \sigma^2_{\eta b}, \sigma^2_{\kappa a}, \sigma^2_{\kappa b}, \mathcal{T}_{11}, \mathcal{T}_{00}$. Sampling from the full posterior of the indicator variable $\mathbf{S}$ is achieved by the following algorithm (Carter and Kohn, 1994):

1. Sample $S_n^{(i)}$ from the filtered state probability distribution $P(S_n|\boldsymbol{\alpha}, \Xi, \mathbf{y}) = P(S_n|\boldsymbol{\eta}, \boldsymbol{\kappa}, \Xi)$.
2. For $t = n-1, \ldots, 1, 0$, sample $S_t^{(i)}$ from the conditional probability distribution:

$$P(S_t|S_{t+1}^{(i)}, \boldsymbol{\eta}, \boldsymbol{\kappa}, \Xi) = \frac{P(S_{t+1}^{(i)}|S_t, \Xi)P(S_t|\boldsymbol{\eta}^t, \boldsymbol{\kappa}^t, \Xi)}{\sum_{S_t} P(S_{t+1}^{(i)}|S_t, \Xi)P(S_t|\boldsymbol{\eta}^t, \boldsymbol{\kappa}^t, \Xi)},$$

where $\boldsymbol{\eta}^t = (\eta_0, \ldots, \eta_t)$ and $\boldsymbol{\kappa}^t = (\kappa_0, \ldots, \kappa_t)$.

The filtered probabilities, $P(S_t|\boldsymbol{\eta}^t, \boldsymbol{\kappa}^t, \Xi)$, are obtained by the following discrete filter:

(i) The filter is started with the initial distribution $P(S_0 = 1|\boldsymbol{\eta}^0, \boldsymbol{\kappa}^0, \Xi) = 1, P(S_0 = 0|\boldsymbol{\eta}^0, \boldsymbol{\kappa}^0, \Xi) = 0$: that is, we impose that S_t started in the high volatility regime.
(ii) For $t = 1, 2, \ldots, n$, compute the one-step-ahead probability distribution $P(S_t|\boldsymbol{\eta}^{t-1}, \boldsymbol{\kappa}^{t-1}, \Xi) = \sum_{S_{t-1}} P(S_t|S_{t-1}, \Xi)P(S_{t-1}|\boldsymbol{\eta}^{t-1}, \boldsymbol{\kappa}^{t-1}, \Xi)$.
(iii) Compute the filtered probabilities:

$$P(S_t|\boldsymbol{\eta}^t, \boldsymbol{\kappa}^t, \Xi) = \frac{f(\eta_t, \kappa_t|S_t, \Xi)P(S_t|\boldsymbol{\eta}^{t-1}, \boldsymbol{\kappa}^{t-1}, \Xi)}{\sum_{S_t} f(\eta_t, \kappa_t|S_t, \Xi)P(S_t|\boldsymbol{\eta}^{t-1}, \boldsymbol{\kappa}^{t-1}, \Xi)},$$

where $f(\eta_t, \kappa_t|S_t, \Xi)$ is the product of two independent Gaussian densities with time-varying scale parameters.

Gerlach, Carter and Kohn (2000) have proposed an alternative sampling scheme for the indicator variable S_t which generates samples from $P(S_t|S_{j\neq t}, \mathbf{y}, \Xi)$ without conditioning on the states or the disturbances. This is more efficient than the above sampler if S_t is highly correlated with the states or the disturbances, which is not the case in our particular application.

Steps 1 and 2 of the GS algorithm are similar but the full posteriors are understood to be conditional on $\mathbf{S}^{(i-1)}$ as well. Furthermore, an additional step, 2(g), is added for sampling from the full conditionals of the transition probabilities, $\mathcal{T}_{11}, \mathcal{T}_{22}$, and the steps 2(b) and 2(c) are replaced as follows:

(b) Generate $\sigma^{2(i)}_{\eta a}$ and $\sigma^{2(i)}_{\eta b}$ from:

$$\sigma^2_{\eta a}|\boldsymbol{\eta}^{(i-1)}, \mathbf{S}^{(i-1)} \sim IG\left(\frac{\nu_\eta + \sum_t S_t^{(i-1)}}{2}, \frac{\delta_\eta + \sum_t S_t^{(i-1)}\eta_t^{(i-1)^2}}{2}\right),$$

$$\sigma^2_{\eta b}|\boldsymbol{\eta}^{(i-1)}, \mathbf{S}^{(i-1)} \sim IG\left(\frac{\nu_\eta + \sum_t (1 - S_t^{(i-1)})}{2}, \frac{\delta_\eta + \sum_t (1 - S_t^{(i-1)})\eta_t^{(i-1)^2}}{2}\right).$$

This assumes that the prior distribution is $\sigma^2_{\eta a}$ and $\sigma^2_{\eta b} \sim IG(\nu_\eta/2, \delta_\eta/2)$.

(c) Generate $\sigma^{2(i)}_{\kappa a}$ and $\sigma^{2(i)}_{\kappa b}$ from:

$$\sigma^2_{\kappa a}|\boldsymbol{\kappa}^{(i-1)}, \mathbf{S}^{(i-1)} \sim IG\left(\frac{\nu_\kappa + \sum_t S_t^{(i-1)}}{2}, \frac{\delta_\kappa + \sum_t S_t^{(i-1)}\kappa_t^{(i-1)^2}}{2}\right),$$

$$\sigma^2_{\kappa b}|\boldsymbol{\kappa}^{(i-1)}, \mathbf{S}^{(i-1)} \sim IG\left(\frac{\nu_\kappa + \sum_t (1 - S_t^{(i-1)})}{2}, \frac{\delta_\kappa + \sum_t (1 - S_t^{(i-1)})\kappa_t^{(i-1)^2}}{2}\right).$$

This assumes that the prior distribution is $\sigma^2_{\kappa a}$ and $\sigma^2_{\kappa b} \sim IG(\nu_\kappa/2, \delta_\kappa/2)$.

(g) Generate $\mathcal{T}_{11}^{(i)}, \mathcal{T}_{10}^{(i)} = 1 - \mathcal{T}_{11}^{(i)}$ and $\mathcal{T}_{00}^{(i)}, \mathcal{T}_{01}^{(i)} = 1 - \mathcal{T}_{00}^{(i)}$ from the posterior:

$$\mathcal{T}_{11}^{(i)}|\mathbf{S}^{(i-1)} \sim B\left(a_1 + N_{11}^{(i-1)}, b_1 + N_{10}^{(i-1)}\right),$$
$$\mathcal{T}_{00}^{(i)}|\mathbf{S}^{(i-1)} \sim B\left(a_0 + N_{00}^{(i-1)}, b_0 + N_{01}^{(i-1)}\right),$$

where $B(a, b)$ is the Beta distribution, $N_{ij}^{(i-1)}$ is the number of transitions from $S_t^{(i-1)} = i$ to $S_{t+1}^{(i-1)} = j$, and $a_i, b_i, i = 0, 1$, are the parameters of the Beta prior distributions (set equal to $a_1 = b_1 = b_0 = 1, a_0 = 5$). Notice that the transition probabilities are conditionally independent of $\boldsymbol{\alpha}$ and the other elements of Ξ, given $\mathbf{S}$.

Figure 9.8 summarizes aspects of the posterior distribution of the cycle, the indicator S_t, and some important parameters using a sample of $M = 2{,}000$ draws from the GS scheme outlined above with a burn-in of 2,000 iterations. Interestingly, the output gap interval estimates are more widely dispersed than in the original specification with no Markov-switching in the disturbance variances. This is so since the GM specification has a further source of variation and uncertainty, related to the state of Markov chain S_t, which in turn drives the changes in the volatility regime. As a result, the Bayesian interval estimates cannot be compared with the classical ones reported in the bottom left panel of Figure 9.6, since those were derived under the assumption that S_t was deterministic and known, and they make no allowance for parameter uncertainty. The estimated posterior probabilities of being in a high volatility regime confirm the general finding that the main stylized fact is a relatively sharp change point taking place in the first quarter of 1984, although there remains some uncertainty around that date. The nonparametric estimates of the posterior distribution of the transition probabilities $\mathcal{T}_{11}$ and $\mathcal{T}_{00}$ are displayed in the last panel of the figure. The posterior distributions of the variance parameters for the trend and cycle disturbances strongly confirm the Great Moderation hypothesis, and quantify it further, as both the permanent and transitory disturbances underwent a significant volatility reduction. The posterior means do not differ from the ML estimates reported in Table 9.2: $\mathrm{E}(\sigma_{\eta a}^2|\mathbf{y}) = 0.60, \mathrm{E}(\sigma_{\eta b}^2|\mathbf{y}) = 0.14$ and $\mathrm{E}(\sigma_{\kappa a}^2|\mathbf{y}) = 0.51, \mathrm{E}(\sigma_{\kappa b}^2|\mathbf{y}) = 0.09$. As far as the inflation equation is concerned, the overall conclusion is unchanged: the output gap is a significant source of variation (the value $-\theta_{\psi 1} = 0$ is estimated to be the 2.6 percentile of the posterior distribution of $-\theta_{\psi 1}$, which measures the change effect, but it drives inflation only in the short run, as the null of long-run neutrality is accepted (the 95% credible set for $\theta_\psi(1)$ is the interval $(-0.01, 0.05)$).

9.3.3 Multivariate extensions

The output gap is related to the deviations of the unemployment rate, u_t, from its "natural rate" or NAIRU via Okun's law. Okun (1962) defined natural unemployment as that level of unemployment occurring when output is equal to its

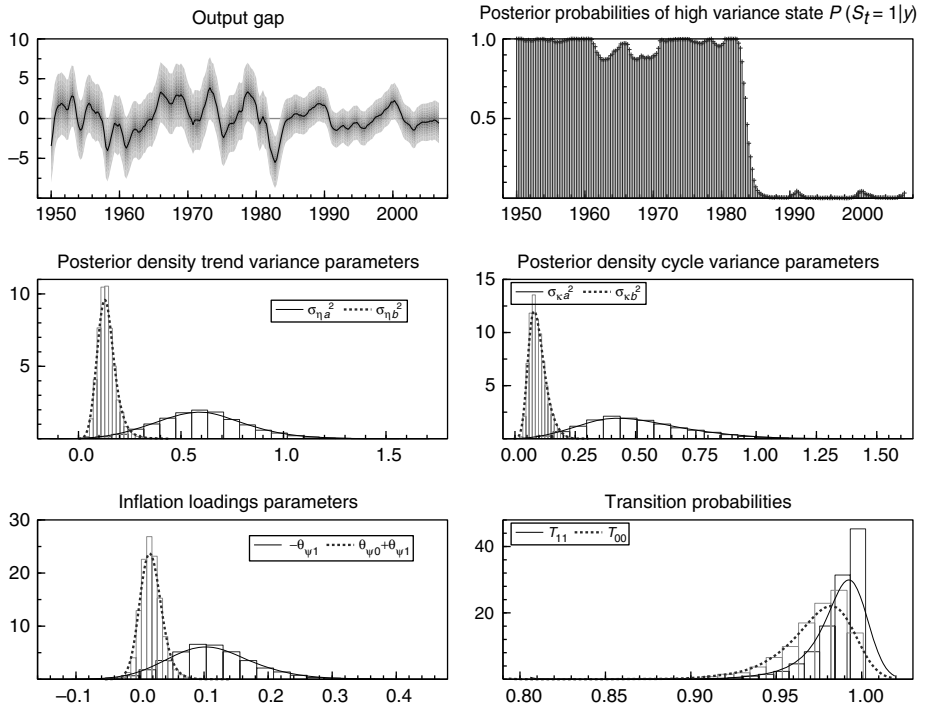

Figure 9.8 Bayesian estimation of the bivariate output gap model with Markov-switching in the variances of the trend and cycle disturbances (GM specification). Point and 95% interval estimates of the output gap; posterior probabilities of the high volatility state, $P(S_t = 1|\mathbf{y})$, and posterior densities of variance and loadings parameters

potential, and established an empirical law of strict proportionality between cyclical unemployment and the output gap. Hence, Okun's law is meant to imply that output and the unemployment rate share a common cycle.

Against this background, Clark (1989) estimated a bivariate model of US real output and unemployment such that output and unemployment are decomposed into two unrelated permanent components and the comovements between the two series result from the presence of a common cycle, represented as an AR(2) stationary component. Apel and Jansson (1999) obtained estimates of the NAIRU and potential output for the UK, the US and Canada, based on an unobserved components model of output, inflation and unemployment rates.

Another important multivariate extension of the basic bivariate model is the *production function approach* (PFA) to the estimation of potential output and the output gap, according to which potential output is obtained from the trend, or "noninflationary," levels of its structural determinants, such as productivity and factor inputs. This approach is currently one of the most popular methods of measuring potential output among statistical agencies being employed by the OECD (2001),

the International Monetary Fund (DeMasi, 1997), the Congressional Budget Office (2001), and the European Commission (see McMorrow and Roeger, 2001).

The PFA assumes that technology can be represented by a Cobb–Douglas production function with constant returns to scale on labor, measured by hours worked or by the number of employed persons, and capital:

$$y_t = f_t + \alpha h_t + (1-\alpha)k_t, \tag{9.23}$$

where f_t is the Solow residual, h_t is hours worked, k_t is the capital stock (all variables expressed in logarithms), and α is the elasticity of output with respect to labor ($0 < \alpha < 1$).

To achieve the decomposition $y_t = \mu_t + \psi_t$, the variables on the right-hand side of equation (9.23) are broken down additively into their permanent (denoted by the superscript P) and transitory (denoted by the superscript T) components, giving:

$$f_t = f_t^{(P)} + f_t^{(T)}, \quad h_t = h_t^{(P)} + h_t^{(T)}, \quad k_t = k_t^{(P)}. \tag{9.24}$$

It should be noticed that potential capital is always assumed to be equal to its actual value; this is so since capacity utilization is absorbed in the cyclical component of the Solow residual. Only survey-based measures of capacity utilization for the manufacturing sector are available for the euro-area.

Hence potential output is the value corresponding to the permanent values of factor inputs and the Solow residual, while the output gap is a linear combination of the transitory components:

$$\begin{aligned} \mu_t &= f_t^{(P)} + \alpha h_t^{(P)} + (1-\alpha)k_t, \\ \psi_t &= f_t^{(T)} + \alpha h_t^{(T)}. \end{aligned} \tag{9.25}$$

Hours worked can be separated into four components that are affected differently by the business cycle, as can be seen from the identity $h_t = n_t + pr_t + er_t + hl_t$, where n_t is the logarithm of working-age population (i.e., population of age 15–64), pr_t is the logarithm of the labor force participation rate (defined as the ratio of the labor force to the working-age population), er_t is the logarithm of the employment rate (defined here as the ratio of employment to the labor force), and hl_t is the logarithm of labor intensity (i.e., average hours worked). Each of these determinants is in turn decomposed into its permanent and transitory component in order to obtain the decomposition:

$$h_t^{(P)} = n_t + pr_t^{(P)} + er_t^{(P)} + hl_t^{(P)}, \quad h_t^{(T)} = pr_t^{(T)} + er_t^{(T)} + hl_t^{(T)}. \tag{9.26}$$

The idea is that population dynamics are fully permanent, whereas labor force participation, employment and average hours are also cyclical. Moreover, since the employment rate can be restated in terms of the unemployment rate, we can relate the output gap to cyclical unemployment and potential output to structural unemployment. As a matter of fact, since the unemployment rate is one minus the employment rate, $u_t = \log(1 - \exp(er_t))$, the variable $cur_t = -er_t$ (the contribution

of the unemployment rate, using a terminology due to Rünstler, 2002), is the first-order Taylor approximation to the unemployment rate. Thus, $cur_t^{(P)}$ can be assimilated to the NAIRU and $cur_t^{(T)}$ to the unemployment gap.

The PFA has the appealing feature that it uses a lot of economic information on the determinants of potential output; however, apart from the stringent data requirements (in particular, it requires the capital stock and hours worked), it requires the decomposition of the series involved into their permanent and transitory components. Proietti, Musso and Westermann (2007) propose a structural time series model-based implementation of the PFA approach, and Proietti and Musso (2007) extend it to carry out a growth accounting analysis for the euro-area.

9.3.4 A multivariate model with mixed frequency data

This section presents the results of fitting a multivariate monthly time series model for the US economy, using quarterly observations for GDP and monthly observations for industrial production, ip_t, the unemployment rate, u_t, and CPI inflation, Δp_t. The equation for the logarithm of GDP is the usual decomposition $y_t = \mu_t + \psi_t$ as in (9.22), with the important difference that the model is now formulated at the monthly frequency. The CPI equation is also specified as in (9.22).

Industrial production is included since it is an important timely coincident indicator: the time series model for ip_t is the trend-cycle decomposition $ip_t = \mu_{ip,t} + \theta_{ip}\psi_t + \psi_{ip,t}$, where $\mu_{ip,t} = \mu_{ip,t-1} + \beta_{ip} + \eta_{ip,t}$, and we assume that the trend disturbance is contemporaneously correlated with the GDP trend disturbance, η_t, $\eta_{ip,t} \sim \mathrm{N}(0, \sigma^2_{\eta,ip})$, $\mathrm{E}(\eta_t \eta_{ip,t}) = \sigma_{y,ip}$. The cyclical component is the combination of a common cycle and the idiosyncratic cycle $\psi_{ip,t} = \phi_{ip,1}\psi_{ip,t-1} + \phi_{ip,1}\psi_{ip,t-2} + \kappa_{ip,t}$.

The unemployment rate, u_t, is decomposed into the NAIRU, $\mu_{u,t}$, and cyclical unemployment, which is a distributed lag combination of the output gap plus an idiosyncratic component, ψ_{ut}, $u_t = \mu_{u,t} + \theta_{u0}\psi_t + \theta_{u1}\psi_{t-1} + \psi_{ut}$, where the NAIRU is a random walk without drift, $\mu_{u,t} = \mu_{u,t-1} + \eta_{u,t}$, and we assume that $\eta_{u,t} \sim \mathrm{NID}(0, \sigma^2_{\eta,u})$ is independent of any other disturbance in the model, whereas $\psi_{ut} = \phi_{u1}\psi_{u,t-1} + \phi_{u1}\psi_{u,t-2} + \kappa_{ut}$, with $\kappa_{ut} \sim \mathrm{NID}(0, \sigma^2_{\kappa u})$, independently of any other disturbance.

The link between the individual time series equations is provided by the output gap, ψ_t, which acts as the common cycle driving the short-run fluctuations; furthermore, the trend disturbances of y_t and ip_t are correlated. As GDP is quarterly, y_t is unobserved, whereas the available observations consist of the aggregated quarterly levels $Y_\tau = \exp(y_{3\tau}) + \exp(y_{3\tau-1}) + \exp(y_{3\tau-2})$, $\tau = 1, 2, \ldots, [n/3]$, where $[\cdot]$ is the integer part of the argument. For the statistical treatment it is useful to convert temporal aggregation into a systematic sampling problem, which is achieved by constructing a cumulator variable, generated by the following time-varying recursion (see Harvey, 1989): $Y_t^C = \varrho_t Y_{t-1}^C + \exp(y_t)$, where ϱ_t is the cumulator coefficient, defined as follows:

$$\varrho_t = \begin{cases} 0 & t = 3(\tau - 1) + 1, \quad \tau = 1, \ldots, [n/3] \\ 1 & \text{otherwise.} \end{cases}$$

Only a systematic sample of the cumulator variable Y_τ^c is available; in particular, the end of quarter value is observed, for $t = 3, 6, 9, \ldots, [n/3]$.

The model is represented in state-space form (see Appendix C) with the cumulator variable included in the state vector in the following way. The transition equation $Y_t^c = \varrho_t Y_{t-1}^c + \exp(y_t)$ is nonlinear, but it can be linearized around a trial estimate $\tilde{y}_t^*$ by a first-order Taylor series expansion:

$$Y_t^c = \varrho_t Y_{t-1}^c + \exp(\tilde{y}_t^*)[1 - \tilde{y}_t^*] + \exp(\tilde{y}_t^*) y_t;$$

replacing $y_t = \mu_t + \psi_t = \mu_{t-1} + \beta + \phi_1 \psi_{t-1} + \phi_2 \psi_{t-2}$ in the previous expression, Y_t^c can be given a first-order inhomogeneous Markovian representation, and thus the model can be cast in state-space form, so that conditionally on $\tilde{y}_t^*$ the model is linear and Gaussian.

The fixed interval smoother (see Appendix C, section 9.7.3) can be applied to the linearized model to yield estimates of the components μ_t and ψ_t of the unobserved monthly GDP (on a logarithmic scale), denoted μ_t^* and ψ_t^*. The latter provides a new $y_t^* = \mu_t^* + \psi_t^*$ value, which is used to build a new linearized Gaussian model, by a first-order Taylor series expansion of Y_t^c around y_t^*. Iterating this process until convergence yields an estimate of the component and of monthly GDP that satisfies the aggregation constraints (see Proietti, 2006b, for the theory and applications).

The model was estimated by ML using data from January 1950 to December 2006. The estimated parameters for the output gap (standard errors in parentheses) are $\hat{\phi}_1 = 1.73$ (0.021), $\hat{\phi}_2 = -0.744$ (0.037), and $\hat{\sigma}_\kappa^2 = 43 \times 10^{-7}$. For potential output $\hat{\beta} = .003$, $\hat{\sigma}_\eta^2 = 204 \times 10^{-7}$. The specific cycles for ip_t and u_t are estimated with zero variance, so that the cyclical components of industrial production and unemployment are related to the output gap. The estimated loading of ip_t on ψ_t is $\hat{\theta}_{ip} = 2.454$ (0.186); furthermore, the ip trend disturbances have variance $\hat{\sigma}_{\eta,ip}^2 = 3.74 \times 10^{-7}$, and are positively correlated (with coefficient 0.38) with the GDP trend disturbances. As far as unemployment is concerned, the estimated loadings on ψ_t are $\hat{\theta}_0 = -4.771$ (0.204) and $\hat{\theta}_1 = -2.904$ (0.267); moreover, $\hat{\sigma}_{\eta,u}^2 = 9304 \times 10^{-7}$, whereas the irregular disturbance variance was set to zero.

For the inflation equation the output gap loadings are estimated as $\hat{\theta}_{\tau 0} = 0.051$ (0.012) and $\hat{\theta}_{\tau 1} = -0.048$ (0.012); the Wald test for long-run neutrality, $H_0 : \theta_{\tau 0} + \theta_{\tau 1} = 0$ takes the value 1.401 with a p-value of 0.24, providing again evidence that the output gap has only transitory effects on inflation. The change effect, $-\theta_{\tau 1}$, is significant and has the expected sign. Finally, the trend disturbance variance for inflation was $\hat{\sigma}_\upsilon^2 = 2 \times 10^{-7}$.

Figure 9.9 presents the smoothed estimates of potential output, the output gap, the NAIRU and core inflation. As a by product, our model produces estimates of monthly GDP that are consistent with the quarterly observed values (the temporal aggregation constraints are satisfied exactly at convergence) and incorporate the information from related series.

Comparing the output gap estimates with those arising from the bivariate quarterly model, it can be argued that the use of an unemployment series makes a

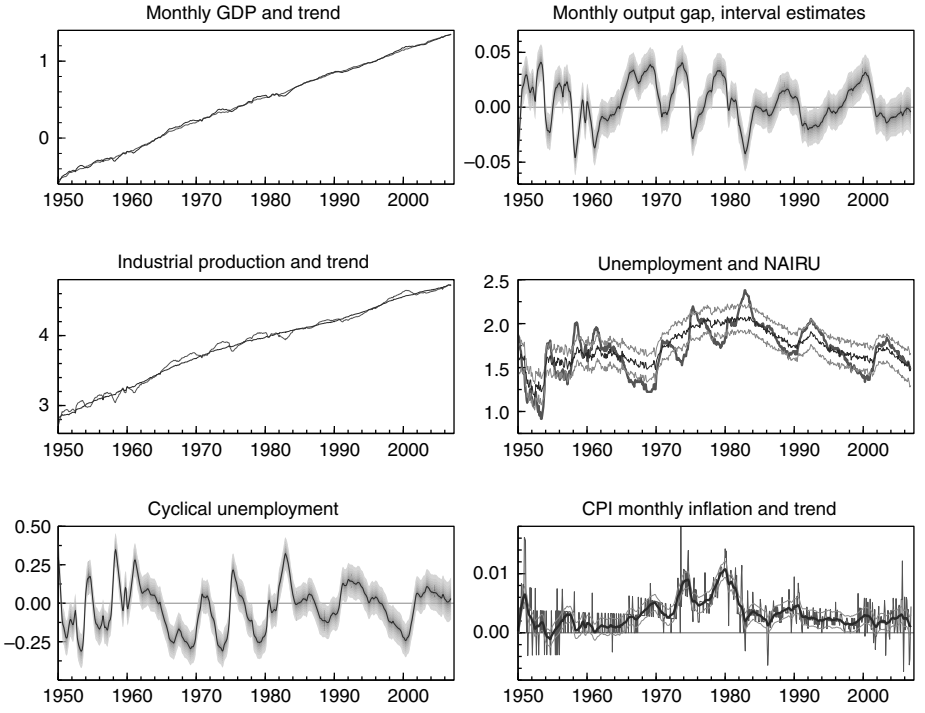

Figure 9.9 Monthly multivariate output gap model with temporal aggregation constraints. Smoothed estimates of monthly GDP, potential output, output gap, NAIRU, cyclical unemployment and core inflation

significant difference at the end of the sample. Also, enlarging the information set is beneficial to the reliability of the output gap estimates.

If the model is extended to allow for correlation between the output gap disturbance κ_t and the trend disturbance η_t, as in section 9.2.5, but in a multivariate set-up, the estimated correlation is $\hat{r} = 0.10$ and does not significantly differ from zero. In fact, the model with correlated disturbances has a likelihood of 7263.51, whereas the maximized likelihood of the restricted model ($r = 0$) is 7263.28. Thus, the LR test of $H_0 : r = 0$ takes the value 0.459, with p-value 0.50.

9.4 The reliability of the output gap measurement

The reliability of the output gap measurement is the subject of rich debate, and also has strong implications for optimal monetary policy. Orphanides and van Norden (2002) and Camba-Méndez and Rodriguez-Palenzuela (2003) discuss the different sources of uncertainty and their empirical assessment. The former conclude that the real-time estimates are unreliable. This conclusion echoes that by Staiger, Stock and Watson (1997) and Laubach (2001) concerning the NAIRU, obtained from a variety of methods. Somewhat different conclusions are reached by Planas

and Rossi (2004) and Proietti, Musso and Westermann (2007). The implications of the uncertainty surrounding the output gap estimates for monetary policy are considered in Orphanides *et al.* (2000) and Ehrmann and Smets (2003), among others.

A full assessment of the output gap reliability is complicated by the very nature of the measurement which, like the NAIRU, core inflation, and so forth, refers to a latent variable, for which there is no underlying "true value" to be elicited by other data collection techniques.

The previous sections have presented different parametric methods that can be used to measure the underlying signals. Assume that there is a true output gap ψ_t and that there is an approximating model, denoted by $\mathcal{M}$, providing a representation for it. The model specifies how the observations are related to the object of the measurement. Let us denote by $\psi_{t,\mathcal{M}}$ this (parametric) representation. Now, let $\tilde{\psi}_{t,\mathcal{M}}$ denote the estimator of ψ_t based on model $\mathcal{M}$, i.e., using the representation $\psi_{t,\mathcal{M}}$. We assume that $\tilde{\psi}_{t,\mathcal{M}}$ is the optimal signal extraction method for $\psi_{t,\mathcal{M}}$. How do we judge the reliability of $\tilde{\psi}_{t,\mathcal{M}}$? Reliability is a statement concerning the closeness of $\tilde{\psi}_{t,\mathcal{M}}$ and ψ_t. Following Boumans (2007), two key features are accuracy and precision, as the discrepancy $\tilde{\psi}_{t,\mathcal{M}} - \psi_t$ can be broken down into two components: $(\tilde{\psi}_{t,\mathcal{M}} - \psi_{t,\mathcal{M}}) + (\psi_{t,\mathcal{M}} - \psi_t)$, which are associated respectively to the precision of the method, and to the accuracy or validity of the representation chosen. Given the information set $\mathcal{F}$, precision is measured by (the inverse of) $\mathrm{Var}(\psi_{t,\mathcal{M}}|\mathcal{F}) = \mathrm{E}[(\tilde{\psi}_{t,\mathcal{M}} - \tilde{\psi}_{t,\mathcal{M}})^2|\mathcal{F}]$.

9.4.1 Validity

Validity is usually difficult to ascertain, as it is related to the appropriateness of $\psi_{t,\mathcal{M}}$ as a model for the signal ψ_t. This is a complex assessment, involving many subjective elements, such as any prior available information and the original motivation for signal extraction. The issue is indissolubly entwined with the nature of ψ_t: the previous paragraphs have considered two main perspectives. The first regards ψ_t as the component of the series that results from the transmission mechanism of demand or nominal shocks. The second view considers ψ_t as the bandpass component of output.

Recently, there has been a surge of interest in model uncertainty and in model averaging. The individual estimates $\tilde{\psi}_{t,\mathcal{M}_i}, i = 1, 2, \ldots, K$, may be combined linearly, giving $\tilde{\psi}_t = \sum_i c_i \tilde{\psi}_{t,\mathcal{M}_i}$, where the coefficients c_i are proportional to the precision of the methods, or the posterior probability in a Bayesian setting.

It is more viable to assess two other aspects of validity, namely concurrent and predictive validity. The first is concerned with the contemporaneous relationship between the measure $\tilde{\psi}_{t,\mathcal{M}}$ and a related alternative measure of the same phenomenon. Such measures are rarely available. Although business surveys are implemented with the objective of collecting informed opinions on latent variables, such as the state of the business cycle, they can hardly be considered as providing a measure of the "true" underlying state of the economy.

Predictive validity relates to the ability to forecast future realizations of y_t or related variables; evaluating the mean forecast error yields useful insight on its

predictive validity, as possible bias would emerge. This criterion is adopted by a number of authors; e.g., Camba-Mendez and Rodriguez-Palenzuela (2003) and Proietti, Musso and Westermann (2007) assess the reliability of alternative output gap estimates through their capability to predict future inflation.

9.4.2 Precision

A measurement method is precise if repeated measurements of the same quantity are in close agreement. Loosely speaking, precision is inversely related to the uncertainty of an estimate. In the measurement of immaterial constructs the sources of uncertainty would include: (i) *parameter uncertainty*, due to the fact that the core parameters Ξ characterizing model $\mathcal{M}$, such as the variance of the disturbances driving the components and the impulse response function, are unknown and have to be estimated; (ii) *estimation error*, the latent components are estimated with a positive variance even if a doubly infinite sample on y_t is available; (iii) *statistical revision*, as new observations become available, the estimate of a signal is updated so as to incorporate the new information; (iv) *data revision*.

The first source can be assessed by various methods in the classical approach; it is automatically incorporated in the interval estimates of the output gap if a Bayesian approach is adopted, as in section 9.3.2.2. The methods rely on the fundamental result that, under regularity conditions, the ML estimator of Ξ has the asymptotic distribution $\tilde{\Xi} \sim \mathrm{N}(\Xi, \mathbf{V})$, where $\mathbf{V}$ is the inverse of the information matrix. Hamilton (1986) proposed a Bayesian marginalization approach, which uses $\tilde{\Xi} \sim \mathrm{N}(\Xi, \mathbf{V})$ as a normal approximation to the posterior distribution of Ξ, given the available data. Then, a measure of the uncertainty of the smoothed estimates of the output gap, which embodies parameter uncertainty, is:

$$\widehat{\mathrm{Var}}(\psi_t|\mathcal{F}) = \frac{1}{K}\sum_{k=1}^{K} \mathrm{Var}(\psi_t|\mathcal{F}, \tilde{\Xi}^{(k)})] + \frac{1}{K}\sum_{k=1}^{K}\left[\mathrm{E}(\psi_t|\mathcal{F}, \tilde{\Xi}^{(k)}) - \hat{\mathrm{E}}(\psi_t|\mathcal{F})\right]^2, \quad (9.27)$$

where $\hat{\mathrm{E}}(\psi_t|\mathcal{F}) = \frac{1}{K}\sum_{k=1}^{K} \mathrm{E}(\psi_t|\mathcal{F}, \tilde{\Xi}^{(k)})$, and the $\tilde{\Xi}^{(k)}$s are independent draws from the multivariate normal density $\mathrm{N}(\tilde{\Xi}, \tilde{\mathbf{V}}), k = 1, \ldots, K$, where $\tilde{\mathbf{V}}$ is evaluated at $\tilde{\Xi}$. According to the *delta method* proposed by Ansley and Kohn (1986), expressing the output gap estimates as a linear function of the parameter estimation error $\Xi - \tilde{\Xi}$ gives:

$$\widehat{\mathrm{Var}}(\psi_t|\mathcal{F}) = \mathrm{Var}(\psi_t|\mathcal{F}, \tilde{\Xi}) + \mathbf{d}(\tilde{\Xi})'\tilde{\mathbf{V}}\mathbf{d}(\tilde{\Xi}), \qquad \mathbf{d}(\tilde{\Xi}) = \frac{\partial}{\partial \boldsymbol{\Xi}}\mathrm{E}(\psi_t|\mathcal{F}, \tilde{\Xi})\,\big|_{\Xi=\tilde{\Xi}}, \quad (9.28)$$

where the derivatives in $\mathbf{d}(\tilde{\Xi})$ are evaluated numerically using the support of the Kalman filter and smoother. Similar methods apply for the real-time estimates, with the ML estimator being based on the information set $\mathcal{F}_t$. Quenneville and Singh (2000) evaluate and compare the two methods, and propose enhancements in a Bayesian perspective.

In an unobserved component framework the Kalman filter and smoother provide all the relevant information for assessing (ii) and (iii). For the latter, we can keep track of revisions by using a *fixed-point smoothing* algorithm (see Anderson and Moore, 1979; de Jong, 1989).

The sources (ii) and (iii) typically arise because the individual components are unobserved and are dependent through time. The availability of additional time series observations helps to improve the estimation of an unobserved component. Multivariate methods are more reliable as they use repeated measures of the same underlying latent variable and this increases the precision of the estimates. It is important to measure the uncertainty that surrounds the real time, or concurrent, estimates, $\mathsf{Var}(\psi_t|\mathcal{F}_t, \tilde{\Xi})$, which are conditional on the information set available to economic agents and policy makers at the time of making the assessment of the state of the economy, as opposed to the historical, or final, estimates. Comparing $\mathsf{Var}(\psi_t|\mathcal{F}_t, \tilde{\boldsymbol{\theta}})$ with the final estimation error variance, $\mathsf{Var}(\psi_t|\mathcal{F}_n, \tilde{\Xi}), n \to \infty$, gives a clue about the magnitude of the revision of the estimates as new observations become available.

In the absence of structural breaks, statistical revisions are sound and a fact of life (i.e., a natural consequence of optimal signal extraction). There is, however, great concern about revisions, especially for policy purposes; Orphanides and van Norden (2002) propose temporal consistency as a yardstick for assessing the reliability of output gap estimates; temporal consistency occurs when real-time (filtered) estimates do not differ significantly from the final (smoothed) estimates.

Finally, an additional source of uncertainty is data revision, which concerns y_t. Timely economic data are only provisional and are revised subsequently with the accrual of more complete information. Data revision is particularly relevant for national accounts aggregates, which require integrating statistical information from different sources and balancing it so as to produce internally consistent estimates.

9.5 Appendix A: Linear filters

A linear filter applied to a univariate series y_t is a weighted linear combination of its consecutive values. A time invariant filter can be represented as:

$$\mathrm{w}(L) = \sum_j \mathrm{w}_j L^j, \tag{9.29}$$

with w_j representing the filter weights. The above filter is symmetric if $\mathrm{w}_j = \mathrm{w}_{-j}$, in which case we can write $\mathrm{w}(L) = w_0 + \sum_j \mathrm{w}_j(L^j + L^{-j})$.

Applying $\mathrm{w}(L)$ to y_t yields $\mathrm{w}(L)y_t$ and has two consequences: the amplitude of the original fluctuations will be compressed or enhanced and the displacement over time of the original fluctuations will be altered. These effects can be fully understood in the frequency domain by considering the frequency response function (FRF) associated with the filter, which is defined as the Fourier transform of (9.29): $\mathrm{w}(e^{-\imath\omega}) = \sum_j \mathrm{w}_j e^{-\imath\omega j} = \mathrm{w}_{\mathcal{R}}(\omega) + \imath w_{\mathcal{I}}(\omega)$, where $\mathrm{w}_{\mathcal{R}}(\omega) = \sum_j \mathrm{w}_j \cos \omega j$ and $\mathrm{w}_{\mathcal{I}}(\omega) = \sum_j \mathrm{w}_j \sin \omega j$. The last equality stresses that, in general, the FRF is a complex quantity, with $w_{\mathcal{R}}(\omega)$ and $\mathrm{w}_{\mathcal{I}}(\omega)$ representing its real and complex part, respectively. The polar representation of the FRF, $\mathrm{w}(e^{-\imath\omega}) = G(\omega)e^{-\imath Ph(\omega)}$, is written in terms of two crucial quantities, the *gain*, $G(\omega) = |\mathrm{w}(e^{-\imath\omega})| = \sqrt{\mathrm{w}_{\mathcal{R}}(\omega)^2 + \mathrm{w}_{\mathcal{I}}(\omega)^2}$,

and the *phase* $Ph(\omega) = \arctan(-\mathrm{w}_{\mathcal{I}}(\omega)/\mathrm{w}_{\mathcal{R}}(\omega))$. The former measures the amplitude effect of the filter, so that if at some frequencies the gain is less than one, then those frequency components will be attenuated in the filtered series; the latter measures the displacement, or the phase shift, of the signal.

If $f_y(\omega)$ denotes the spectrum of y_t, the spectrum of $\mathrm{w}(L)y_t$ is equal to $|\mathrm{w}(e^{-i\omega})|^2 f_y(\omega)$, and therefore the square of the gain function (also known as the *power transfer function*) provides the factor by which the spectrum of the input series is multiplied to obtain that of the filtered series. In the important special case when $\mathrm{w}(L)$ is symmetric, the phase displacement is zero, and the gain is simply $G(\omega) = |\mathrm{w}_0 + 2\sum_{j=1}^{m} \mathrm{w}_j \cos \omega j|$.

9.6 Appendix B: The Wiener–Kolmogorov filter

The classical Wiener–Kolmogorov prediction theory, which is restricted to stationary processes, deals with optimal signal extraction of an unobserved component. Letting μ_t denote some stationary signal and y_t an indeterministic linear process with Wold representation $y_t = \nu(L)\xi_t, \nu(L) = 1 + \nu_1 L + \nu_2 L^2 + \cdots, \sum |\nu_j| < \infty$, $\xi_t \sim \mathrm{WN}(0, \sigma^2)$, the minimum mean square linear estimator of μ_{t+l} based on a semi-infinite sample $y_{t-j}, j = 0, 1, \ldots, \infty$, is:

$$\tilde{\mu}_{t+l|t} = \frac{1}{\sigma^2 \nu(L)} \left[\frac{g_{\mu y}(L)}{\nu(L^{-1})} L^{-l} \right]_+ y_t. \tag{9.30}$$

Here, $g_{\mu y}(L)$ denotes the cross-covariance generating function of μ_t and y_t, $g_{\mu y}(L) = \sum_j \gamma_{\mu y, j} L^j$, where $\gamma_{\mu y, j}$ is the cross-covariance at lag j, $\mathrm{E}[(\mu_t - \mathrm{E}(\mu_t))(y_{t-j} - \mathrm{E}(y_t))]$, and for $h(L) = \sum_{j=-\infty}^{\infty} h_j L^j$, $[h(L)]_+ = \sum_{j=0}^{\infty} h_j L^j$, i.e., a polynomial containing only non-negative powers of L; see Whittle (1983, p. 42). The formula for $l \leq 0$ provides the weights for signal extraction (contemporaneous filtering for $l = 0$).

If an infinite realization of future y_t was also available, the minimum mean square linear estimator is:

$$\tilde{\mu}_{t|\infty} = \frac{g_{\mu y}(L)}{g_y(L)} y_t,$$

where $g_y(L)$ is the autocovariance generating function of y_t, $g_y(L) = |\nu(L)|^2 \sigma^2$, and $|\nu(L)|^2 = \nu(L)\nu(L^{-1})$. If the series is decomposed into two orthogonal components, $y_t = \mu_t + \psi_t$, $g_{\mu y}(L) = g_\mu(L)$ (see Whittle, 1983, Ch. 5).

These formulae also hold when y_t and μ_t are non-stationary (see Pierce, 1979). As an example of their application, the expressions for the final and concurrent estimators of the trend component for model (9.2), with $\sigma_\eta^2 = 0$ and $\sigma_\psi^2/\sigma_\zeta^2 = \lambda$ (Leser–HP filter), are:

$$\tilde{\mu}_{t|\infty} = \frac{1}{1 + \lambda|1 - L|^4} y_t, \quad \tilde{\mu}_{t|t} = \frac{\theta(1)}{\theta(L)} y_t,$$

and the corresponding detrending filters are:

$$\tilde{\psi}_{t|\infty} = \frac{\lambda|1-L|^4}{1+\lambda|1-L|^4}y_t, \qquad \tilde{\psi}_{t|t} = \frac{\theta(L)-\theta(1)}{\theta(L)}y_t.$$

Here, $\theta(L) = 1+\theta_1 L+\theta_2 L^2$ is the reduced form MA polynomial of the local linear trend model (9.2). The numerator of the filtered detrended series can be rewritten: $\theta(L)-\theta(1) = \Delta\theta^*(1)L + \Delta^2\theta_0^*$, with $\theta^*(L) = \theta_0^* + \theta_1^* L = -(\theta_1+\theta_2) - \theta_2 L$.

The expression for $\tilde{\psi}_{t|\infty}$ is sometimes mistakenly taken to imply that the Leser–HP cycle filter makes stationary series that are integrated up to the fourth order, due to the presence of $|1-L|^4 = (1-L)^2(1-L^{-1})^2$ in the numerator of the filter. It should be recalled that the above formula holds true only for a doubly-infinite sample, and the real-time filter for extracting $\tilde{\psi}_{t|t}$ contains only the factor Δ^2.

9.7 Appendix C: State-space models and methods

The models considered in this chapter admit the state-space representation:

$$\begin{aligned} \mathbf{y}_t &= \mathbf{Z}_t\boldsymbol{\alpha}_t + \mathbf{G}_t\boldsymbol{\epsilon}_t, \quad t = 1,2,\ldots,n, \\ \boldsymbol{\alpha}_t &= \mathbf{T}_t\boldsymbol{\alpha}_{t-1} + \mathbf{H}_t\boldsymbol{\eta}_t, \end{aligned} \tag{9.31}$$

where $\boldsymbol{\epsilon}_t \sim \text{NID}(\mathbf{0},\mathbf{I})$, $\boldsymbol{\eta}_t \sim \text{NID}(\mathbf{0},\mathbf{I})$, and $\text{E}(\boldsymbol{\epsilon}_t\boldsymbol{\eta}_t') = \mathbf{0}$. The initial conditions are specified as follows: $\boldsymbol{\alpha}_0 = \tilde{\boldsymbol{\alpha}}_{0|0}^* + \mathbf{W}_0\boldsymbol{\delta} + \mathbf{H}_0\boldsymbol{\eta}_0$, so that $\boldsymbol{\alpha}_1|\boldsymbol{\delta} \sim \text{N}(\tilde{\boldsymbol{\alpha}}_{1|0}^* + \mathbf{W}_1\boldsymbol{\delta}, \mathbf{P}_{1|0}^*)$, where $\tilde{\boldsymbol{\alpha}}_{1|0}^* = \mathbf{T}_1\tilde{\boldsymbol{\alpha}}_{0|0}^*, \mathbf{W}_1 = \mathbf{T}_1\mathbf{W}_0$, and $\mathbf{P}_{1|0}^* = \mathbf{H}_1\mathbf{H}_1' + \mathbf{T}_1\mathbf{H}_0\mathbf{H}_0'\mathbf{T}_1'$. The random vector $\boldsymbol{\delta}$ captures the initial conditions for non-stationary state components and is assumed to have a diffuse distribution, $\boldsymbol{\delta} \sim \text{N}(\mathbf{0}, \Sigma_\delta)$, with $\Sigma_\delta^{-1} \to 0$. The matrices $\mathbf{Z}_t, \mathbf{G}_t, \mathbf{T}_t, \mathbf{H}_t, \mathbf{W}_0$ are deterministically related to a set of hyperparameters, Ξ.

For instance, for the bivariate model of output and inflation considered in section 9.3.1, $\mathbf{y}_t$ is a bivariate time series, $\boldsymbol{\alpha}_t = (\mu_t, \beta_t, \psi_t, \psi_{t-1}, \tau_t)'$, $\mathbf{Z}_t = \mathbf{Z} = (\mathbf{z}_y, \mathbf{z}_p)'$, $\mathbf{z}_y' = (1,0,1,0,0)$, $\mathbf{z}_p' = (0,0,0,0,1)$, $\boldsymbol{\epsilon}_t = \varepsilon_t/\sigma_\varepsilon$, $\mathbf{G}_t = \mathbf{G} = (0,\sigma_\varepsilon)'$, $\boldsymbol{\eta}_t = (\eta_t/\sigma_\eta, \kappa_t/\sigma_\kappa, \upsilon_t/\sigma_\upsilon)'$, $\boldsymbol{\delta} = (\mu_0, \beta_0, \tau_0)'$, $\tilde{\boldsymbol{\alpha}}_{0|0}^* = \mathbf{0}$,

$$\mathbf{T}_t = \mathbf{T} = \begin{pmatrix} \mathbf{T}_\mu & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{T}_\psi & \mathbf{0} \\ \mathbf{0}' & \mathbf{t}_p' & 1 \end{pmatrix}, \mathbf{T}_\mu = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \mathbf{T}_\psi = \begin{pmatrix} \phi_1 & \phi_2 \\ 1 & 0 \end{pmatrix}, \mathbf{t}_p = \begin{pmatrix} \theta_{\tau 0}\phi_1 + \theta_{\tau 1} \\ \theta_{\tau 0}\phi_2 \end{pmatrix},$$

$$\mathbf{H}_t = \mathbf{H} = \begin{pmatrix} \sigma_\eta & 0 & 0 \\ 0 & 0 & 0 \\ 0 & \sigma_\kappa & 0 \\ 0 & 0 & 0 \\ 0 & \theta_{\tau 0}\sigma_\kappa & 0 \end{pmatrix}, \mathbf{W}_0 = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \boldsymbol{\eta}_0 \sim \text{N}(\mathbf{0}, \mathbf{I}_2), \mathbf{H}_0 = \begin{pmatrix} \mathbf{0} \\ \mathbf{C}_\psi \\ 0 \end{pmatrix},$$

where $\mathbf{C}_\psi$ is such that $\text{E}(\boldsymbol{\psi}_0\boldsymbol{\psi}_0') = \mathbf{C}_\psi\mathbf{C}_\psi'$, $\boldsymbol{\psi}_0 = (\psi_0, \psi_{-1})'$.

9.7.1 The augmented Kalman filter

The Kalman filter (KF) is a fundamental algorithm for the statistical treatment of a state-space model. Under the Gaussian assumption it produces the minimum mean square estimator of the state vector along with its mean square error matrix, conditional on past information; this is used to build the one-step-ahead predictor of $\mathbf{y}_t$ and its mean square error matrix. Due to the independence of the one-step-ahead prediction errors, the likelihood can be evaluated via the prediction error decomposition.

The case when $\boldsymbol{\delta}$ is a fixed vector (fixed initial conditions) has been considered by Rosenberg (1973). He showed that $\boldsymbol{\delta}$ can be concentrated out of the likelihood function and that its generalized least square estimate is obtained from the output of an augmented KF. The diffuse case has been dealt with by de Jong (1989).

Defining $\mathbf{A}_{1|0} = -\mathbf{W}_1$, $q_0 = 0, \mathbf{s}_0 = \mathbf{0}, \mathbf{S}_0 = \mathbf{0}$, the augmented KF is given by the following recursive formulae and definitions for $t = 1, \ldots, n$:

$$
\begin{array}{ll}
\mathbf{v}_t^* = \mathbf{y}_t - \mathbf{Z}_t\tilde{\boldsymbol{\alpha}}_{t|t-1}^*, & \mathbf{V}_t = -\mathbf{Z}_t\mathbf{A}_{t|t-1}, \\
\mathbf{F}_t^* = \mathbf{Z}_t\mathbf{P}_{t|t-1}^*\mathbf{Z}_t' + \mathbf{G}_t\mathbf{G}_t', & \mathbf{K}_t = \mathbf{T}_{t+1}\mathbf{P}_{t|t-1}^*\mathbf{Z}_t'\mathbf{F}_t^{*-1}, \\
q_t = q_{t-1} + \mathbf{v}_t^{*'}\mathbf{F}_t^{*-1}\mathbf{v}_t^*, \;\; \mathbf{s}_t = \mathbf{s}_{t-1} + \mathbf{V}_t'\mathbf{F}_t^{*-1}\mathbf{v}_t^*, & \mathbf{S}_t = \mathbf{S}_{t-1} + \mathbf{V}_t'\mathbf{F}_t^{*-1}\mathbf{V}_t, \\
\tilde{\boldsymbol{\alpha}}_{t+1|t}^* = \mathbf{T}_{t+1}\tilde{\boldsymbol{\alpha}}_{t|t-1}^* + \mathbf{K}_t\mathbf{v}_t^*, & \mathbf{A}_{t+1|t} = \mathbf{T}_{t+1}\mathbf{A}_{t|t-1} + \mathbf{K}_t\mathbf{V}_t \\
\mathbf{P}_{t+1|t}^* = \mathbf{T}_{t+1}\mathbf{P}_{t|t-1}^*\mathbf{T}_{t+1}' + \mathbf{H}_{t+1}\mathbf{H}_{t+1}' - \mathbf{K}_t\mathbf{F}_t^*\mathbf{K}_t'. &
\end{array}
\tag{9.32}
$$

The diffuse likelihood is defined as follows (de Jong, 1991):

$$
\ell(\mathbf{y}_1, \ldots, \mathbf{y}_n; \Xi) = -\frac{1}{2}\left(\sum_t \ln|\mathbf{F}_t^*| + \ln|\mathbf{S}_n| + q_n - \mathbf{s}_n'\mathbf{S}_n^{-1}\mathbf{s}_n\right). \tag{9.33}
$$

Denoting $\mathbf{Y}_t = \{\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_t\}$, the innovations, $\mathbf{v}_t = \mathbf{y}_t - \mathrm{E}(\mathbf{y}_t|\mathbf{Y}_{t-1})$, the conditional covariance matrix $\mathbf{F}_t = \mathrm{Var}(\mathbf{y}_t|\mathbf{Y}_{t-1})$, the one-step-ahead prediction of the state vector $\tilde{\boldsymbol{\alpha}}_{t|t-1} = \mathrm{E}(\boldsymbol{\alpha}_t|\mathbf{Y}_{t-1})$, and the corresponding covariance matrices, $\mathrm{Var}(\boldsymbol{\alpha}_t|\mathbf{Y}_{t-1}) = \mathbf{P}_{t|t-1}$, are given by:

$$
\begin{array}{lcllcl}
\mathbf{v}_t & = & \mathbf{v}_t^* - \mathbf{V}_t\mathbf{S}_{t-1}^{-1}\mathbf{s}_{t-1}, & \mathbf{F}_t & = & \mathbf{F}_t^* + \mathbf{V}_t\mathbf{S}_{t-1}^{-1}\mathbf{V}_t', \\
\tilde{\boldsymbol{\alpha}}_{t|t-1} & = & \tilde{\boldsymbol{\alpha}}_{t|t-1}^* - \mathbf{A}_{t|t-1}\mathbf{S}_{t-1}^{-1}\mathbf{s}_{t-1}, & \mathbf{P}_{t|t-1} & = & \mathbf{P}_{t|t-1}^* + \mathbf{A}_{t|t-1}\mathbf{S}_{t-1}^{-1}\mathbf{A}_{t|t-1}'.
\end{array}
\tag{9.34}
$$

9.7.2 Real-time (updated) estimates

The *updated* (or *real-time*, *filtered*) estimates of the state vector, $\tilde{\boldsymbol{\alpha}}_{t|t} = \mathrm{E}(\boldsymbol{\alpha}_t|\mathbf{Y}_t)$, and the covariance matrix of the real-time estimation error are, respectively:

$$
\begin{aligned}
\tilde{\boldsymbol{\alpha}}_{t|t} &= \tilde{\boldsymbol{\alpha}}_{t|t-1}^* - \mathbf{A}_{t|t-1}\mathbf{S}_t^{-1}\mathbf{s}_t + \mathbf{P}_{t|t-1}^*\mathbf{Z}_t'\mathbf{F}_t^{-1}(\mathbf{v}_t^* - \mathbf{V}_t\mathbf{S}_t^{-1}\mathbf{s}_t), \\
\mathbf{P}_{t|t} &= \mathbf{P}_{t|t-1}^* - \mathbf{P}_{t|t-1}^*\mathbf{Z}_t'\mathbf{F}_t^{*-1}\mathbf{Z}_t\mathbf{P}_{t|t-1}^* + (\mathbf{A}_{t|t-1} + \mathbf{P}_{t|t-1}^*\mathbf{Z}_t'\mathbf{F}_t^{*-1}\mathbf{V}_t)\mathbf{S}_t^{-1}(\mathbf{A}_{t|t-1} \\
&\quad + \mathbf{P}_{t|t-1}^*\mathbf{Z}_t'\mathbf{F}_t^{*-1}\mathbf{V}_t)'.
\end{aligned}
$$

9.7.3 Smoothing

Smoothing deals with the estimation of the components and the disturbances based on the full sample of observations. In the Gaussian case the *fixed interval smoother* provides the minimum mean square estimator of $\boldsymbol{\alpha}_t$ using $\mathbf{Y}_n$, $\tilde{\boldsymbol{\alpha}}_{t|n} = \mathrm{E}(\boldsymbol{\alpha}_t|\mathbf{Y}_n)$, along with its covariance matrix $\mathbf{P}_{t|n} = \mathrm{E}[(\boldsymbol{\alpha}_t - \tilde{\boldsymbol{\alpha}}_{t|n})(\boldsymbol{\alpha}_t - \tilde{\boldsymbol{\alpha}}_{t|n})'|\mathbf{Y}_n]$. The computations can be carried out efficiently using the following backwards recursive formulae, given by Bryson and Ho (1969) and de Jong (1989), starting at $t = n$, with initial values $\mathbf{r}_n = 0, \mathbf{R}_n = \mathbf{0}$ and $\mathbf{N}_n = 0$:

$$\mathbf{r}_{t-1} = \mathbf{L}_t'\mathbf{r}_t + \mathbf{Z}_t'\mathbf{F}_t^{*-1}\mathbf{v}_t, \quad \mathbf{R}_{t-1} = \mathbf{L}_t'\mathbf{R}_t + \mathbf{Z}_t'\mathbf{F}_t^{*-1}\mathbf{V}_t, t = n-1, \ldots, 1.$$

$$\mathbf{N}_{t-1} = \mathbf{L}_t'\mathbf{N}_t\mathbf{L}_t + \mathbf{Z}_t'\mathbf{F}_t^{*-1}\mathbf{Z}_t,$$

$$\tilde{\boldsymbol{\alpha}}_{t|n} = \tilde{\boldsymbol{\alpha}}_{t|t-1}^* - \mathbf{A}_{t|t-1}\mathbf{S}_n^{-1}\mathbf{s}_n + \mathbf{P}_{t|t-1}^*(\mathbf{r}_{t-1} - \mathbf{R}_{t-1}\mathbf{S}_n^{-1}\mathbf{s}_n),$$

$$\mathbf{P}_{t|n} = \mathbf{P}_{t|t-1}^* - \mathbf{P}_{t|t-1}^*\mathbf{N}_{t-1}\mathbf{P}_{t|t-1}^* + (\mathbf{A}_{t|t-1} + \mathbf{P}_{t|t-1}^*\mathbf{R}_{t-1})\mathbf{S}_n^{-1}(\mathbf{A}_{t|t-1} + \mathbf{P}_{t|t-1}^*\mathbf{R}_{t-1})', \tag{9.35}$$

where $\mathbf{L}_t = \mathbf{T}_{t+1} - \mathbf{K}_t\mathbf{Z}_t'$. A preliminary forward KF pass is required to store the quantities $\tilde{\boldsymbol{\alpha}}_{t|t-1}^*$, $\mathbf{A}_{t|t-1}$, $\mathbf{P}_{t|t-1}^*$, $\mathbf{v}_t^*$, $\mathbf{V}_t$, $\mathbf{F}_t^*$ and $\mathbf{K}_t$.

The smoothed estimates of the disturbances are given by $\mathbf{H}_t\tilde{\boldsymbol{\eta}}_t = \mathrm{E}(\mathbf{H}_t\boldsymbol{\eta}_t|\mathbf{Y}_n) = \mathbf{H}_t\mathbf{H}_t'(\mathbf{r}_{t-1} - \mathbf{R}_{t-1}\mathbf{S}_n^{-1}\mathbf{s}_n)$, and $\mathbf{G}_t\tilde{\boldsymbol{\epsilon}}_t = \mathrm{E}(\mathbf{G}_t\boldsymbol{\epsilon}_t|\mathbf{Y}_n) = \mathbf{G}_t\mathbf{G}_t'\left[\mathbf{F}_t^{*-1}(\mathbf{v}_t - \mathbf{V}_t\mathbf{S}_n^{-1}\mathbf{s}_n) + \mathbf{K}_t'(\mathbf{r}_t - \mathbf{R}_t\mathbf{S}_n^{-1}\mathbf{s}_n)\right]$.

9.7.4 The simulation smoother

The simulation smoother is an algorithm which draws samples from the conditional distribution of the states and the disturbances given the observations and the hyperparameters. Carlin, Polson and Stoffer (1992) proposed a single-move state sampler, by which the states are sampled one at a time. This proves to be inefficient in the presence of highly autocorrelated state components. Gamerman (1998) proposed a single move disturbance sampler, which is more efficient since the disturbances driving the components are much less persistent and autocorrelated over time. Along with reparameterization, an effective strategy is blocking, through the adoption of a multi-move sampler as in Carter and Kohn (1994) and Früwirth-Schnatter (1994), who focus on sampling the states. Again, a more efficient multi-move sampler can be constructed by focusing on the disturbances, rather than the states. This is the idea underlying the simulation smoother proposed by de Jong and Shephard (1996).

Let $\boldsymbol{\varsigma}_t = \mathbf{C}[\boldsymbol{\epsilon}_t', \boldsymbol{\eta}_t']'$ denote a sub-set of the disturbances of the series, with $\mathbf{C}$ being a selection matrix. The structure of the state-space model model is such that the states are a (possibly singular) linear transformation of the disturbances and that $\mathbf{G}_t\boldsymbol{\epsilon}_t$ can be recovered from $\mathbf{H}_t\boldsymbol{\eta}_t$ via the measurement equation, which implies that the distribution of $(\boldsymbol{\epsilon}', \boldsymbol{\eta}')'|\mathbf{Y}_n$ is singular. Hence, to achieve efficiency and to avoid degeneracies, we need to focus on a suitably selected sub-set of the disturbances. The simulation smoother hinges on the following factorization of

the joint posterior density:

$$f(\varsigma_0, \ldots, \varsigma_n|\mathbf{Y}_n) = f(\varsigma_n|\mathbf{y}) \prod_{t=0}^{n-1} f(\varsigma_t|\varsigma_{t+1}, \ldots, \varsigma_n; \mathbf{Y}_n).$$

Conditional random vectors are generated recursively: in the forward step the Kalman filter is run and the innovations, their covariance matrix and the Kalman gain are stored. In the backwards sampling step conditional random vectors are generated recursively from $\varsigma_t|\varsigma_{t+1}, \ldots, \varsigma_n; \mathbf{y}$; the algorithm keeps track of all the changes in the mean and the covariance matrix of these conditional densities. The simulated disturbances are then inserted into the transition equation to obtain a sample from $\boldsymbol{\alpha}|\mathbf{Y}_n$.

A more efficient simulation smoother has been developed by Durbin and Koopman (2002). The gain in efficiency arises from the fact that only the first conditional moments of the states or the disturbances need to be evaluated. Let us redefine $\varsigma_t = (\boldsymbol{\epsilon}_t', \boldsymbol{\eta}_t')'$ and let $\tilde{\varsigma} = \mathrm{E}(\varsigma|\mathbf{Y}_n)$, where ς is the stack of the vectors ς_t; $\tilde{\varsigma}$ is computed by the disturbance smoother (see Koopman, 1993, and Appendix C, section 9.7.3). We can write $\varsigma = \tilde{\varsigma} + \varsigma^*$, where $\varsigma^* = \varsigma - \tilde{\varsigma}$ is the disturbance smoothing error, with conditional distribution $\varsigma^*|\mathbf{Y}_n \sim \mathrm{N}(\mathbf{0}, \mathbf{V})$, such that the covariance matrix $\mathbf{V}$ does not depend on the observations, and thus does not vary across the simulations (the diagonal blocks are computed by the smoothing algorithm in Appendix C, section 9.7.3). A sample from $\varsigma^*|\mathbf{Y}_n$ is constructed as follows: we first draw the disturbances from their unconditional Gaussian distribution $\varsigma^+ \sim \mathrm{NID}(0, \mathbf{I})$ and construct the pseudo observations $\mathbf{y}^+$ recursively from $\boldsymbol{\alpha}_t^+ = \mathbf{T}_t\boldsymbol{\alpha}_{t-1}^+ + \mathbf{H}_t\boldsymbol{\eta}_t^+, \mathbf{y}_t^+ = \mathbf{Z}_t\boldsymbol{\alpha}_t^+ + \mathbf{G}_t\boldsymbol{\epsilon}_t^+, t = 1, 2, \ldots, n$, where the initial draw is $\boldsymbol{\alpha}_0^+ \sim \mathrm{N}(\mathbf{0}, \mathbf{H}_0\mathbf{H}_0')$. The Kalman filter and the smoothing algorithm computed on the simulated observations $\mathbf{y}_t^+$ will produce $\tilde{\varsigma}_t^+$ and $\tilde{\boldsymbol{\alpha}}_t^+$, and $\varsigma_t^+ - \tilde{\varsigma}_t^+$ will be the desired draw from $\varsigma^*|\mathbf{Y}_n$. Hence, $\tilde{\varsigma} + \varsigma_t^+ - \tilde{\varsigma}_t^+$ is a sample from $\varsigma|\mathbf{Y}_n \sim \mathrm{N}(\tilde{\varsigma}, \mathbf{V})$.

Acknowledgments

The author wishes to thank Andrew Harvey, Terence Mills and Alberto Musso for their useful suggestions.

Notes

1. Assuming $\boldsymbol{\mu}_* = (\mu_1, \mu_2)' \sim \mathrm{N}(\mathbf{0}, \Sigma_\mu)$, and that the process μ_t has started in the indefinite past, $\Sigma_\mu^{-1} \to \mathbf{0}$, and thus the quadratic form $\boldsymbol{\mu}_*'\Sigma_\mu^{-1}\boldsymbol{\mu}_*$ converges to zero.
2. All the computations in this chapter have been performed using Ox version 4 (see Doornik, 2006).
3. The slope parameter is included in the state vector; the transition equation is $\beta_t = \beta_{t-1}$, with β_0 being a diffuse parameter (see Appendix C, section 9.7).

Fractional Integration and Cointegration: An Overview and an Empirical Application

Luis A. Gil-Alana and Javier Hualde

Abstract

In this chapter we first review the theoretical and empirical work on fractional integration and cointegration, placing special emphasis on the estimation procedures for fractionally cointegrated systems. An empirical application is then carried out using some of the more recently developed techniques in this area. In particular, we investigate the purchasing power parity hypothesis for four bivariate price series, the US ("domestic") versus the "foreign" countries Australia, Canada, Italy and the UK. Fractional cointegration is found in the US–UK relationship.

10.1 Introduction

One characteristic of many economic and financial time series is its non-stationary nature. There exists a great variety of models to describe such non-stationarity.

Until the 1980s a standard approach was to impose a deterministic (linear or quadratic) function of time, thus assuming that the residuals from the regression model were stationary. Later on, and especially after the seminal work of Nelson and Plosser (1982), there was a general agreement that the non-stationary component of most series was stochastic, and unit roots (or first differences) were commonly adopted. However, the unit root is merely one particular model to describe such behavior. In fact, the number of differences required to get to stationarity may not necessarily be an integer value but any point in the real line.[1] In such a case, the process is said to be fractionally integrated or $I(d)$. The $I(d)$ models belong to a wider class of processes called long memory, which we can define in either the time or the frequency domains.

Let us consider a zero mean process $\{x_t,\ t = 0, \pm 1, \ldots\}$ with $\gamma_u = E(x_t x_{t+u})$. The time domain definition of long memory states that:

$$\sum_{u=-\infty}^{\infty} |\gamma_u| = \infty.$$

Now, assuming that x_t has an absolutely continuous spectral distribution, so that it has spectral density function:

$$f(\lambda) = \frac{1}{2\pi}\left(\gamma_0 + 2\sum_{u=1}^{\infty}\gamma_u \cos(\lambda u)\right),$$

the frequency domain definition of long memory states that the spectral density function is unbounded at some frequency in the interval $[0, \pi)$. Most of the empirical literature has concentrated on the case where the singularity, or pole, in the spectrum takes place at the zero frequency. This is the standard case of $I(d)$ models of the form:

$$(1 - L)^d x_t = u_t, \quad t = 0, \pm 1, \ldots, \tag{10.1}$$

where L is the lag operator ($Lx_t = x_{t-1}$) and u_t is $I(0)$. However, fractional integration may also occur at some other frequencies away from zero, as in the case of seasonal/cyclical models.

In the multivariate case, the natural extension of fractional integration is the concept of fractional cointegration. Though the original idea of cointegration, as espoused by Engle and Granger (1987), allows for fractional orders of integration, all the empirical work carried out during the 1990s was restricted to the case of integer degrees of differencing. Only in recent years have fractional values also been taken into account.

In this chapter we review fractional integration and cointegration, placing special emphasis on the latter concept, which has recently emerged in the time series literature. We also present an empirical application using some of the most novel techniques in this area. The outline of the chapter is as follows. Section 10.2 concentrates on fractional integration and some of its most recent developments. Section 10.3 deals with fractional cointegration, while section 10.4 is devoted to an empirical example.

10.2 Fractional integration

10.2.1 Concept and modelization

The idea of fractional integration was introduced by Granger and Joyeux (1980), Granger (1980, 1981) and Hosking (1981), though Adenstedt (1974) and Taqqu (1975) earlier showed an awareness of its representation. Assuming that x_t is given by equation (10.1), the first point we have to deal with is the treatment of pre-sample observations. In short memory contexts (that is, $d = 0$), different initial value conventions lead to parameter estimates which typically share the same first-order asymptotic properties but have different finite-sample properties. In empirical work zeros or the sample mean often initiate the series, with early observations being thrown away. Different conventions have also been followed in non-stationary series with an autoregressive unit root. In stationary fractional processes, infinitely many pre-sample values have to be chosen, so the potential divergence between rival methods and parameter estimates is greater, though first-order asymptotic properties are again robust. In fractional contexts, two definitions of fractional integration have been employed. From equation (10.1), for $d < 1/2$:

$$x_t = \Delta^{-d} u_t, t = 0, \pm 1, \ldots,$$

where $\Delta = 1 - L$. For integer $d_a \geq 0$:

$$z_{at} = \Delta^{-d_a} x_t^{\#}, \quad t = 0, \pm 1, \ldots,$$

is called a Type I $(d + d_a)$ process, where the # superscript attached to a scalar or vector sequence has the meaning $w_t^{\#} = w_t 1(t > 0)$, $1(\cdot)$ being the indicator function. Similarly:

$$z_{bt} = \Delta^{-d_a - d} u_t^{\#}, \quad t = 0, \pm 1, \ldots,$$

is called a Type II $(d + d_a)$ process. When $d = 0$, $x_t^{\#} = u_t^{\#}$ and hence $z_{at} = z_{bt}$, so both definitions are equivalent in non-fractional contexts.[2] Note that the polynomial on the left-hand side of (10.1) can be expanded as:

$$(1 - L)^d = \sum_{j=0}^{\infty} \binom{d}{j} (-1)^j L^j = 1 - dL + \frac{d(d-1)}{2} L^2 - \ldots.$$

Thus, if d is an integer value, x_t will be a function of a finite number of past observations, while if d is real, x_t depends upon values of the time series far in the past. The higher the value of d, the higher the level of association between the observations.

There exist several sources that might produce $I(d)$ processes, aggregation being the usual argument. Robinson (1978) and Granger (1980) showed that fractionally integrated data could arise as a result of aggregation when: (i) data are aggregated across heterogeneous autoregressive (AR) processes, and (ii) data involving heterogeneous dynamic relationships at the individual level are then aggregated to form the time series. Cioczek-Georges and Mandelbrot (1995), Taqqu, Willinger and

Sherman (1997) and Chambers (1998) also use aggregation to motivate long memory processes, while Parke (1999) uses a closely related discrete time error duration model. More recently, Diebold and Inoue (2001) proposed another source of long memory based on regime-switching models.[3]

Note that u_t in (10.1) may also include some type of weak dependence structure: for example, a stationary and invertible autoregressive moving average (ARMA) process of the form:

$$\phi(L)u_t = \theta(L)\varepsilon_t, \quad t = 0, \pm 1, \ldots,$$

where ε_t is an independent and identically distributed (i.i.d.) sequence. Thus, when $d < 1/2$, x_t in (10.1) can be written as:

$$\phi(L)(1-L)^d x_t = \theta(L)\varepsilon_t, \quad t = 0, \pm 1, \ldots, \tag{10.2}$$

which is usually called an autoregressive fractionally integrated moving average (ARFIMA) process. Sowell (1992a) analyzed the exact maximum likelihood (ML) estimator of the parameters of the ARFIMA model (10.2) in the time domain, using a recursive procedure that allows quick evaluation of the likelihood function, which is given by:

$$(2\pi)^{-n/2} |\Sigma|^{-1/2} \exp\left(-\frac{1}{2} X_n' \Sigma^{-1} X_n\right),$$

where $X_n = (x_1, x_2, \ldots, x_n)'$ and $X_n \sim N(0, \Sigma)$. Other parametric methods of estimating d in the frequency domain were proposed, among others, by Fox and Taqqu (1986) and Dahlhaus (1989). Small sample properties of these and other estimators were examined in Smith, Taylor and Yadav (1997) and Hauser (1999). In the former, several semiparametric procedures were compared with Sowell's (1992a) ML estimation method, finding that Sowell's procedure outperforms the semiparametric ones in terms of bias and mean square error. Hauser also compares Sowell's procedure with others based on the exact and the Whittle likelihood function in the time and the frequency domain, and shows that Sowell's procedure dominates the others in the case of fractionally integrated models. A semiparametric frequency domain estimator is the log-periodogram estimator proposed by Geweke and Porter-Hudak (1983).[4] Other parametric and semiparametric methods have been proposed: see, for example, Robinson (1994a, 1995a, 1995b), Tanaka (1999), Velasco (1999a, 1999b), and Phillips and Shimotsu (2004, 2005).[5]

So far we have focused on the case where the singularity occurs at the zero frequency. Let us consider now the following process:

$$(1 - 2\cos w_r L + L^2)^d x_t = u_t, \quad t = 0, \pm 1, \ldots, \tag{10.3}$$

where w_r is a real value equal to $2\pi r/n$, with $r = n/c$. In this context, if $d > 0$, the process is also fractionally integrated, although the pole (unboundedness) in the spectrum now occurs at a (cyclical) frequency $\lambda \neq 0$, and c will be an indicator of the number of periods per cycle. These processes were introduced by Gray, Yhang and Woodward (1989, 1994), who showed that the polynomial in (10.3) can be

expressed in terms of the Gegenbauer polynomial such that, for all $d \neq 0$, and setting $\mu = \cos w_r$:

$$(1 - 2\mu L + L^2)^{-d} = \sum_{j=0}^{\infty} C_{j,d}(\mu) L^j,$$

where:

$$C_{j,d}(\mu) = \sum_{k=0}^{j} \frac{(-1)^k (d)_{j-k} (2\mu)^{j-2k}}{k!(j-2k)!}; \quad (d)_j = \frac{\Gamma(d+j)}{\Gamma(d)},$$

and $\Gamma(x)$ is the Gamma function. Alternatively, we can use the recursive formula $C_{0,d}(\mu) = 1$, $C_{1,d}(\mu) = 2\mu d$, and:

$$C_{j,d}(\mu) = 2\mu \left(\frac{d-1}{j} + 1 \right) C_{j-1,d}(\mu) - \left(2\frac{d-1}{j} + 1 \right) C_{j-2,d}(\mu), \quad j = 2, 3, \ldots.$$

(See, for instance, Magnus, Oberhettinger and Soni, 1966, or Rainville, 1960, for further details on Gegenbauer polynomials.) Gray, Yhang and Woodward (1989) showed that x_t in (10.3) is stationary if $d < 0.5$ for $|\mu = \cos w_r| < 1$ and if $d < 0.25$ for $|\mu| = 1$. Lobato and Robinson (1998) proposed a semiparametric approach for testing this type of model, and Dalla and Hidalgo (2005) suggested a parametric test where the unbounded frequency in the spectrum is assumed to be unknown.[6]

As mentioned above, these processes are characterized by an unbounded spectral density function at a single frequency. There may be cases, however, where the spectrum is unbounded at several frequencies simultaneously, the most typical corresponding to a seasonal process. We can consider a model of the form:

$$(1 - L^s)^d x_t = u_t, \quad t = 0, \pm 1, \ldots, \tag{10.4}$$

where s refers to the number of time periods per year (that is, $s = 4$ with quarterly data, $s = 12$ with monthly). Similarly to (10.1), the (seasonal) fractional polynomial above can be expressed as:

$$(1 - L^s)^d = \sum_{j=0}^{\infty} \binom{d}{j} (-1)^j L^{js} = 1 - dL^s + \frac{d(d-1)}{2} L^{2s} - \ldots,$$

for all real d, so that d becomes crucial for describing the degree of seasonal persistence. The notion of fractional Gaussian noise with seasonality was initially suggested by Abrahams and Dempster (1979) and Jonas (1981), and extended to a Bayesian framework by Carlin, Dempster and Jonas (1985) and Carlin and Dempster (1989). Note that if, for example, $s = 4$, the polynomial $(1 - L^4)$ can be decomposed into $(1 - L)(1 + L)(1 + L^2)$, which is thus a case of multiple poles in the spectrum (at zero, π, and $\pi/2$ ($3\pi/2$) of a 2π cycle), all of them, according to (10.4), with the same order of integration d.

10.2.2 Empirical evidence of fractional integration

The empirical literature on fractional integration is large. In the 1960s, Granger (1966) and Adelman (1965) had pointed out that most aggregate economic time

series have a typical shape where by the spectral density increases dramatically as the frequency approaches zero. However, differencing the data frequently leads to overdifferencing at the zero frequency. Some 15 years later, Robinson (1978) and Granger (1980) showed that aggregation could be a source of fractional integration. Since then, fractional processes have been widely employed to describe the dynamics of many time series. Given the vast amount of empirical work, this section is divided into various sub-sections according to the different nature of the series under examination.

10.2.2.1 Applications to macroeconomics

Diebold and Rudebusch (1989) and Sowell (1992b) analyzed US quarterly post-war real output data and obtained estimates of d below unity. Nevertheless, their results were in line with Rudebusch's (1993) and Christiano and Eichembaum's (1990) conclusions in the sense that their confidence intervals for d included the unit root and, in Sowell's case, also the trend-stationary $I(0)$ representation. Haubrich and Lo (1991) examined US real output using R/S techniques and found little evidence of long-range dependence in the business cycle. Using Bayesian techniques, Koop *et al.* (1997) also examined real US GNP and found some evidence of long memory, although their results also reflected model uncertainty. Michelacci and Zaffaroni (2000) showed that GDP per capita in 16 OECD countries exhibited long memory. Mayoral (2006) also finds evidence of fractional integration in real GNP and GNP per capita in the US, showing that their results are robust to the presence of structural breaks in the deterministic components.[7]

Long memory in inflation rates is another topic that has been widely examined in the empirical literature. Much of the evidence supports the view that inflation is fractionally integrated with a differencing parameter that is significantly different from zero or unity. For US monthly data, Backus and Zin (1993) found a fractional degree of integration. They argue that aggregation across agents with heterogeneous beliefs results in long memory in inflation. Hassler (1993) and Delgado and Robinson (1994) provide strong evidence of long memory in the Swiss and Spanish inflation rates respectively. Baillie, Chung and Tieslau (1996) examined monthly post-World War II CPI inflation in ten countries, and found evidence of long memory with mean-reverting (with smaller memory than one) behavior in all countries except Japan. Similar evidence was found in Hassler and Wolters (1995) and Baum, Barkoulas and Caglayan (1999). In the context of structural breaks, Bos, Franses and Ooms (1999, 2001) examined inflation in the G7 countries, finding that long memory is quite resistant to level shifts, although, for a few inflation rates, they found that the evidence for long memory disappeared. Evidence of long memory behavior in the conditional mean of inflation is found in Baillie, Chung and Tieslau (1996) and Baillie, Han and Kwon (2002). Other recent papers relating long memory and structural breaks in inflation rates are Gadea, Sabate and Serrano (2004), Franses, Hyung and Penn (2006) and Gil-Alana (2008a), and forecasting issues are examined in Franses and Ooms (1997) and Barkoulas and Baum (2006).

Other variables, such as consumption and income, have been analyzed from a fractional viewpoint in Diebold and Rudebusch (1991), Haubrich (1993) and Dolado and Marmol (2004). Finally, Crato and Rothman (1994a) and Gil-Alana and Robinson (1997) analyzed updated versions of Nelson and Plosser's (1982) dataset, which has 14 US macroeconomic series, and found evidence of fractional integration in practically all series.

10.2.2.2 Applications to exchange rates

The theory of purchasing power parity (PPP) occupies a central place in international economics, being a key building block in monetary models of exchange rate determination. In a flexible-price monetary model, PPP is assumed to hold continuously. In a sticky-price model, PPP does not hold, but is a maintained assumption for the long run. The question of interest is to determine if deviations from PPP are transitory or permanent. Applying R/S techniques to daily rates for the British pound, French franc and Deutsche mark, Booth, Kaen and Koveos (1982) found positive memory during the flexible exchange rate period (1973–79) but negative memory (that is, anti-persistence) during the fixed exchange rate period (1965–71). Later, Cheung (1993) also found evidence of long memory behavior in foreign exchange markets during the managed floating regime. On the other hand, Baum, Barkoulas and Caglayan (1999) estimated ARFIMA models for real exchange rates in the post-Bretton Woods era and found almost no evidence to support long-run PPP. Additional papers on exchange rate dynamics using fractional integration are Fang, Lai and Lai (1994), Crato and Ray (2000) and Wang (2004). The volatility dynamics in foreign exchange rates with fractional integration has been examined with the FIGARCH-model, introduced by Baillie, Bollerslev and Mikkelsen (1996), and subsequent papers using this approach are Andersen and Bollerslev (1997, 1998), Tse (1998), Baillie, Cecen and Han (2000), Kihc (2004) and Morana and Beltratti (2004).

10.2.2.3 Applications to interest rates

Shea (1991) investigated the consequences of long memory in interest rates for tests of the expectations hypothesis of the term structure. He found that allowing for the possibility of long memory significantly improves the performance of the model, even though the expectations hypothesis cannot be fully resurrected. In related work, Backus and Zin (1993) observed that the volatility of bond yields does not decline exponentially when the maturity of the bond increases; in fact, they noticed that the decline was hyperbolic, consistent with the fractionally integrated specification. Lai (1997) and Phillips (1998) provided evidence, based on semiparametric methods, that *ex ante* and *ex post* US real interest rates are fractionally integrated. Tsay (2000) employs an ARFIMA model to provide evidence that the US real interest rate can be described as an $I(d)$ process. Further evidence can be found in Barkoulas and Baum (1997), Meade and Maier (2003) and Gil-Alana (2004a, 2004b). Couchman, Gounder and Su (2006) estimated ARFIMA models for *ex post* and *ex ante* interest rates from 16 countries. Their results suggest that, for

the majority of countries, the fractional differencing parameter lies between 0 and 1, and it seems to be considerably smaller for *ex post* real rates than for *ex ante* rates.

10.2.2.4 Applications to stock markets

Long memory analysis was first conducted in stock return series in Greene and Fielitz (1977). They report evidence of persistence in daily US stock return series using R/S methods. However, Aydogan and Booth (1988) concluded that there was no significant evidence of long memory in common stock returns. Lo (1991) used the modified R/S method, along with spectral regression methods, and found no evidence of long memory in stock returns. Many other authors have found little or no evidence of long memory in stock markets (see, for example, Hiemstra and Jones, 1997). On the other hand, Crato (1994), Cheung and Lai (1995), Barkoulas and Baum (1996), Barkoulas, Baum, and Travlos (2000), Sadique and Silvapulle (2001), Henry (2002), Tolvi (2003) and Gil-Alana (2006) are among those who find evidence of long memory in monthly, weekly, and daily stock market returns.

Several papers use the Standard & Poor (S&P) 500 index over a long span of daily observations. Granger and Ding (1995a, 1995b) focus on power transformations of the absolute value of the returns (which they use as a proxy for volatility). They estimate a long memory process to study persistence in volatility, and establish some stylized facts concerning the temporal and distributional properties of absolute returns. However, in a related study, Granger and Ding (1996) find that the parameters of the long memory model vary considerably from one sub-series to the next. The issue of fractional integration with structural breaks in stock markets has been examined in Mikosch and Starica (2000) and Granger and Hyung (2004). Stochastic volatility models using fractional integration have been implemented in Crato and de Lima (1994), Bollerslev and Mikkelsen (1996), Ding and Granger (1996), Breidt, Crato, and de Lima (1997, 1998), Arteche (2004) and Baillie *et al.* (2007).

10.2.2.5 Applications to geophysics and other sciences

Fractional integration has also been applied in many other areas. Examples include meteorology (Haslett and Raftery, 1989; Bloomfield, 1992; Hussain and Elbergali, 1999; Gil-Alana, 2005a, 2008b); etternet (and internet) traffic traces (Abry and Veitch, 1998; Karagiannis, Molle and Faloutsos, 2004); hydrology (Montanari, Rosso and Taqqu, 1997, 2000; Rao and Bhattacharya, 1999; Wang *et al.*, 2005; Wang *et al.*, 2007); and political sciences (Box-Steffensmeier and Smith, 1996, 1998; Byers, Davidson and Peel, 1997, 2000; Dolado, Gonzalo and Mayoral, 2003).

10.2.2.6 Applications using seasonal and cyclical FI models

This review has so far focused exclusively on models with the pole or singularity in the spectrum occurring at the zero frequency. In this sub-section we briefly review the empirical literature on seasonal and cyclical fractional models. Starting with the seasonal model in (10.4), Porter-Hudak (1990) applied a seasonally fractionally integrated model to quarterly US monetary aggregates, concluding

that a fractional model could be more appropriate than standard ARIMAs. Advantages of seasonally fractionally integrated models for forecasting are illustrated in Ray (1993) and Sutcliffe (1994), and other empirical applications using quarterly seasonal models can be found in Gil-Alana and Robinson (2001) and Gil-Alana (2005b). Monthly data in the context of seasonal fractional integration have been examined in Gil-Alana (1999) and Ooms and Franses (2001).

Applications using the cyclical model based on the Gegenbauer process described by equation (10.3) can be found, for example, in Arteche and Robinson (2000), Bierens (2001) and Gil-Alana (2001), and empirical work based on multiple cyclical structures (*k*-factor Gegenbauer processes) can be found in Ferrara and Guegan (2001), Sadek and Khotanzad (2004) and Gil-Alana (2007).

10.3 Fractional cointegration

The concept of fractional integration leads naturally to an extension of the standard notion of cointegration (which involves series with integer orders of integration) to the fractional case, where equilibrium relations among fractional processes could be captured. In the present section, we introduce this concept, give an overview of the different estimation methods proposed so far in the literature, and give evidence of the empirical relevance of this idea.

10.3.1 The concept and modelization of fractional cointegration

Engle and Granger (1987) suggested that, if two processes x_t and y_t are both $I(d)$, then it is generally true that, for a certain scalar $a \neq 0$, a linear combination $w_t = y_t - ax_t$ will also be $I(d)$, although it is possible that w_t be $I(d-b)$ with $b > 0$. This idea characterizes the concept of cointegration, which they adapted from Granger (1981) and Granger and Weiss (1983). They provided the following definition for multivariate series. Given two real numbers d, b, the components of the vector z_t are said to be cointegrated of order d, b, denoted $z_t \sim CI(d, b)$, if:

(i) all the components of z_t are $I(d)$,
(ii) there exists a vector $\alpha \neq 0$ such that $w_t = \alpha' z_t \sim I(d-b)$, $b > 0$.

Here, α and w_t are called the cointegrating vector and error respectively. Engle and Granger (1987) offered some intuition behind this crucial concept in modern time series econometrics, suggesting the existence of forces which tend to keep series not too far apart. Given a vector of economic variables z_t, and a certain vector $\alpha \neq 0$, economic theory would say that the variables are in equilibrium if $\alpha' z_t = 0$. This is a very tight notion of equilibrium, and it is a very narrow view that this equality could hold for every time period t. Alternatively, we might think of an equilibrium error as $w_t = \alpha' z_t$, which accommodates deviations from equilibrium. If, for example, in Engle and Granger's (1987) definition $d = b = 1$, what characterizes cointegration as a "long-run equilibrium" relationship is that a linear combination of $I(1)$ processes is $I(0)$, so that the series in z_t cannot drift too far apart.

To be fair, the idea of equilibrium between $I(1)$ processes was hinted at long before in the statistical literature. In the AR model:

$$y_t = \rho y_{t-1} + \varepsilon_t, \quad t > 0; \quad y_t = 0, \quad t \leq 0,$$

ε_t being a sequence of independent normally distributed random variables with mean 0 and finite variance, Dickey and Fuller (1979) studied the properties of the regression estimate of ρ, $\hat{\rho}$, under the assumption that $\rho = 1$. In fact, this represents a situation of cointegration between the $I(1)$ processes y_t and y_{t-1}, as the linear combination $y_t - y_{t-1}$ is $I(0)$. This is a particular case of what Park (1992) called "singular cointegration," which is characterized by cointegrating errors being linear combinations of innovations which generate the regressors.

Engle and Granger (1987) introduced another important concept. If the multivariate $I(d)$ process z_t has $p > 2$ components, there may be several linearly independent cointegrating vectors, representing the case where several equilibrium relations drive the joint movement of the variables in z_t. It is easy to see that the maximum number of linearly independent cointegrating vectors is $r \leq p - 1$, the value r defining the "cointegrating rank" of z_t.

Even considering only integer orders of integration, a more general definition of cointegration than the one given by Engle and Granger (1987) is possible, one that allows for a multivariate process with components having different orders of integration. Denoting d_1 and d_p to be the largest and smallest of these orders, respectively, Johansen (1996) proposed that any vector z_t such that $\alpha' z_t \sim I(d_w)$, with $d_w < d_1$, is a cointegrating vector. Flôres and Szafarz (1996) narrowed Johansen's definition, proposing instead that the vector series is cointegrated if there is a non-trivial linear combination of its components (with at least a non-zero scalar multiplying d_1) which is integrated of order $d_w < d_1$. Alternatively, Robinson and Marinucci (2003) define z_t to be cointegrated if there exists a vector $\alpha \neq 0$ such that $\alpha' z_t \sim I(d_w)$, with $d_w < d_p$, which is a much stronger requirement. Robinson and Yajima (2002) offered an alternative (although rather more involved) definition and a comparison of the different definitions that have appeared in the literature.

Once fractional integration is defined, the concept of fractional cointegration appears as a natural extension of traditional cointegration. In fact, the standard definition of cointegration by Engle and Granger (1987) does not necessarily refer to integer orders of integration. In the simple bivariate case, two series y_t, x_t, sharing the same order of integration, say δ, are cointegrated if there exists a vector $\alpha \neq 0$ such that $\alpha' z_t \sim I(\gamma)$, with $\gamma < \delta$, with $z_t = (y_t, x_t)'$. This prompts consideration of an extension of Phillips' (1991a) triangular system, which, for a very simple bivariate case, is:

$$y_t = \nu x_t + u_{1t}(-\gamma), \tag{10.5}$$

$$x_t = u_{2t}(-\delta), \tag{10.6}$$

for $t = 0, \pm 1, \ldots$, where, for any vector or scalar sequence w_t and any c, we introduce the notation $w_t\,(c) = \Delta^{c} w_t^{\#}$. $u_t = (u_{1t}, u_{2t})'$ is a bivariate zero mean covariance stationary $I(0)$ unobservable process and $\nu \neq 0$, $\gamma < \delta$. The truncation in (10.6)

ensures that x_t has finite variance, and implies that $x_t = 0$, $t \leq 0$. This restriction is unnecessary if $\gamma < 1/2$ because, in that case, $y_t - \nu x_t$ is covariance stationary without it and "asymptotically covariance stationary" with it, but it is imposed for the sake of a uniform treatment, implying that $y_t = 0$, $t \leq 0$. Under (10.5)–(10.6), x_t is $I(\delta)$, as is y_t by construction, while the cointegrating error $y_t - \nu x_t$ is $I(\gamma)$. Model (10.5)–(10.6) reduces to the bivariate version of Phillips' triangular form when $\gamma = 0$ and $\delta = 1$, which is one of the most popular models displaying $CI(1,1)$ cointegration considered in both the empirical and theoretical literatures. This model allows greater flexibility in representing equilibrium relationships between economic variables than the traditional $CI(1,1)$ prescription. On the one hand, it is plausible that there exists long-run co-movements between non-stationary series which are not precisely $I(1)$. On the other hand, there is usually no *a priori* reason for restricting analysis to just $I(0)$ cointegrating errors, as the convergence to equilibrium of any cointegrating relation could be much slower than the adjustment implied by, for example, a finite ARMA cointegrating error. Furthermore, we could also consider cointegration among (asymptotically) stationary variables, with some linear combinations producing cointegrating errors characterized by having weaker memory than that of the observed series. Also, it could be that the cointegrating error is purely non-stationary but mean-reverting, so that a certain long-run equilibrium among non-mean-reverting observables holds.[8]

There are various directions in which model (10.5)–(10.6) has been generalized. Robinson and Iacone (2005), still within a bivariate framework, allow for deterministic components, extending (10.5)–(10.6) to:

$$y_t = \nu x_t + \sum_{j=1}^{p_1} \mu_{1j} t^{\phi_{1j} - 1/2} + u_{1t}(-\gamma), \tag{10.7}$$

$$x_t = \sum_{j=1}^{p_2} \mu_{2j} t^{\phi_{2j} - 1/2} + u_{2t}(-\delta), \tag{10.8}$$

where $\delta > \max(\gamma, 0.5)$, and the ϕ_{ij} are real numbers satisfying $\phi_{11} > \cdots > \phi_{1p_1} > 0$; $\phi_{21} > \cdots > \phi_{2p_2} > 0$, noting that an intercept appears in (10.7)–(10.8) when $\phi_{1j} = \phi_{2j} = 1/2$, while integer powers are also possible.

Kim and Phillips (2002) proposed a multivariate version of (10.5)–(10.6), employing the Type I definition of fractionally integrated processes instead, so that:

$$\tilde{y}_t = \nu \tilde{x}_t + v_{1t}^{(\gamma)}, \quad t \geq 1, \tag{10.9}$$

$$\tilde{x}_t = v_{21}^{(\delta)} + \cdots + v_{2t}^{(\delta)}, \quad t \geq 1, \tag{10.10}$$

where $v_{1t}^{(\gamma)}$ and $v_{2t}^{(\delta)}$ are jointly stationary Type I fractionally integrated processes of orders γ and $\delta - 1$, respectively, with $|\gamma| < 0.5$, $0.5 < \delta < 1.5$, $\tilde{y}_t$ and $\tilde{x}_t$ are $p \times 1$ and $q \times 1$ vectors, respectively, and ν is a $p \times q$ matrix of cointegrating parameters. Note that, when $p = q = 1$ and $\gamma = 0$, $\delta = 1$, $\left(v_{1t}^{(\gamma)}, v_{2t}^{(\delta)}\right)' \equiv \left(u_{1t}, u_{2t}\right)'$ implies that $\left(\tilde{x}_t, \tilde{y}_t\right)' = \left(x_t, y_t\right)'$, but more generally this is not the case. Model (10.9)–(10.10) is

also a particular case of the fractional setting proposed by Jeganathan (1999, 2001). This multivariate modelization is a straightforward generalization of the bivariate setting, given that the time series involved still depend on two integration orders, γ and δ. A richer structure is proposed by Hualde and Robinson (2006), who consider the model:

$$\Psi z_t = \Delta^{-1}(\delta)\, u_t^{\#}, \tag{10.11}$$

where $\delta = \left(\delta_1, \ldots, \delta_p\right)'$, z_t is a $p \times 1$ vector observable process, $\Delta(\delta) = diag\left(\Delta^{\delta_1}, \ldots, \Delta^{\delta_p}\right)$ and u_t is a $p \times 1$ zero mean covariance stationary unobservable process. The presence of the various integration orders in δ poses additional difficulties and, unless δ and Ψ are restricted, (10.11) does not ensure cointegration and identification. Hualde and Robinson (2006) impose restrictions (simplifying matters substantially in an already complicated setting) which ensure identifiability and imply that z_t is $I\left(\delta_p\right)$ (δ_p is assumed to be the largest fractional order among those in δ). The restrictions also imply that there are r cointegrating relations among the elements of z_t, and allow the integration orders of the r cointegrating errors to vary, unlike in previous models of multivariate fractional cointegration. In a different setting, Chen and Hurvich (2003a) model a $q \times 1$ time series, z_t, such that its $(p-1)$th difference (where p is an integer), y_t, is a covariance stationary process with common memory parameter $d \in (-p + 0.5, 0.5)$. They assume that y_t has the common-components representation:

$$y_t = Ax_t + Bu_t, \tag{10.12}$$

where, for $1 \leq r \leq q-1$, A, B are $q \times (q-r)$ and $q \times r$ unknown deterministic matrices of ranks $q-r$ and r, respectively, and x_t, u_t, are $(q-r) \times 1$ and $r \times 1$, unknown unobserved processes with memories d and d_u, respectively, where $d_u \in (-p + 0.5,\ 0.5) < d$. Basically, these conditions imply that y_t is cointegrated, with cointegrating space identified by the null space of A' ($Ker(A')$), noting that, if $\alpha \in Ker(A')$, then $\alpha' y_t = \alpha' B u_t$, which has at most memory d_u. Chen and Hurvich (2006) further enrich this setting by means of a common components model in which the components have different memory parameters, while still allowing the $q \times 1$ vector of observed series to have just one common memory parameter. Thus, using notation similar to Chen and Hurvich (2003a), they set:

$$y_t = A_0 u_t^{(0)} + A_1 u_t^{(1)} + \cdots + A_s u_t^{(s)}, \tag{10.13}$$

where, for $k = 1, \ldots, s$, the A_k are $q \times a_k$ unknown deterministic matrices with $a_0 = q - r$, $\sum_{j=1}^{s} a_j = r$, the $u_t^{(k)}$ are $a_k \times 1$ unobservable processes with memory d_k, such that $-p + 0.5 < d_s < \cdots < d_0 < 0.5$, and all rows of A_0 are non-zero. This setting ensures that all the components in y_t have common memory d_0, the cointegrating rank is r, such that $1 \leq r < q$, and there are s cointegrating subspaces, with $1 \leq s \leq r$. In this framework, Chen and Hurvich (2006) define s different cointegrating sub-spaces B_k, $k = 1, \ldots, s$, with the main characteristic being that, if $\beta \in B_k$, $\beta' A_l = 0, l = 0, \ldots, k-1$, and $\beta' A_k \neq 0$.

Finally, Johansen (2008) proposes a new vector autoregressive model:

$$\Delta^d z_t = \alpha\beta' \Delta^{d-b} L_b z_t + \sum_{i=1}^{k} \Gamma_i \Delta^d L_b^i z_t + \varepsilon_t, \tag{10.14}$$

where $L_b = 1 - \Delta^b$ is a particularly useful lag operator with $0 < b \leq d$. Here, if there is a unit root in an associated characteristic polynomial, (10.14) generates a fractional process z_t of order d, for which the $r \times 1$ vector $\beta' z_t$ is fractional of order $d - b$.

10.3.2 Estimation methods for fractional cointegration

Depending on the cointegrating model considered, different estimation techniques have been proposed. For simplicity, we deal initially with the estimation of ν in the bivariate system (10.5)–(10.6), although the estimation methods below can be straightforwardly generalized to cover multivariate situations where the observables and cointegrating errors still depend on two integration orders, δ and γ, respectively.

The most obvious proposal is to estimate ν in (10.5)–(10.6) by the ordinary least squares (OLS) estimator:

$$\hat{\nu}_{\text{OLS}} = \frac{\sum_{t=1}^{n} x_t y_t}{\sum_{t=1}^{n} x_t^2}. \tag{10.15}$$

Here, in the standard cointegrating setting, with $\gamma = 0$ and $\delta = 1$, it has been shown (see, for example, Phillips and Durlauf, 1986) that $\hat{\nu}_{\text{OLS}}$ is n-consistent with non-standard asymptotic distribution, in general. In fractional settings, the properties of OLS could be very different from those in this standard framework. For example, Robinson (1994b) showed the inconsistency of $\hat{\nu}_{\text{OLS}}$ when $\delta < 0.5$, which has been termed stationary cointegration (with special importance in finance, see section 10.3.3).[9] When the observables are purely non-stationary (so that $\delta \geq 0.5$), consistency of $\hat{\nu}_{\text{OLS}}$ is retained, but its rate of convergence and asymptotic distribution depends crucially on γ and δ. In particular, Robinson and Marinucci (2001) showed, for a model slightly more general than (10.5)–(10.6), that if $\delta \geq 0.5$, $\gamma \geq 0$, the rate of convergence of OLS is $n^{\min(2\delta-1,\delta-\gamma)}$, except when $\gamma > 0$ and $\gamma + \delta = 1$, where OLS is $n^{\delta-\gamma}/\log n$-consistent. In all these cases OLS has non-standard limiting distributions in general. An alternative method of estimating ν was developed from the following observation. Equation (10.15) is obviously a time-domain representation of the estimate, but it can easily be shown that:

$$\hat{\nu}_{\text{OLS}} = \frac{\sum_{j=0}^{n-1} I_{xy}\left(\lambda_j\right)}{\sum_{j=0}^{n-1} I_x\left(\lambda_j\right)}, \tag{10.16}$$

where $\lambda_j = 2\pi j/n$, $j = 1, \ldots, n$, are the Fourier frequencies, and for arbitrary sequences ξ_t, ζ_t, (possibly the same as ξ_t), we define the discrete Fourier transform

and (cross-) periodogram:

$$w_\xi(\lambda) = \frac{1}{\sqrt{2\pi n}} \sum_{t=1}^{n} \xi_t e^{it\lambda}, \quad I_{\xi\zeta}(\lambda) = w_\xi(\lambda) w'_\zeta(-\lambda), \quad I_\xi(\lambda) = I_{\xi\xi}(\lambda).$$

Here, the discrete Fourier transform at a given frequency captures the components of the series related to this particular frequency. Thus, noting that cointegration is a long-run phenomenon, when estimating ν one could concentrate just on low frequencies, which are precisely those representing the long-run components of the series, hence neglecting information from high frequencies, associated with the short run, which could have a distorting effect on estimation. Robinson (1994b) proposed the narrow band least squares (NBLS) estimator, which is related to the band estimator proposed by Hannan (1963), and is given by:

$$\hat{\nu}_{\text{NBLS}} = \frac{\sum_{j=0}^{m} s_j \text{Re} I_{xy}\left(\lambda_j\right)}{\sum_{j=0}^{m} s_j I_x\left(\lambda_j\right)}, \tag{10.17}$$

where $1 \leq m \leq n/2$, $s_j = 1$ for $j = 0, n/2$, $s_j = 2$ otherwise, and $(1/m) + (m/n) \to 0$ as $n \to \infty$. Robinson (1994b) showed the consistency of this estimator under stationary cointegration, using the fact that focusing on a degenerating band of low frequencies reduces the bias due to the contemporaneous correlation between u_{1t} and u_{2t}, which was precisely the reason why OLS was inconsistent. For the case $\delta < 0.5$, $\gamma \geq 0$, Robinson and Marinucci (2003) conjectured the rate of convergence to be $(n/m)^{\delta-\gamma}$ and, later, in a similar framework, Christensen and Nielsen (2006) showed that the better rate of convergence $m^{1/2}(n/m)^{\delta-\gamma}$ (and, in fact, asymptotic normality) was achievable if the coherency at frequency zero between u_{1t} and u_{2t} was zero, a restriction that is not satisfied in general by standard weak dependent processes (like, for example, ARMA processes).

In the non-stationary setting, Robinson and Marinucci (2001) showed that, if $\delta + \gamma < 1$ or $\delta + \gamma = 1$ with $\gamma > 0$, the rates of convergence previously given for OLS can be improved, being now $m^{\delta+\gamma-1} n^{\delta-\gamma}$ if $\delta + \gamma < 1$ and $n^{\delta-\gamma}/\log m$ if $\delta + \gamma = 1$ with $\gamma > 0$. As with OLS, NBLS has a non-standard limiting distribution in general.

With the aim of obtaining estimates of ν having improved asymptotic properties (optimal rate of convergence, median unbiasedness, asymptotic mixed-normality leading to standard inference procedures), more developed techniques to estimate ν have been proposed in the fractional setting. These are related to the work of Johansen (1988, 1991), Phillips and Hansen (1990), Phillips (1991a, 1991b), Phillips and Loretan (1991), Saikkonen (1991), Park (1992) and Stock and Watson (1993), who all proposed estimators with optimal asymptotic properties (under Gaussianity) in the standard cointegrating setting with $\gamma = 0$, $\delta = 1$. However, in all these estimators knowledge of γ, δ, was assumed (usually after pretesting), and in fractional circumstances this is hard to justify. Dolado and Marmol (1996) proposed an extension to the fractional setting of the fully modified (FM)-OLS

estimator of Phillips and Hansen (1990), assuming knowledge of γ and δ. Kim and Phillips (2002) considered an alternative extension to FM-OLS, and analyzed its relationship to Gaussian ML estimation in (10.9)–(10.10), assuming parametric autocorrelation in $\left(v_{1t}^{(\gamma)}, v_{2t}^{(\delta)}\right)'$. Jeganathan (1999, 2001) considered ML estimation of (10.9)–(10.10) assuming knowledge of the distribution of the innovations and also of γ and δ, although he did include some discussion of their estimation (as also did Kim and Phillips, 2002).

In model (10.5)–(10.6), and assuming the bivariate process u_t has a parametric spectral density $f(\lambda) = f(\lambda;\theta)$, where θ is an unknown vector of short memory parameters, Robinson and Hualde (2003), based on generalized least squares (GLS) type corrections, propose time and frequency domain methods to estimate optimally (under Gaussianity) ν when $\delta - \gamma > 0.5$ (denoted strong cointegration). For simplicity, we just present the frequency domain approach, which is asymptotically equivalent (to first-order properties) to that of the time domain, and which will be applied to empirical data in section 10.4. Denoting:

$$z_t(c,d) = (y_t(c), x_t(d))', \quad \zeta = (1,0)', \quad p(\lambda;h) = \zeta' f(\lambda;h)^{-1},$$

$$a(c,d,h) = \sum_{j=1}^{n} p(\lambda_j;h) w_{x(c)}(-\lambda_j) w_{z(c,d)}(\lambda_j), \quad q(\lambda;h) = \zeta' f(\lambda;h)^{-1} \zeta,$$

$$b(c,d) = \sum_{j=1}^{n} q(\lambda_j;h) I_{x(c)}(\lambda_j),$$

and defining:

$$\hat{\nu}(c,d,h) = \frac{a(c,d,h)}{b(c,h)},$$

they considered five different estimators, given by:

$$\hat{\nu}(\gamma,\delta,\theta), \hat{\nu}(\gamma,\delta,\hat{\theta}), \hat{\nu}(\gamma,\hat{\delta},\hat{\theta}), \hat{\nu}(\hat{\gamma},\delta,\hat{\theta}), \hat{\nu}(\hat{\gamma},\hat{\delta},\hat{\theta}), \tag{10.18}$$

where $\hat{\gamma}, \hat{\delta}, \hat{\theta}$ are corresponding estimators of the nuisance parameters γ, δ, θ. The estimators in (10.18) reflect different knowledge about the structure of the model, the first being in general infeasible, the second assuming just knowledge of the integration orders (as was done previously in the standard cointegrating literature), whereas the last estimator represents the most realistic situation. Under regularity conditions,[10] Robinson and Hualde (2003) showed that any of the estimators in (10.18) is $n^{\delta-\gamma}$-consistent with identical mixed-Gaussian asymptotic distributions, leading to Wald tests on the parameter ν:

$$W(\gamma,\delta,\theta), W(\gamma,\delta,\hat{\theta}), W(\gamma,\hat{\delta},\hat{\theta}), W(\hat{\gamma},\delta,\hat{\theta}), W(\hat{\gamma},\hat{\delta},\hat{\theta}), \tag{10.19}$$

where $W(c,d,h) = b(c,h)\{\hat{\nu}(c,d,h) - 1\}^2$, with a chi-squared limit.

Hualde and Robinson (2007) propose an estimator of ν in (10.5)–(10.6) under the more adverse situation $\delta - \gamma < 0.5$ (denoted weak cointegration). Assuming u_t

is generated by a vector autoregressive (VAR) process:

$$u_t = \sum_{j=1}^{p} B_j u_{t-j} + \varepsilon_t,$$

and defining:

$$Z_t(c,d) = \left(x_t(c), x_t(d), w'_{t-1}(c,d), \ldots, w'_{t-p}(c,d)\right)',$$

where $w_t(c,d) = \left(x_t(c), x_t(d), y_t(c)\right)'$, they analyzed the behavior of the estimators $\hat{\nu}(\gamma,\delta), \hat{\nu}(\hat{\gamma},\hat{\delta})$, where $\hat{\gamma},\hat{\delta}$ are corresponding estimators of γ,δ, and $\hat{\nu}(c,d) = i_1' G(c,d)^{-1} g(c,d)$. Here, $i_1 = (1,0,\ldots,0)'$:

$$G(c,d) = Q\frac{1}{n}\sum_{t=p+1}^{n} Z_t(c,d) Z_t'(c,d) Q', \quad g(c,d) = Q\frac{1}{n}\sum_{t=p+1}^{n} Z_t(c,d) y_t(c),$$

where Q caters for the possibility of prior zero restrictions on the B_j's. As in Robinson and Hualde (2003), this method is based on a GLS-type of correction. Hualde and Robinson (2007) showed that both estimators are $\sqrt{n}$-consistent and asymptotically normal, but with different asymptotic variance, which in the case of $\hat{\nu}(\hat{\gamma},\hat{\delta})$ depends on how γ, δ, are estimated. Here, it is important to note that, in order to get a $\sqrt{n}$-consistent $\hat{\nu}(\hat{\gamma},\hat{\delta})$, it is essential that γ, δ, are $\sqrt{n}$-consistently estimated, and Hualde and Robinson (2007) proposed a feasible method of estimation for the case where B_j is upper-triangular for all $j = 1,\ldots,p$.

Robinson and Iacone (2005) consider the data-generating process (10.7)–(10.8), and deal with estimation of ν and of those elements in μ_{1j}, $j = 1,\ldots,p_1$, μ_{2j}, $j = 1,\ldots,p_2$, whose associated deterministic trends are not dominated (in the precise way defined in Robinson and Iacone, 2005) by stochastic components. They consider three different estimators of the parameters of interest. First, they analyze the properties of (10.16), concluding that when the deterministic term in (10.7) dominates the stochastic and deterministic components in x_t, $\hat{\nu}_{OLS}$ is not even consistent. Otherwise, consistency is retained, and the authors offer a very detailed analysis of the different possibilities involved. The second scenario refers to estimating by OLS ν and μ_1 in (10.7), where μ_1 collects the μ_{1j}'s associated with the deterministic terms not dominated by $u_{1t}(-\gamma)$ (which are the only ones which could be consistently estimated). Here, due to the accounting of the deterministic components, the estimate of ν is always consistent, with asymptotic properties very dependent on $(\gamma,\delta,\phi_{2\forall})$, where $\phi_{2\forall}$ is the maximum value of those ϕ_{2j}'s for which $\mu_{2j} \neq 0$. Finally, they also consider GLS estimation, taking into account the deterministic terms in (10.7)–(10.8), thus extending the time and frequency domain estimators of Robinson and Hualde (2003), also for $\delta - \gamma > 0.5$. Under identical regularity conditions, when $\delta > \phi_{2\forall}$, the estimate of ν has identical asymptotic properties to that of Robinson and Hualde (2003); when $\delta = \phi_{2\forall}$, the rate of convergence remains the same, but the limiting distribution changes, whereas if $\delta < \phi_{2\forall}$,

a higher rate of convergence is achieved and the limiting distribution is normal, which is natural given that now the deterministic component in x_t is dominant.[11]

In the multivariate setting (10.11), by considering the spectral density of u_t to be a nonparametric function, Hualde and Robinson (2006) propose an extension of the estimators of Robinson and Hualde (2003), allowing for the simultaneous presence of strong and weak cointegrating relations. Because of the generality of the framework, the representation of the estimators and asymptotic results are rather involved but, essentially, the same properties as in Robinson and Hualde (2003) are achieved by the estimators of the cointegrating parameters in strong cointegrating relations, whereas the estimators of parameters in weak cointegrating relations are asymptotically normal, but with a slower rate of convergence than the parametric one ($\sqrt{n}$) given by $m^{1/2}(n/m)^{\delta_p-\gamma}$, where δ_p, γ denote the common integration order of the observables and that of the cointegrating error of the particular weak cointegrating relation, respectively. This result leads to Wald statistics for testing linear restrictions among the elements of Ψ in (10.11) having a standard null chi-squared limit distribution, irrespective of the type of cointegrating relations present in the model.

In the different setting of Chen and Hurvich (2003a), whose focus is on estimating the space of cointegration and not cointegrating regressions, then, on assuming the cointegrating rank is r, this space is estimated by the eigenvectors corresponding to the r smallest eigenvalues of the averaged tapered periodogram matrix of y_t. The intuition behind this result is the following. Noting (10.12):

$$\sum_{j=1}^{m} \mathrm{Re}\, I_y\left(\lambda_j\right) = A \sum_{j=1}^{m} \mathrm{Re}\, I_x\left(\lambda_j\right) A' + A \sum_{j=1}^{m} \mathrm{Re}\, I_{xu}\left(\lambda_j\right) B' + B \sum_{j=1}^{m} \mathrm{Re}\, I_{ux}\left(\lambda_j\right) A' + B \sum_{j=1}^{m} \mathrm{Re}\, I_u\left(\lambda_j\right) B'.$$

Given that $d > d_u$, the right-hand side of the above equation is dominated by the first term, and setting conditions ensuring that $\sum_{j=1}^{m} \mathrm{Re} I_x(\lambda_j)$ is positive definite with probability approaching one (basically meaning that there is no cointegration among the elements of x_t), then, with probability approaching one, the cointegrating space ($Ker(A')$) is the space of eigenvectors of $A \sum_{j=1}^{m} \mathrm{Re} I_x(\lambda_j) A'$, with corresponding eigenvalues equal to zero. Finally, Chen and Hurvich (2006), in the more general setting (10.13), estimate separately each cointegrating sub-space using appropriate sets of eigenvectors of an averaged periodogram matrix of tapered observations.

10.3.3 Evidence of fractional cointegration

Since the early 1990s fractional cointegration has attracted the attention of many empirical researchers working in different fields. We detail below some of the most relevant applications.

10.3.3.1 Applications to exchange rates

The initial applications of the concept of fractional cointegration were devoted to analyzing PPP. This refers to the tendency for nominal exchange rates and prices to adjust in such a way that the real exchange rate reverts (perhaps slowly) to its parity value. Thus the (log) real exchange rate could be viewed as the cointegrating error in a linear combination of (log) nominal exchange rates and (log) prices with cointegrating vector $(1, -1)'$. Here the literature mainly provided evidence of weak fractional cointegration ($\delta - \gamma < 0.5$), with (approximately) unit root observables with non-stationary but mean-reverting cointegrating errors, as presented by Diebold, Husted and Rush (1991). Although the authors approximated the log of the real exchange rate in a particular way, and not as the difference of the logs of the nominal exchange rate and prices, their empirical analysis, taking into account that the (log) nominal exchange rate is $I(1)$ (see, for example, Baillie and Bollerslev, 1994a, 1994b), reported some cases where the estimated memory of the real exchange rates (for example, France–Germany, Germany–UK) were non-stationary mean-reverting, while for others there was evidence of stationary long memory. In a similar framework, Cheung and Lai (1993) proposed checking the PPP hypothesis via a regression of a foreign price index, converted to domestic (US) currency units, on a domestic price index, with the errors of this relation capturing deviations from PPP. While they provided evidence of the unit root character of the observables, they stated that PPP will be characterized by stationarity, or at least mean reversion, in the cointegrating error. They estimated the degree of memory of the cointegrating error for different countries and bandwidths and, in 11 out of 15 cases, these estimates were suggestive of $\delta - \gamma < 0.5$ instead of $\delta - \gamma > 0.5$.

In a similar setting to Diebold, Husted and Rush (1991), Crato and Rothman (1994b) provided estimates of the (log) real bilateral sterling exchange rates for different countries. Of the nine countries analyzed, for only two of them (Netherlands and Italy) was there very clear evidence that $\delta - \gamma < 0.5$, whereas for another two (Canada and Sweden) there were conflicting results.

Chou and Shih (1997) investigated long-run PPP in the relationship of four Asian countries (Hong Kong, Singapore, South Korea and Taiwan) with the US dollar in an unrestricted trivariate model (involving the logs of the nominal exchange rate and domestic and foreign price levels), allowing for a linear trend and using quarterly data from 1965 to 1992. Using the Geweke and Porter-Hudak (1983) (GPH) test for fractional cointegration (that is, estimating the memory of the cointegrating error by the GPH estimate applied to the cointegrating regression residuals and testing whether this memory is significantly smaller than the integration order of the observables, assumed to be one in this case), they found some evidence of fractional cointegration, with $\delta - \gamma > 0.5$ for the South Korea–US relationship.

Choudhry (1999a) investigated PPP between the US and four high-inflation Eastern European countries (Poland, Romania, Russia and Slovenia), using monthly data from 1991 to 1997. The author estimated a regression model of the log of the nominal exchange rate on the log ratio of domestic to foreign prices, the absolute

version of PPP being characterized by a slope equal to 1, while evidence of fractional cointegration implies a weaker (relative) version of PPP. Using the GPH test, Choudhry provided evidence of relative PPP for Russia and Slovenia (with unit root observables and estimates of the integration order of the cointegrating error close to 0 and 0.5, respectively), but failed to find evidence for absolute PPP.

In a different setting, Baillie and Bollerslev (1994a) argued whether seven spot exchange rates appear to be tied together in the long run or not, taking into account that there does not seem to be much discussion in the literature about the unit root character of these series, which makes much more fragile the idea that they are cointegrated (see, for example, Sephton and Larsen, 1991; Diebold, Gardeazabal and Yilmaz, 1994). Baillie and Bollerslev's (1994a) explanation was that unit root tests, which serve traditionally to detect the presence of unit roots, have very low power against fractional alternatives, so that a situation of fractional cointegration with long memory cointegrating error could be hidden. In fact, their estimate of the memory of the cointegrating error was 0.89, over five standard errors away from 1, thus providing evidence of fractional cointegration with $\delta - \gamma < 0.5$. Similarly, Pan and Liu (1999), using the same nominal exchange rate data as Baillie and Bollerslev (1994a), analyzed the presence of cointegration in different sub-samples by means of the GPH test. Interestingly, they only found evidence of fractional cointegration (with $\delta - \gamma < 0.5$) for the 1980–84 sample, whereas standard cointegration was found for the most recent period 1985–92, supporting the conjecture that the fractional cointegration feature could vary across different time spans.[12]

Another important topic in the literature of exchange rates is the analysis of the forward premium, $f_t - s_t$, where s_t and f_t are logs of the spot exchange rate and of the forward rate respectively. Here, noting the "overwhelming" evidence of unit roots in spot exchange rates, the difference $f_t - s_t$ could be considered as a cointegrating error with cointegrating vector $(1, -1)'$. Baillie and Bollerslev (1994b) claimed that unit root tests generally reject that the forward premium is $I(0)$, which is paradoxical as, given that the forward premium is associated with risk, it seems hard to see any theoretical reason for an $I(1)$ risk premium. The purpose of their paper was to show that the forward premium is indeed mean-reverting, the estimates of the memory of the forward premium for Canada, Germany and UK (with respect to US) being 0.45, 0.77 and 0.55 respectively, suggesting stronger evidence in favor of weak cointegration relations.

Choudhry (1999b) analyzed, by means of the GPH test, nine forward premiums (with respect to US), showing evidence of (weak) cointegration for three of them (Canada, Hong Kong and Italy). He also tested the unbiased forward rate hypothesis (in short, that the forward exchange rate is an unbiased predictor of the corresponding future spot rate), which was examined by analyzing the existence of fractional cointegration in a regression of s_{t+k} on f_t (although two other alternative specifications were also considered), and testing for a unit slope, which ensures that the forward rate is an unbiased predictor of the future spot rate. Evidence of cointegration was found but not of the unbiasedness hypothesis (with the exception of South Africa).

Still concerning the forward premium, much effort has also been devoted to explanations of the so-called "forward premium anomaly." This refers to surprising negative estimates from regressions of the change in the log of the spot exchange rate on the forward premium, where theory predicts a value of 1 for that slope (see, for example, Bekaert, 1996; Bekaert, Hodrick and Marshall, 1997). Baillie and Bollerslev (2000) consider this issue to be a statistical problem caused by the different integration orders of the dependent variable and regressor in the equation mentioned above. They indicate that the spot exchange rate is approximately a unit root, whereas there seems to be evidence in favor of a mean-reverting (but non-stationary) forward premium. Under these circumstances, Maynard and Phillips (2001) showed that the slope coefficient of such a regression (with a short memory dependent variable and a non-stationary but mean-reverting regressor) converges in probability to zero, the long left tail of the asymptotic distribution of this estimator giving further support to the puzzling negative values obtained in the literature. Baillie, Han and Koul (2002) provided further evidence regarding the imbalance of the forward premium regression equation with high-frequency data, so that the forward premium anomaly seems to be an intrinsic property of exchange rates, and they conjectured that the phenomenon is not due to regime shifts or structural breaks.

Finally, there is a more recent literature trying to explain, by means of fractional cointegration, the connection between exchange rates and fundamentals. Caporale and Gil-Alana (2004a) examined the issue of whether real exchange rates were cointegrated with real interest rates and labor productivity differentials in the DM–US$, Yen–US$ relations using quarterly data (1975–98). They provided evidence of unit roots in the observables and also, by estimating parametrically the memory of the cointegrating error from cointegrating residuals, conjectured the existence of fractional cointegration, with the estimated integration order of the residuals fluctuating between 0 and 0.5 in the case of Germany and between 0.1 and 0.6 in the case of Japan.

Dufrénot *et al.* (2006) explored the real exchange rate misalignments of five European countries during the period 1979–99. They posited an equilibrium relation between real exchange rates and macroeconomic fundamentals (terms of trade, prices, foreign assets, fiscal wedge, interest rate differential), with each variable representing the value in a particular country related to a weighted average of the same variable for other countries. They estimated the memory of the cointegrating residuals by means of the modified R/S statistic of Lo (1991), the GPH estimator and the exact ML estimator of Sowell (1992a). In view of their results, there seems to be strong evidence of fractional cointegration for the Netherlands, with mixed evidence for France and the UK.

10.3.3.2 Applications to financial series

Within this area of research, the main focus has been the study of the volatility of financial series, providing evidence of long memory covariance stationary observables with weakly dependent cointegrating errors. The first explicit reference

to this type of cointegration, denoted stationary cointegration, appears in Robinson (1994b). Robinson and Marinucci (2003) investigated further this situation, indicating that the phenomenon of cointegration between stationary variables had recently emerged in finance, and emphasizing the difficulty of distinguishing between a unit root process and a stationary long memory process with an autoregressive part having a root near the unit circle.

Andersen *et al.* (2001) examined "realized" daily equity return volatilities and correlations obtained from high-frequency transaction prices on individual stocks in the Dow Jones Industrial Average. They provided evidence of long memory for certain time series of logarithmic standard deviations and correlations, and stressed the evidence of comovements in volatility across assets. Christensen and Nielsen (2006) make a similar point and argue for the existence of stationary cointegration between the volatility implied in option prices and the subsequent realized return volatility of the underlying asset, since, in their view, the observables (log-volatilities) were integrated of order between 0.35 and 0.40, whereas the cointegrating error seemed weakly dependent. By using an NBLS estimator, they obtained a much higher value for the estimate of the slope of their cointegration relation than that obtained in similar work by Christensen and Prabhala (1998), who used OLS, which, as shown by Robinson (1994b), is inconsistent in the case of stationary cointegration.

Brunetti and Gilbert (2000) proposed a bivariate cointegrated fractional volatility (FIGARCH) model, and applied it to the volatility (measured in terms of squared and absolute returns) of the New York NYMEX and London IPE crude oil markets. They concluded that both processes were highly persistent, with a common degree of fractional integration (around 0.4), and were fractionally cointegrated. Using similar series, Robinson and Yajima (2002) analyzed stationary cointegration in the context of testing for cointegration rank, finding support for this type of behavior in spot closing prices of crude oil.

Beltratti and Morana (2006) also provided evidence of fractional cointegration in stock market volatility. They analyzed the relationship between S&P 500 returns volatility and that of some macroeconomic variables over 1970–2001 using monthly data and allowing for both long memory and structural breaks. They found evidence of long memory and structural change in the volatility, the break possibly being related to break processes in the volatility of the macroeconomic factors, and carried out a fractional cointegration analysis on break-free processes. They found a common memory parameter of 0.25 for the series and concluded in favor of the existence of three cointegrating relations among the variables using the cointegrating test of Robinson and Yajima (2002).

Finally, Caporale and Gil-Alana (2004b) tested the present value model by checking for cointegration between stock prices and dividends using annual data for the period 1871–1995 (updating the series employed by Campbell and Shiller, 1987). They provided evidence of the unit root nature of these series and, by applying Robinson's (1994a) test to OLS residuals, concluded that the series were fractionally cointegrated with long memory cointegrating error and mixed evidence about the type of cointegrating relation (weak or strong) which characterizes the data.

10.3.3.3 Applications to interest rates

This has not been a very popular application of fractional cointegration, but we can mention at least two relevant works. First, Dueker and Startz (1998) proposed an ARFIMA model and discussed its estimation, the main feature being to provide joint estimates of the common integration order of the observables and cointegrating error. They illustrated their method by analyzing the relation between US and Canadian bond rates (using monthly data for 1987–97). The authors suggested that it is not desirable to rely on an assumed value for the order of integration of the observables (usually one), as traditionally was done in previous empirical analyses related to fractional cointegration. They provided evidence of fractional cointegration, their estimates of the memory of the observables and the cointegrating error being 0.674 and 0.200, respectively, which could be evidence in favor of a weak cointegration relation.

In a different setting, Barkoulas, Baum and Oguz (1996) analyzed cointegration among long-term interest rates from five countries (the US, Canada, Germany, the UK and Japan) using monthly data for the period 1967–90. They justified the unit root condition of the series and examined the possibility of cointegration by means of the GPH test applied to different sub-systems of observables, concluding in favor of the existence of strong co-movements between Canadian and US interest rates.

10.3.3.4 Applications to electricity prices

This is probably the most recent (and one of the most promising) application of fractional integration and cointegration techniques. Haldrup and Nielsen (2006) mention the possibility of cointegration in a regime-switching model which allows for fractional cointegration in each of the regime states. They analyzed hourly spot electricity prices (January 2000–October 2003) for the Nord Pool area (Mid Norway, South Norway, West Denmark, East Denmark, Sweden and Finland). Two different regimes are allowed, congestion (where prices differ across areas) and non-congestion (where prices are identical for every area). Two main conclusions can be drawn from their results. First, the memory properties of the individual series seem to differ substantially across regimes (although, in all cases, series appear to be stationary). Second, the use of a non-switching model could lead to wrong conclusions regarding the cointegration of the series (which are analyzed in pairs), which could be driven by the extreme type of cointegration which characterizes the data when the series are in a non-congestion state.

10.3.3.5 Applications to political studies

There are different political issues which have been analyzed in recent times by fractional integration and cointegration techniques. As Robinson (1978) and Granger (1980) demonstrated, fractional integration could originate from aggregation of data which exhibits heterogeneous dynamic behavior at the individual level. This has an important appeal for political data, where series are obtained by aggregating the opinions of possibly very heterogeneous individuals. The first topic

where fractional cointegration has attracted attention is the analysis of the linkage between political opinions and economic indicators. Box-Steffensmeier and Tomlinson (2000) analyzed the relation between congressional approval and economic expectations in the US, using quarterly data from 1974 to 1993. They estimated parametrically the integration orders of both series (0.72 and 0.86 respectively), computed by OLS the relationship between them, and estimated parametrically the memory of the cointegrating error (0.40). They considered their results to be inconclusive about the existence of cointegration because of large standard errors.

Similarly, Davidson (2003), using quarterly data from 1955 to 1996, examined the relation between political opinion (measured as the end-of-quarter difference between support for the governing party and that for the opposition) and economic indicators in the UK by means of bootstrap methods. The author provides support for the non-stationary, but mean-reverting, nature of the political opinion variable, concluding that there is little or no evidence of linkages between political and economic cycles.

Another interesting issue is the relationship between governing party and prime ministerial support. In principle, it seems plausible that both variables are cointegrated, and different studies have provided support for this conjecture. Clarke and Lebo (2003), using monthly data from 1979 to 1996, linked governing party support, prime ministerial approval and four subjective economic evaluations. Using different methods, the authors concluded that the series are non-stationary but mean-reverting, suggesting the possibility of cointegration between governing party support and prime ministerial approval. Additionally, they found that, whereas personal economic evaluations were influential, national ones are not significant. Similarly, Davidson, Peel and Byers (2006) proposed two variants of a fractionally integrated vector error correction model and applied them to the relationship between the respective performances of prime minister and government in the UK. Evidence of cointegration was provided.

Finally, a different issue was addressed by Lebo and Moore (2003), who analyzed an action–reaction model of foreign policy behavior for different pairs of countries, including Egypt–Israel and US–Russia. They provided strong evidence that those foreign policy series are fractionally integrated (mainly stationary and in all cases mean-reverting), and suggested the possibility of cointegration in the Egypt–Israel relation during the period 1948–76.

10.4 The empirical investigation: the PPP hypothesis

Numerous empirical studies have cast significant doubt on the PPP hypothesis with respect to the short run, but have yielded mixed evidence with respect to the long run (see, for example, Corbae and Ouliaris, 1988; Enders, 1988; Kim, 1990; Taylor, 1988). As mentioned earlier, Cheung and Lai (1993) proposed a fractional version of the PPP specification, essentially (10.5)–(10.6) with x_t representing the domestic price index and y_t the foreign price index, converted to domestic currency units. The coefficient ν in (10.5) is unity according to the absolute or homogeneous

version of PPP, so this is testable by the Wald statistic of (10.19). Using unit root tests, Cheung and Lai (1993) failed to reject the hypothesis of $\delta = 1$ and then, using differenced OLS residuals, computed semiparametric log-periodogram estimates of $\gamma - 1$ and tested the non-cointegration null hypothesis of $\delta - \gamma = 0$ against the alternative $\delta - \gamma > 0$, using critical values computed by simulation. They found evidence of cointegration in a number of bivariate series, but did not test $\nu = 1$. We employ a step-by-step approach, first testing whether the integration orders, δ_x and δ_y, of x_t and y_t are the same, then testing for the presence of cointegration, then testing for $\delta - \gamma > 0.5$ and, finally, given that all these hurdles have been crossed, testing $\nu = 1$. In the first three steps we use semiparametric procedures (as did Cheung and Lai, 1993; Marinucci and Robinson, 2001), while in the final step we identify parametric models for the autocorrelation in u_t and hence compute estimates of ν and Wald statistics.

The semiparametric estimates of integration orders were all Robinson's (1995b) versions of log-periodogram estimates, but without trimming, using first differences and then adding back 1. We estimated δ_x and δ_y separately, and then tested $\delta_x = \delta_y (= \delta)$ by an adaptation of Robinson and Yajima's (2002) statistic $\hat{T}_{ab}$ to log-periodogram estimation, with their trimming sequence $h(n)$ chosen as $b^{-1/(5+2i)}$ for $i = 1, \ldots, 4$, with b the bandwidth used in the estimation. Given $\delta_x = \delta_y$ is not rejected, we performed the Hausman test for no-cointegration of Marinucci and Robinson (2001), comparing the estimate $\tilde{\delta}_x$ of δ_x with the more efficient bivariate one of Robinson (1995b), which uses the information that $\delta_x = \delta_y$. Given cointegration is not rejected, the null $\delta - \gamma = 0.5$ was rejected in favor of $\delta - \gamma > 0.5$ if and only if a studentized $\tilde{\delta}_x - \tilde{\gamma} - 0.5$ was significantly large relative to the standard normal distribution, where $\tilde{\gamma}$ is the estimate of γ using OLS residuals.

Using annual data (as is relevant to the long-run version of PPP) of Obstfeld and Taylor (2002) for the period 1870–1992 (with $n = 123$), we applied the above methodology to four bivariate series, the US ("domestic") versus the "foreign" countries, Australia, Canada, Italy and the UK. Strong evidence against equality of integration orders was found in the case of Australia and Italy, and against cointegration in the case of Canada. However, the UK "passed" all three initial tests. Across the range $b = 10, \ldots, 29$, $(\tilde{\delta}_x, \tilde{\delta}_y)$ varied between the extremes (1.341, 1.095) and (1.572, 1.376), and across $b = 16, \ldots, 25$ and the four $h(n)$ choices, $\delta_x = \delta_y$ was rejected in only 9 out of 40 cases, and these were all at the 10% level. For the same b, no-cointegration was rejected at the 10% level in all cases, at 5% in 4 cases, and at 1% in 3 cases, while $\delta - \gamma = 0.5$ was rejected against $\delta - \gamma > 0.5$ at the 1% level in all cases.

For the US–UK data, we identified parametric models for $f(\lambda)$ as follows. We consider:

$$u_t = A(L)\varepsilon_t, \tag{10.20}$$

where ε_t is considered to be an i.i.d. process. Throughout, $A(L)$ in (10.20) was diagonal, and u_{1t}, u_{2t} treated separately. They were proxied by $\Delta^{\tilde{\gamma}}(y_t - \hat{v}_{OLS} x_t)$, $\Delta^{\tilde{\delta}_x} x_t$, for each of the extreme $\tilde{\gamma}, \tilde{\delta}_x$, namely $\tilde{\gamma} = 0.374$, 0.698 and $\tilde{\delta}_x = 1.572$,

1.341, and then Box-Jenkins-type procedures identified models within the ARMA class. This resulted in AR(1) and ARMA(1,1) models for u_{1t} and white noise and ARMA(1,1) models for u_{2t}, and we fitted all four combinations. We also fitted bivariate versions of Bloomfield's (1973) model, where:

$$A(s) = diag\left\{\exp\left(\sum_{j=1}^{p}\theta_{1j}s^{j}\right), \exp\left(\sum_{j=1}^{p}\theta_{2j}s^{j}\right)\right\},$$

for $p = 1, 2, 3$. For each model we applied the univariate Whittle procedure of Velasco and Robinson (2000), using untapered, differenced data and adding back 1. We summarize the seven models and the resulting $(\hat{\delta}, \hat{\gamma})$ as follows:

Model 1: u_{1t} is AR(1) and u_{2t} is white noise	$(\hat{\delta}, \hat{\gamma}) = (1.612, 0.669)$
Model 2: u_{1t} is AR(1) and u_{2t} is ARMA(1,1)	$(\hat{\delta}, \hat{\gamma}) = (1.408, 0.669)$
Model 3: u_{1t} is ARMA(1,1) and u_{2t} is white noise	$(\hat{\delta}, \hat{\gamma}) = (1.612, 0.660)$
Model 4: u_{1t} is ARMA(1,1) and u_{2t} is ARMA(1,1)	$(\hat{\delta}, \hat{\gamma}) = (1.408, 0.660)$
Model 5: u_t is bivariate Bloomfield with $p = 1$	$(\hat{\delta}, \hat{\gamma}) = (1.214, 0.710)$
Model 6: u_t is bivariate Bloomfield with $p = 2$	$(\hat{\delta}, \hat{\gamma}) = (1.434, 0.701)$
Model 7: u_t is bivariate Bloomfield with $p = 3$	$(\hat{\delta}, \hat{\gamma}) = (1.323, 0.547)$

The $\hat{\gamma}$ seem very robust to the short memory specification, the $\hat{\delta}$ rather less so. We also took the opportunity to examine a further question which, in one form or another, always arises with applications of fractional models, and perhaps most acutely when non-stationary data are involved. This is the matter of truncation. When estimated innovations from a stationary fractional model are computed, the (infinite) AR representation has to be truncated because the data begins at time "1," not at time "$-\infty$." Now, in our model (10.5)–(10.6) for non-stationary data, the truncation is actually inherent in the model, so strictly speaking there is no "error" associated with it. However, the model reflects the time when the data begin, and if we were to drop the first observation, say, and start the model off at the second, the degree of filtering applied to all subsequent observations would change, and it is possible that this could have a marked effect, especially with non-stationary data. Thus, in Table 10.1 we report computations of our estimates $\hat{v}(\hat{\gamma}, \hat{\delta}, \hat{\theta}) = \bar{v}_i$ and Wald statistics:

$$b(\hat{\gamma}, \hat{\theta})\{\hat{v}(\hat{\gamma}, \hat{\delta}, \hat{\theta}) - 1\}^2 = W_i,$$

for models $i = 1, \ldots, 7$, based on the last $n' = n - j$ observations, for $j = 0, 1, \ldots, 10$, in order to explore sensitivity to starting value. Substantial variation is evident across the larger n', with all $\bar{v}_i$ exceeding 1 and the homogeneity hypothesis being strongly rejected when $n' = 123$ across all seven models, but as n' decreases, things stabilize. For $n' \leq 119$ some sensitivity to the u_{2t} specification was found, the white-noise cases (Models 1 and 3) providing estimates of v less than 0.9, whereas for the other models they all exceed 0.9, with the largest values for Model 7. For $n' \leq 122$ the homogeneity hypothesis $v = 1$ is never rejected even at the 10% level.

From certain perspectives, practitioners could consider our empirical analysis simplistic, as we do not take into account possible alternative features of our

Table 10.1 PPP empirical example estimates of ν and Wald tests of $\nu = 1$ for Models 1–7 computed from the last $n' = 113, \ldots, 123$ observations of US/UK

n'	123	122	121	120	119	118	117	116	115	114	113

data. In particular, we did not check for the possibility of structural breaks or nonlinearities in our long time series. Admittedly, these are relevant issues, whose linkages with fractional processes are mainly undiscovered, but which have already attracted the attention of some researchers. For example, Granger (1999) showed that structural break processes could produce "long memory" properties of the data, while he suggested that, among nonlinear time series, there could be other plausible alternatives to $I(d)$ processes. Undoubtedly, a very rigorous and exhaustive analysis of the PPP hypothesis should contemplate these issues but, at this stage, our intention was simply to propose a sensible methodology incorporating the techniques developed in the literature and which, at the same time, motivated our testing problem appropriately.

Acknowledgments

The two authors gratefully acknowledge financial support from the Ministerio de Educación y Ciencia through the SEJ2005-07657/ECON project, and the second author also through a Ramón y Cajal contract. Thanks to Peter M. Robinson for useful comments on section 10.4 and to Alan M. Taylor for providing the data we employ in that section.

Notes

1. For the purpose of the present work we define an $I(0)$ process as a covariance stationary process with spectral density function that is positive and bounded at any frequency. Alternatively, a time domain definition corresponds to a process where the infinite sum of the autocovariances is finite.
2. The Type I definition of fractional integration has been used by Sowell (1990), Hurvich and Ray (1995), Chan and Terrin (1995), Jeganathan (1999), Velasco (1999a, 1999b), Marinucci (2000), Velasco and Robinson (2000) and others, whilst the Type II definition has been used by Robinson and Marinucci (2001), Kim and Phillips (2002), Robinson and Hualde (2003) and others.

3. Excellent surveys can be found in Beran (1994), Baillie (1996), Doukhan, Oppenheim, and Taqqu (2003) and Robinson (2003).
4. Much earlier, Hurst (1951) proposed the adjusted rescaled range, or R/S statistic. This specific estimator of d can be found in Mandelbrot and Wallis (1968) and its properties were analyzed in Mandelbrot and Wallis (1969), Mandelbrot (1972, 1975) and Mandelbrot and Taqqu (1979): see also Lo (1991) and Giraitis *et al.* (2003).
5. Multivariate methods of fractional integration (not involving cointegrating relationships) have been examined by Gil-Alana (2003a, 2003b) and Nielsen (2004, 2005).
6. See also Hidalgo and Soulier (2004) and Hidalgo (2005) for recent developments in this area.
7. The issue of fractional integration in the context of structural breaks has received increasing attention in recent years. For a review, see Banerjee and Urga (2005).
8. Note that a normalization has been carried out in (10.5), the cointegration vector corresponding to Engle and Granger's (1987) definition being now $(1, -\nu)'$. As demonstrated by Phillips and Loretan (1991), (10.5)–(10.6) with $\gamma = 0$, $\delta = 1$, represents "a typical cointegrated system" in structural form. (10.5) could be regarded as a stochastic version of the partial equilibrium $y_t - \nu x_t$, with $u_{1t}\,(-\gamma)$ representing deviations from this equilibrium. (10.6) is a reduced form equation.
9. He did not analyze exactly the model (10.5)–(10.6), but a similar one where y_t and x_t were covariance stationary long memory processes.
10. These conditions refer to the smoothness of f and convergence rates of the estimates of the nuisance parameters.
11. Chen and Hurvich (2003b) also propose estimators of the cointegrating parameter in a system with deterministic trends, but their framework is much more specific than that of Robinson and Iacone (2005), and their objective is different, because by means of tapering and differentiating the data appropriately, they present a tapered NBLS which is invariant with respect to deterministic polynomial trends in the series.
12. Kim and Phillips (2002) also provided a similar analysis to the one by Baillie and Bollerslev (1994a), assuming also the memory of certain series of exchange rates to be one.

Discrete Choice Modeling

William Greene

Abstract

We detail the basic theory for models of discrete choice. This encompasses methods of estimation and analysis of models with discrete dependent variables. Entry level theory is presented for the practitioner. We then describe a few of the recent, frontier developments in theory and practice.

11.1 Introduction

This chapter will survey models for outcomes that arise through measurement of discrete consumer choices, such as whether to vote for a particular candidate, whether to purchase a car, how to get to work, whether to purchase insurance, where to shop, or whether to rent or buy a home or a car. Traditional economic theory for consumer choice – focused on utility maximization over bundles of continuous commodities – is relatively quiet on the subject of discrete choice among a set of specific alternatives. Econometric theory and applications, in contrast, contain a vast array of analyzes of discrete outcomes; discrete choice modeling has been one of the most fruitful areas of study in econometrics for several decades. There is a useful commonality in much of this. One can build an overview of models for discrete outcomes on a platform of individual maximizing behavior. Given that the literature is as vast as it is, and we have but a small number of pages within which to package it, this seems like a useful approach. In what follows, we will survey some of the techniques used to analyze individual random utility maximizing behavior.

We emphasize that we have chosen to focus on models for discrete *choice*, rather than models for discrete *dependent variables*. This provides us with several opportunities to focus and narrow this review. First, it allows us to limit the scope of the survey to a reasonably manageable few types of models. As noted, the literature on this topic is vast. We will use this framework to select a few classes of models that are used by analysts of individual choice. It also gives us license to make a few major omissions that might otherwise fall under the umbrella of discrete outcomes. One conspicuous case will be models for counts. Event counts are obviously discrete – models for them are used to study, e.g., traffic incidents, incidence of disease, health care system utilization, credit and financial markets, and an array of other settings. Models for counts can occupy an entire library of its own in this area – two excellent references are Cameron and Trivedi (1998) and Winkelmann (2003) – but this area will extend far beyond our reach. On the other hand, applications in health economics (system utilization) and industrial organization (patents and innovations) do lead to some settings in which individual or firm choice produces a count response. We will briefly consider models for counts from this standpoint. The reader will no doubt note other areas of discrete response analysis that are certainly important. Space limitations force us to consider a fairly small number of cases.

This chapter proceeds as follows. Section 11.2 details the estimation and inference tools used throughout the remainder of the survey, including the basic results in maximum likelihood estimation. Section 11.3 analyzes in detail the fundamental pillar of analysis of discrete choice, the model for binary choice – the choice between two alternatives. Most of the applications that follow are obtained by extending or building on the basic binary choice model. Thus we examine the binary choice model in greater detail than the others, as it also provides a convenient setting in which to develop the estimation and inferential concepts that carry over to the other models. Section 11.4 considers the immediate extension of the binary choice, bivariate and multivariate binary choice models. Section 11.5 returns to the single choice setting and examines ordered choice models. Models for count data are examined in section 11.6. Finally, section 11.7 turns to an area of literature in its own right, multinomial choice modeling. As before, but even more so here, we face the problem of surveying a huge literature in a few pages. We therefore describe the most fundamental elements of multinomial choice analysis, and point the reader toward more detailed sources in the literature. Section 11.8 concludes.

11.2 Specification, estimation and inference for discrete choice models

The classical theory of consumer behavior provides the departure point for economic models of discrete individual choice.[1] A representative consumer with preferences represented by a utility function defined over the consumption of a vector of goods, $U(\mathbf{d})$, is assumed to maximize this utility subject to a budget

constraint, $\mathbf{x}'\mathbf{d} \leq y$, where $\mathbf{x}$ is a vector of prices and y is income (or total expenditure). Assuming the necessary continuity and curvature conditions, a complete set of demand equations, $\mathbf{d}^* = \mathbf{d}(\mathbf{x}, y)$ results.[2] To extend the model of individual choice to observed market data, the demand system is assumed to hold at the aggregate level, and random elements (disturbances) are introduced to account for measurement error or optimization errors.

Since the 1960s, the availability of survey data on individual behavior has obviated the heroic assumption underlying the aggregate utility function or the (perhaps slightly less heroic) assumptions underlying the aggregate demand system. That progression has evolved to the contemporary literature with the appearance of large, detailed, high quality panel surveys, such as the German Socio-Economic Panel Survey (GSOEP) (see Hujer and Schneider, 1989) that we will use in this study and the British Household Panel Survey (BHPS) (http://www.iser.essex.ac.uk/ulsc/bhps), to name only two of many. The analysis of individual data to which the original theory applies has called for (at least) two more detailed developments of that theory.

First, the classical theory has relatively little to say about the *discrete* choices that consumers make. Individual data detail career choices, voting preferences, travel mode choices, discretized measures of the strength of preferences, and participation decisions of all sorts, such as labor supply behavior, whether to make a large purchase, whether to migrate, etc. The classical, calculus based theory of decisions made at the margins of consumption will comment on, e.g., how large a refrigerator a consumer will buy, but not whether they will buy a refrigerator instead of a car (this year), or what brand of car or refrigerator they will buy.

Second, the introduction of random elements in models of choice behavior as *disturbances* is much less comfortable at the individual level than in market demands. Researchers have considered more carefully the appropriate sources and form of random variation in individual models of discrete choice.

The *random utility model* of discrete choice provides the most general platform for the analysis of discrete choice. The extension of the classical theory of utility maximization to the choice among multiple discrete alternatives provides a straightforward framework for analyzing discrete choice in probabilistic, statistical, ultimately econometric, terms.

11.2.1 Discrete choice models and discrete dependent variables

Denote by "i" a consumer who is making a choice among a set of J_{it} choices in choice situation t. To put this in a context, which will help to secure the notation, envision a *stated choice experiment* in which individual i is offered the choice of several, J_{i1}, brands of automobiles with differing prices and characteristics and asked which they most prefer. In a second round of the experiment, the interviewer changes some of the features of some of the cars, and repeats the question. Denote by $A_{it,1}, \ldots, A_{it,Jit}$, $J_{it} \geq 2$, the set of alternatives available to the individual in choice situation t. It will be convenient to adopt the panel data notation, in which "t" denotes "*time*." The generality of the notation allows the choice set to vary from one individual to another, and across choice situations for the same individual. In

most of what follows, we will not need this level of generality, but the models to be developed will accommodate it.

We will formulate a model that describes the consumer choice in probabilistic terms. (A bit more of the underlying behavioral theory is presented in section 11.8.) The "model" will consist of a probability distribution defined over the set of choices:

$$P_{it,j} = \text{Prob(consumer } i \text{ makes choice } j \text{ at time } t \mid \text{choice set}), \quad j = 1, \ldots, J_{it}.$$

The manner in which the probabilities arise is an essential feature of the model. As noted earlier, choices are dependent on the environment in which they are made, which we characterize in terms of income, y, and prices, $\mathbf{x}$. Individual heterogeneity may be measured by such indicators as family size, gender, location, etc., which we collect in a set of variables, $\mathbf{z}$, and unmeasured, and therefore random from the point of view of the analyst, indicators, which we denote as $\mathbf{u}$. Common elements of the choice mechanism that constitute the interesting quantities that the analyst seeks to draw statistical inference about will be parameters, $\boldsymbol{\beta}$, $\boldsymbol{\gamma}$, etc.[3] For purposes of translating the underlying choice process into an estimable econometric model, we define the choice indicators:

$$d_{it,j} = 1 \text{ if individual } i \text{ makes choice } j \text{ at time } t, \text{ and 0 otherwise.}$$

With all this in place, our discrete probability distribution will be defined by:

$$P_{it,j} = \text{Prob}\left(d_{it,j} = 1 | \mathbf{X}_{it}, \mathbf{z}_{it}, \mathbf{u}_{it}, \boldsymbol{\beta}, \boldsymbol{\gamma}, \ldots\right), \quad j = 1, \ldots, J_{it}$$

where $\mathbf{X}_{it}$ is the set of attributes of all J_{it} choices in the choice set for individual i at time t. Note that being characteristics of the individual, and not the choices, $\mathbf{z}_{it}$ and $\mathbf{u}_{it}$ do not vary across the choices. Whether the preference parameters, $\boldsymbol{\beta}, \boldsymbol{\gamma}, \ldots$, should be allowed to vary (i.e., whether they do vary) across individuals – i.e., whether the parameters of the utility functions are heterogeneous – is a question that we will pursue at several points below. We will assume (not completely innocently) that in any choice situation, the individual actually makes a choice. It follows that:

$$\sum_{j=1}^{J_{it}} d_{it,j} = 1 \quad \text{and} \quad \sum_{j=1}^{J_{it}} P_{it,j} = 1.$$

The "model" consists of the interesting or useful features of $P_{it,j}$. The preceding discussion assumes that, at time t, the consumer makes a single decision. It will be necessary in section 11.4 to extend the model to cases of two or more decisions. This is straightforward, but requires a small change in notation and interpretation. We will defer that extension until we encounter it in the discussion in section 11.4.

We close this section with some definitions of terms that will be used throughout the text. The individual *characteristics*, such as gender or education, are denoted $\mathbf{z}_{it}$. Attributes of the choices, such as prices, are denoted $x_{it,j}$. We denote by *binomial* or *multinomial choice*, the single choice made between either two or more than two

choices. The term *binary choice* is often used interchangeably with the former. A *bivariate choice* or *multivariate choice* is the set of two or more choices made in a single choice situation. In one of our applications, an individual chooses not to visit a physician or to visit at least once; this is a binomial choice. This coupled with a second decision, whether to visit the hospital, constitutes a bivariate choice. In a different application, the choice of which of four modes to use for travel constitutes a multinomial choice.

11.2.2 Estimation and inference

"Estimation" in this setting is less clearly defined than in the familiar linear regression model. If the model is fully parametric, then the way that the parameters interact with the variables in the model, and the particular function that applies to the problem, are all fully specified. The model is then:

$$P_{it,j} = F_{it}\left(j, \mathbf{X}_{it}, \mathbf{z}_{it}, \boldsymbol{\beta}, \boldsymbol{\gamma}, \mathbf{u}_{it}\right) \quad j = 1, \ldots, J_u.$$

We will consider models that accommodate unobserved individual heterogeneity, $\mathbf{u}_{it}$, in sections 11.6 and 11.7. For the present, to avoid an inconvenience in the formulation, we consider a model involving only the observed data. Various approaches to estimation of parameters and derivative quantities in this model have been proposed, but the likelihood based estimator is by far the method of choice in the received literature. The log-likelihood for the model is:

$$\ln L = \sum_{i=1}^{n} \sum_{t=1}^{T_i} \sum_{j=1}^{J_{it}} d_{it,j} \ln F_{it}(j, \mathbf{X}_{it}, \mathbf{z}_{it}, \boldsymbol{\beta}, \boldsymbol{\gamma}), \quad i = 1, \ldots, n \quad t = 1, \ldots, T_i.$$

The maximum likelihood estimator is that function of the data that maximizes $\ln L$.[4] (See, e.g., Greene, 2008a, Ch. 14, for discussion of maximum likelihood estimation.) The Bayesian estimator will be the mean of the posterior density:

$$p(\boldsymbol{\beta}, \boldsymbol{\gamma} | \mathbf{D}, \mathbf{X}, \mathbf{Z}) = \frac{L \times g(\boldsymbol{\beta}, \boldsymbol{\gamma})}{\int_{\beta,\gamma} L \times g(\boldsymbol{\beta}, \boldsymbol{\gamma}) d\boldsymbol{\beta} d\boldsymbol{\gamma}}.$$

where $g(\boldsymbol{\beta}, \boldsymbol{\gamma})$ is the prior density for the model parameters and (**D**,**X**,**Z**) is the full sample of data on all variables in the model. (General discussions of Bayesian methods may be found in Koop, 2003; Lancaster, 2004; Geweke, 2005.) Semiparametric methods, generally in the index form, but without a specific distributional assumption, are common in the received literature, particularly in the analysis of binary choices and panel data. These will be considered briefly in sections 11.3.4 and 11.7.2. Nonparametric analysis of discrete choice data is on the frontier of the theory, and does not play much of a role in the empirical literature. We will note this segment of the development briefly in section 11.3.4.

Estimation and inference about model parameters is discussed in the sections to follow. Though the model is commonly formulated as an "index function" model, i.e.:

$$P_{it,j} = F_{it}\left(j, \mathbf{X}_{it}'\boldsymbol{\beta}, \mathbf{z}_{it}'\boldsymbol{\gamma}\right) \quad j = 1, \ldots, J_{it},$$

even in this form, it will generally bear little resemblance to the linear regression model. As in other nonlinear cases, the interpretation of the model coefficients is ambiguous. Partial effects on the probabilities associated with the choices for individual i at time t are defined as:

$$\boldsymbol{\delta}_{it}(j, \mathbf{X}_{it}'\boldsymbol{\beta}, \mathbf{z}_{it}'\boldsymbol{\gamma}) = \partial F_{it}(j, \mathbf{X}_{it}'\boldsymbol{\beta}, \mathbf{z}_{it}'\boldsymbol{\gamma})/\partial \begin{pmatrix} \mathbf{x}_{it,j} \\ \mathbf{z}_{it} \end{pmatrix} = F_{it}'(j, \mathbf{X}_{it}\boldsymbol{\beta}, \mathbf{z}_{it}'\boldsymbol{\gamma}) \begin{pmatrix} \boldsymbol{\beta} \\ \boldsymbol{\gamma} \end{pmatrix}.$$

These are likely to be of interest for particular individuals, or averaged across individuals in the sample. A crucial implication for use of the model is that these partial effects may be quite different from the coefficients themselves. Since there is no "regression" model at work, this calls into question the interpretation of the model and its parts. No generality is possible at this point. We will return to the issue below.

A related exercise in marginal analysis of the sample and estimated model is to examine the aggregate outcomes predicted by the model:

$$\hat{n}_{t,j} = \sum_{i=1}^{n} \hat{F}_{it}(j, \mathbf{X}_{it}\boldsymbol{\beta}, \mathbf{z}_{it}'\boldsymbol{\gamma}) = \sum_{i=1}^{n} \hat{d}_{it,j}.$$

where the "ˆ" indicates the estimate from the model. For example, if $x_{it,j,k}$ denotes a policy variable, a price or a tax, say, we might be interested in:

$$\Delta\hat{n}_{t,j} = \sum_{i=1}^{n} \hat{F}_{it}(j, \mathbf{X}_{it}\boldsymbol{\beta}, \mathbf{z}_{it}'\boldsymbol{\gamma}|x_{it,j,k}^{1}) - \sum_{i=1}^{n} \hat{F}_{it}(j, \mathbf{X}_{it}\boldsymbol{\beta}, \mathbf{z}_{it}'\boldsymbol{\gamma}|x_{it,j,k}^{0}).$$

Although the subject of the impact in the partial effect is already scaled – it is a probability between zero and one – it is still common for researchers to report elasticities of probabilities rather than partial effects. These are:

$$\eta_{it,j}(\text{variable}_{it,j,k}) = \frac{F_{it}'(j, \mathbf{X}_{it}\boldsymbol{\beta}, \mathbf{z}_{it}'\boldsymbol{\gamma})}{F_{it}(j, \mathbf{X}_{it}\boldsymbol{\beta}, \mathbf{z}_{it}'\boldsymbol{\gamma})} \times \text{variable}_{it,j,k} \times \text{coefficient}_{k}.$$

This is prominently the case in the analysis of multinomial choice models, as we will explore in section 11.7.

Finally, again because the model does not correspond to a regression except in a very loose sense, the concept of fit measures is also ambiguous. There is no counterpart to "explained variation" or "total variation" in this class of models, so the idea behind the coefficient of determination (R^2) in linear regression has no meaning here. What is required to assess the fit of the model is, first, a specification of how the model will be used to predict the outcome (choice), then an assessment of how well the estimated model does in that regard.

11.2.3 Application

It will be helpful in the exposition below to illustrate the computations with a few concrete examples based on "live" data. We will use two familiar datasets. The RWM

Health Care data (our appelation) was used in Riphahn, Wambach and Million (2003) to analyze utilization of the German health care system. The dataset used is an unbalanced panel of 7,293 individual families observed over seven periods. It is part of the GSOEP, which can be downloaded from the archive site of the *Journal of Applied Econometrics* (http://qed.econ.queensu.ca/jae/2003-v18.4/riphahn-wambach-million/). We will use these to illustrate the single equation and panel data binary and ordered choice models and models for counts presented in sections 11.3–11.6. The second dataset is also widely used to illustrate multinomial choice models. These data, from Hensher and Greene (e.g., 2003), are a survey of 210 travelers between Sydney and Melbourne who chose among four modes, air, train, bus and car. We will use these data to illustrate a few multinomial choice models in section 11.7.

11.3 Binary choice

The second fundamental building block in the development of discrete choice models (after the model of random utility) is the basic model for choice between two alternatives. We would formulate this in a random utility framework with the utility of two choices:

$$U_{i,1} = \mathbf{x}_{i,1}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_{i,1}$$
$$U_{i,2} = \mathbf{x}_{i,2}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_{i,2}.$$

For convenience at this point, we assume there is a single choice made, so $T_i = 1$. The utility functions are in the index form, with characteristics and attributes and common (generic) coefficients. The random terms, $\varepsilon_{i,1}$ and $\varepsilon_{i,2}$, represent unmeasured influences on utility. (Looking forward, without these random terms, the model would imply that with sufficient data (and consistent parameter estimators), utility could be "observed" exactly, which seems improbable at best.) Consistent with the earlier description, the analyst observes the choice most preferred by the individual, that is, the one with the greater utility, say choice 1. Thus, the observed outcome reveals that:

$$U_{i,1} > U_{i,2},$$

or:

$$\mathbf{x}_{i,1}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_{i,1} > \mathbf{x}_{i,2}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_{i,2},$$

or:

$$(\mathbf{x}_{i,1}'\boldsymbol{\beta} - \mathbf{x}_{i,2}'\boldsymbol{\beta}) + (\mathbf{z}_i'\boldsymbol{\gamma} - \mathbf{z}_i'\boldsymbol{\gamma}) > (\varepsilon_{i,2} - \varepsilon_{i,1}), \tag{11.1}$$

or:

$$(\mathbf{x}_{i,1} - \mathbf{x}_{i,2})'\boldsymbol{\beta} > (\varepsilon_{i,2} - \varepsilon_{i,1}).$$

This exercise reveals several identification problems in the model as stated so far. First, we have implicitly assumed that, in the event that the two utilities are equal, the consumer chooses alternative 2. This is a normalization: recall that we assumed

earlier that the individual makes exactly one choice. Second, it is evident that, in describing the choice of process in this fashion, it is the relative values of the attributes of the choices that matter: the difference between $\mathbf{x}_{i,1}$ and $\mathbf{x}_{i,2}$ is the determinant of the observed outcome, not the specific values of either. Third, note that the choice of invariant component, $\mathbf{z}_i$, has fallen out of the choice process. The implication is that, unless the characteristics influence the utilities differently, it is not possible to measure their impact on the choice process. Finally, $\varepsilon_{i,1}$ and $\varepsilon_{i,2}$ are random variables with so far unspecified means and variances. With respect to the means, if they are μ_1 and μ_2, only $\mu_2 - \mu_1$ enters the choice. As such, if the means were $\mu_1 + \phi$ and $\mu_2 + \phi$, the same outcome would be observed. These means cannot be measured with observed data, so at least one is normalized to zero. Finally, consider the outcome of scaling both utilities by an arbitrary constant, σ. The new random components would be $\sigma\varepsilon_{i,1} = \varepsilon^*_{i,1}$ and $\sigma\varepsilon_{i,2} = \varepsilon^*_{i,2}$, and $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ would be scaled likewise. However, this scaling of the model would have no impact on the observed outcome in the last line of equation (11.1). The same choice would be observed whatever positive value σ takes. Thus, there is yet one more indeterminacy in the model. This can be resolved in several ways. The most common expedient is to normalize the scaling of the random components to one.

Combining all of these, we obtain a conventional form of the model for the choice between two alternatives:

$$\begin{aligned}
&\Delta U_i = \mu + (\Delta \mathbf{x}_i)'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_i, \quad E[\varepsilon_i|\mathbf{X}_i, \mathbf{z}_i] = 0, \quad Var[\varepsilon_i|\mathbf{X}_i, \mathbf{z}_i] = 1.\\
&d_{i1} = 1 \text{ if } \Delta U_i > 0 \text{ and } d_{i1} = 0 \text{ otherwise},\\
&d_{i2} = 1 - d_{i1}.
\end{aligned}$$

In a more familiar arrangement, we would have:

$$\begin{aligned}
d_i^* &= \mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_i\\
d_i &= 1 \text{ if } d_i^* > 0, \text{ and } d_i = 0 \text{ otherwise,}
\end{aligned} \tag{11.2}$$

where $d_i = 1$ indicates that choice 1 is selected and where the correspondence to the components of the more detailed model is direct.

11.3.1 Regression models

The preceding sections describe an underlying theoretical platform for a binary choice, based on a model of random utility. In order to translate it into an econometric model, we will add the assumptions behind the stochastic component of the specification, ε_i. To this point, the specification is semiparametric. We have not assumed anything specific about the underlying distribution, only that ε_i represents the random (from the point of view of the econometrician) element in the utility function of individual *i*. The restrictions imposed (zero mean, unit variance) are normalizations related to the identification issue and are not intended to be substantive restrictions on behavior. (Indeed, the unit variance assumption turns out to be unnecessary for some treatments. We will return to this below.)

We can approach the specification in equation (11.2) from a different viewpoint. The random utility approach specifies that d_i^* represents the strength of the individual's preference for alternative 1 relative to alternative 2. An alternative approach regards (11.2) as a *latent regression model*. The dependent variable is assumed to be unobservable; the observation is a censored variable that measures d_i^* relative to a benchmark, zero. For an example, consider a model of loan default. One would not typically think of loan default as a utility maximizing choice. On the other hand, in the context of (11.2), one might think of d_i^* as a latent measure of the financial distress of individual i. If d_i^* is high enough, the individual defaults, and we observe $d_i = 1$. By this construction, the appropriate model for d_i is a *censored regression*. Once we endow ε_i with a proper probability distribution, (11.2) can be construed as a regression model.

With the assumption of a specific distribution for ε_i, we obtain a statement of the choice probabilities:

$$\begin{aligned}\text{Prob}(d_i = 1|\mathbf{X}_i, \mathbf{z}_i) &= \text{Prob}(d_i^* > 0|\mathbf{X}_i, \mathbf{z}_i) \\ &= \text{Prob}(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_i > 0). \\ &= \text{Prob}[\varepsilon_i > -(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})] \\ &= 1 - \text{Prob}[\varepsilon_i \leq -(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})].\end{aligned}$$

It follows that:

$$\begin{aligned}E[d_i|\mathbf{X}_i, \mathbf{z}_i] &= 0 \times \text{Prob}(d_i = 0|\mathbf{X}_i, \mathbf{z}_i) + 1 \times \text{Prob}(d_i = 1|\mathbf{X}_i,\ \mathbf{z}_i) \\ &= \text{Prob}(d_i = 1|\mathbf{X}_i,\ \mathbf{z}_i),\end{aligned}$$

so we now have a regression model to manipulate as well. The implied probability endowed by our assumption of the distribution of ε_i becomes the regression of d_i on $\mathbf{X}_i$ and $\mathbf{z}_i$. By this construction, one might bypass the random utility apparatus, and simply embark on modeling:

$$\begin{aligned}d_i &= E[d_i|\mathbf{X}_i, \mathbf{z}_i] + a_i \\ &= \text{Prob}(d_i = 1|\mathbf{X}_i, \mathbf{z}_i) + a_i,\end{aligned}$$

where, by construction, a_i has zero mean, conditioned on the probability function. A remaining step is to construct the appropriate conditional mean function. This specification has suggested in some settings the *linear probability model*:

$$d_i = \mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + a_i.$$

(See, e.g., Aldrich and Nelson, 1984; Caudill, 1988; Heckman and Snyder, 1997; Angrist, 2001.) The linear probability model has some significant shortcomings, the most important of which is that the linear function cannot be constrained to lie between zero and one, so its interpretation as a probability model is suspect. With few exceptions, including those noted above, researchers have employed

proper probability models for the implied regressions. The logit and probit models described in the next section are the overwhelming choices in the received literature.

11.3.2 Estimation and inference in parametric binary choice models

A parametric model is completed by specifying a distribution for ε_i. Many candidates have been proposed, though there is little in the way of observable evidence that one can use to choose among the candidates.[5] For convenience, we will assume a symmetric distribution, such as the normal or logistic which are used in the overwhelming majority of studies. For a symmetric distribution:

$$\begin{aligned} 1 - \text{Prob}[\varepsilon_i \leq -(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})] &= \text{Prob}(\varepsilon_i \leq \mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}) \\ &= F(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}). \end{aligned}$$

Once again relying on the symmetry of the distribution, the probabilities associated with the two outcomes are:

$$\text{Prob}(d_i = 1|\mathbf{x}_i, \mathbf{z}_i) = F(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}),$$

and:

$$\text{Prob}(d_i = 0|\mathbf{x}_i, \mathbf{z}_i) = F[-(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})].$$

For the two outcomes $d_i = j, j = 0, 1$, these may be combined in the form suggested earlier:

$$F(j, \mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}) = F[(2j - 1)(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})],$$

where:

$$F(t) = \Lambda(t) = \frac{\exp(t)}{1 + \exp(t)} \text{ for the logistic distribution,}$$

and:

$$F(t) = \Phi(t) = \int_{-\infty}^{t} \frac{1}{\sqrt{2\pi}} \exp(-\frac{1}{2}z^2)dz \text{ for the normal distribution.}$$

The assumption of the logistic distribution gives rise to the logit model, while the normal distribution produces the probit model.

11.3.2.1 Parameter estimation

The model is now fully parameterized, so the analysis can proceed based either on the likelihood function or the posterior density. We consider the maximum likelihood estimator (MLE) first, and the Bayesian estimator in section 11.3.3.

The log-likelihood function for the observed data is:

$$\begin{aligned}\ln L &= \sum_{i=1}^{n} \ln \text{Prob}(d_i|\mathbf{x}_i, \mathbf{z}_i) \\ &= \sum_{d_i=1} \ln \text{Prob}(d_i = 1|\mathbf{x}_i, \mathbf{z}_i) + \sum_{d_i=0} \ln \text{Prob}(d_i = 0|\mathbf{x}_i, \mathbf{z}_i) \\ &= \sum_{i=1}^{n} \ln F[(2d_i - 1)(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})].\end{aligned}$$

Estimation by maximizing the log-likelihood is straightforward for this model. The gradient of the log-likelihood is:

$$\frac{\partial \ln L}{\partial \begin{pmatrix} \boldsymbol{\beta} \\ \boldsymbol{\gamma} \end{pmatrix}} = \sum_{i=1}^{n} (2d_i - 1) \frac{F'[(2d_i - 1)(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})]}{F[(2d_i - 1)(\mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})]} \begin{pmatrix} \mathbf{x}_i \\ \mathbf{z}_i \end{pmatrix} = \sum_{i=1}^{n} \mathbf{g}_i = \mathbf{g}.$$

The maximum likelihood estimators of the parameters are found by equating $\mathbf{g}$ to zero, an optimization problem that requires an iterative solution.[6] For convenience in what follows, we will define:

$$q_i = (2d_i - 1), \mathbf{w}_i = \begin{pmatrix} \mathbf{x}_i \\ \mathbf{z}_i \end{pmatrix}, \boldsymbol{\theta} = \begin{pmatrix} \boldsymbol{\beta} \\ \boldsymbol{\gamma} \end{pmatrix}, t_i = q_i \mathbf{w}_i'\boldsymbol{\theta}, F_i = F(t_i), F_i' = dF_i/dt_i = f_i.$$

(Thus, F_i is the cumulative density function (c.d.f.) and f_i is the density for the assumed distribution.) It follows that:

$$\mathbf{g}_i = q_i F_i'(t_i)\mathbf{w}_i = q_i f_i \mathbf{w}_i.$$

Statistical inference about the parameters is made using one of the three conventional estimators of the asymptotic covariance matrix: the Berndt, Hall, Hall and Hausman (BHHH) (1974) estimator, based on the outer products of the first derivatives:

$$\mathbf{V}_{\text{BHHH}} = \left[\sum_{i=1}^{n} \mathbf{g}_i \mathbf{g}_i'\right]^{-1},$$

the actual Hessian:

$$\mathbf{V}_{\text{H}} = \left[-\sum_{i=1}^{n} \frac{\partial^2 \ln L}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'}\right]^{-1} = \left[-\sum_{i=1}^{n} \frac{F_i F_i'' - (F_i')^2}{F_i^2}, \mathbf{w}_i \mathbf{w}_i'\right]^{-1},$$

or the expected Hessian, which can be shown to equal:

$$\mathbf{V}_{\text{EH}} = \left[-\sum_{i=1}^{n} E_{d_i}\left(\frac{\partial^2 \ln L}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}'}\right)\right]^{-1} = \left[-\sum_{i=1}^{n} \frac{f(\mathbf{w}_i'\boldsymbol{\theta}) f(-\mathbf{w}_i'\boldsymbol{\theta})}{F_i(1 - F_i)} \mathbf{w}_i \mathbf{w}_i'\right]^{-1}.$$

It has become common, even *de rigueur*, to compute a "robust" covariance matrix for the MLE using $\mathbf{V}_{\text{H}} \times \mathbf{V}_{\text{BHHH}}^{-1} \times \mathbf{V}_H$, under the assumption that the MLE is robust to failures of the specification of the model. In fact, there is no obvious failure of

the assumptions of the model (distribution, omitted variables, heteroskedasticity, and correlation across observations) for which the MLE remains consistent, so the virtue of the "corrected" covariance matrix is questionable (see Freedman, 2006).

For the two distributions considered here, the derivatives are relatively simple. For the logistic:

$$F(t) = \Lambda(t), \quad f(t) = F'(t) = \Lambda(t)[1 - \Lambda(t)], \quad F''(t) = F'(t)[1 - 2\Lambda(t)].$$

For the normal distribution (probit model), the counterparts are:

$$F(t) = \Phi(t), \quad f(t) = F'(t) = \phi(t), \quad F''(t) = -t\phi(t).$$

In both cases, $f(t) = f(-t)$ and $F(-t) = 1 - F(t)$. For estimation and inference purposes, a further convenient result is, for the logistic distribution:

$$-[F(t)F''(t) - (F'(t))^2]/F(t)^2 = \Lambda(t)(1 - \Lambda(t)) > 0 \text{ for all } t,$$

while for the normal distribution:

$$-[F(t)F''(t) - (F'(t))^2]/F(t)^2 = t[\phi(t)/\Phi(t)] + [\phi(t)/\Phi(t)]^2 > 0 \text{ for all } t.^{7}$$

The implication is that both the second derivatives matrix and the expected second derivatives matrix are negative definite for all values of the parameters and data. Optimization using Newton's method or the method of scoring will always converge to the unique maximum of the log-likelihood function, so long as the weighting matrix ($\mathbf{V}_{\text{BHHH}}$, $\mathbf{V}_{\text{H}}$ or $\mathbf{V}_{\text{EH}}$) is not singular.[8]

11.3.2.2 Residuals and predictions

Two additional useful results are obtained from the necessary conditions for maximizing the log-likelihood function. First, the component of the score function that corresponds to the constant term is:

$$\sum_{i=1}^{n} q_i \frac{F'(q_i \mathbf{w}_i'\boldsymbol{\theta})}{F(q_i \mathbf{w}_i'\boldsymbol{\theta})} = 0.$$

The terms in this sum are the *generalized residuals* of the model. As do the ordinary residuals in the regression model, the generalized residuals sum to zero at the MLE. These terms have been used for specification testing in this model (see Chesher and Irish, 1987). For the logit model, it can be shown that the result above implies that:

$$\frac{1}{n}\sum_{i=1}^{n} d_i = \frac{1}{n}\sum_{i=1}^{n} F(\mathbf{w}_i'\boldsymbol{\theta}),$$

when F is evaluated at the MLEs of the parameters. The implication is that the average of the predicted probabilities from the logit model will equal the proportion of the observations that are equal to one. A similar (albeit inexact) outcome will be seen in empirical results for the probit model. The theoretical result has not been shown analytically.

11.3.2.3 Marginal effects

Partial effects in the binary choice model are computed for continuous variables using the general result:

$$\boldsymbol{\delta}_i = \frac{\partial \text{Prob}(d_i = 1|\mathbf{w}_i)}{\partial \mathbf{w}_i} = f(\mathbf{w}_i'\boldsymbol{\theta})\boldsymbol{\theta}.$$

For a binary variable, such as gender or degree attained, the counterpart would be:

$$\Delta_i = F(\mathbf{w}_i'\boldsymbol{\theta} + \gamma_k) - F(\mathbf{w}_i'\boldsymbol{\theta})$$

where γ_k is the coefficient on the dummy variable of interest (assumed to be a characteristic of the individual). These are typically evaluated for the average individual in the sample, though current practice somewhat favors the *average partial effect*:

$$\begin{aligned}\overline{\boldsymbol{\delta}} &= \frac{1}{n}\sum_{i=1}^{n} \frac{\partial \text{Prob}(d_i=1|\mathbf{w}_i)}{\partial \mathbf{w}_i} \\ &= \frac{1}{n}\sum_{i=1}^{n} f(\mathbf{w}_i'\boldsymbol{\theta})\boldsymbol{\theta} \\ &= \left(\frac{1}{n}\sum_{i=1}^{n} f(\mathbf{w}_i'\boldsymbol{\theta})\right)\boldsymbol{\theta}.\end{aligned}$$

(The two estimators will typically not differ substantively.) Standard errors for partial effects are usually computed using the delta method. Let $\mathbf{V}$ denote the estimator of the asymptotic covariance matrix of the MLE of $\boldsymbol{\theta}$. For a particular vector, $\mathbf{w}_i$:

$$\boldsymbol{\Gamma}_i = \frac{\partial \boldsymbol{\delta}_i}{\partial \boldsymbol{\theta}'} = \left[f'(\mathbf{w}_i'\boldsymbol{\theta})\right] I + [f(\mathbf{w}_i'\boldsymbol{\theta})]\boldsymbol{\theta}\mathbf{w}_i'.$$

For a binary variable in the model, in addition to (or in) the $\mathbf{w}_i$, the corresponding row of $\boldsymbol{\Gamma}_i$ would be:

$$\boldsymbol{\Gamma}_{i,k} = \partial \Delta_{i,k}/\partial(\boldsymbol{\theta}', \gamma_k) = f(\mathbf{w}_i'\boldsymbol{\theta} + \gamma_k)[\mathbf{w}_i, 1] - f(\mathbf{w}_i'\boldsymbol{\theta})[\mathbf{w}_i, 0].$$

For the particular choice of $\mathbf{w}_i$, then, the estimator of the asymptotic covariance matrix for $\boldsymbol{\delta}_i$ would be $\boldsymbol{\Gamma}_i\mathbf{V}\boldsymbol{\Gamma}_i'$, computed at the maximum likelihood estimates. It is common to do this computation at the means of the data, $\overline{\mathbf{w}} = \frac{1}{n}\Sigma_{i=1}^{n}\mathbf{w}_i$. For the average partial effect, the computation is complicated a bit because the terms in $\overline{\boldsymbol{\delta}}$ are correlated – they use the same estimator of the parameters – so the variance of the mean is not $(1/n)$ times the sum of the variances. It can be shown (see Greene, 2008, Ch. 23) that the appropriate computation reduces to:

$$\text{Est.Asy.Var}[\overline{\boldsymbol{\delta}}] = \overline{\boldsymbol{\Gamma}}\mathbf{V}\overline{\boldsymbol{\Gamma}}', \text{ where } \overline{\boldsymbol{\Gamma}} = \frac{1}{n}\sum_{i=1}^{n}\boldsymbol{\Gamma}_i.$$

An alternative approach to computing standard errors for the marginal effects is the method of Krinsky and Robb (1986). A set of R random draws is taken from the estimated (asymptotic) normal population with mean $\hat{\boldsymbol{\theta}}_{MLE}$ and variance $\mathbf{V}$ and the empirical mean squared deviation of the estimated partial effects is computed using the MLE:

$$\text{Est.Asy.Var}[\overline{\boldsymbol{\delta}}] = \frac{1}{R}\sum_{r=1}^{R}\left(\overline{\boldsymbol{\delta}}_r - \overline{\boldsymbol{\delta}}\right)\left(\overline{\boldsymbol{\delta}}_r - \overline{\boldsymbol{\delta}}\right)',$$

where $\overline{\boldsymbol{\delta}}_r$ is computed at the random draw and $\overline{\boldsymbol{\delta}}$ is computed at $\hat{\boldsymbol{\theta}}_{MLE}$.

An empirical conundrum can arise when doing inference about partial effects rather than coefficients. For any particular variable, $\mathbf{w}_k$, the preceding theory does not guarantee that both the estimated coefficient, θ_k, and the associated partial effect, δ_k, will be "statistically significant," or statistically insignificant. In the event of a conflict, one is left with the uncomfortable problem of simultaneously rejecting and not rejecting the hypothesis that a variable should appear in the model. Opinions differ on how to proceed. Arguably, the inference should be about θ_k, not δ_k, since in the latter case, one is testing a hypothesis about a function of all the coefficients, not just the one of interest.

11.3.2.4 Hypothesis tests

Conventional hypothesis tests about restrictions on the model coefficients, $\boldsymbol{\theta}$, can be carried out using any of the three familiar procedures. Given the simplicity of the computations for the MLE, the likelihood ratio test is a natural candidate. The likelihood ratio statistic is:

$$\lambda_{\text{LR}} = 2[\ln L_1 - \ln L_0]$$

where "1" and "0" indicate the values of the log-likelihood computed at the unrestricted (alternative) estimator and the restricted (null) estimator, respectively. A hypothesis that is usually of interest in this setting is the null hypothesis that all coefficients save for the constant term are equal to zero. In this instance, it is simple to show that, regardless of the assumed distribution:

$$\ln L_0 = n[P_1 \ln P_1 + P_0 \ln P_0],$$

where P_1 is the proportion of observations for which d_i equals one, which is also $\overline{d} = \frac{1}{n}\Sigma_{i=1}^{n} d_i$, and $P_0 = 1 - P_1$. Wald statistics use the familiar results, all based on the unrestricted model. The general procedure assesses departures from the null hypothesis

$$\text{H}_0 : \mathbf{r}(\boldsymbol{\theta}, \mathbf{c}) = \mathbf{0},$$

where $\mathbf{r}(\boldsymbol{\theta}, \mathbf{c})$ is a vector of J functionally independent restrictions on $\boldsymbol{\theta}$ and $\mathbf{c}$ is a vector of constants. The typical case is the set of linear restrictions, $\text{H}_0 : \mathbf{r}\boldsymbol{\theta} - \mathbf{c} = 0$, where $\mathbf{r}$ is a matrix of constants. The Wald statistic for testing the null hypothesis is constructed using the delta method to obtain an asymptotic covariance matrix for $\mathbf{r}(\boldsymbol{\theta}, \mathbf{c})$. The statistic is:

$$\lambda_{\text{WALD}} = [\mathbf{r}(\boldsymbol{\theta}, \mathbf{c})]'[\mathbf{R}(\boldsymbol{\theta}, \mathbf{c})\mathbf{V}\mathbf{R}(\boldsymbol{\theta}, \mathbf{c})']^{-1}[\mathbf{r}(\boldsymbol{\theta}, \mathbf{c})],$$

where $\mathbf{R}(\boldsymbol{\theta}, \mathbf{c}) = \partial \mathbf{r}(\boldsymbol{\theta}, \mathbf{c})/\partial \boldsymbol{\theta}'$ and all computations are carried out using the unrestricted maximum likelihood estimator. The standard "t-test" of the significance of a coefficient is the most familiar example. The Lagrange multiplier (LM) statistic is:

$$\lambda_{\text{LM}} = \mathbf{g}^{0\prime}\mathbf{V}^0\mathbf{g}^0,$$

where "0" indicates that the computations are done using the restricted estimator and $\mathbf{V}$ is any of the estimators of the asymptotic covariance matrix of the MLE

mentioned earlier. Using $\mathbf{V}_{\text{BHHH}}$ produces a particularly convenient computation, as well as an interesting and surprisingly simple test of the null hypothesis that all coefficients save the constant are zero. Using $\mathbf{V}_{\text{BHHH}}$ and expanding the terms, we have:

$$\lambda_{\text{LM}} = \left(\sum_{i=1}^{n} q_i \mathbf{w}_i f_i^0\right)' \left(\sum_{i=1}^{n} q_i^2 (f_i^0)^2 \mathbf{w}_i \mathbf{w}_i'\right)^{-1} \left(\sum_{i=1}^{n} q_i \mathbf{w}_i f_i^0\right),$$

and an immediate simplification occurs because $q_i^2 = 1$. The density is computed at the restricted estimator, however obtained. If the null hypothesis is that all coefficients are zero save for the constant, then, for the logit model, $f_i^0 = f^0 = P_1(1-P_1)$. For the probit model, the estimator of the constant term will be $\Phi^{-1}(P_1)$ and $f^0 = \phi[\Phi^{-1}(P_1)]$. Taking this constant outside the summation in $\mathbf{g}$ leaves $\Sigma_{i=1}^{n} q_i \mathbf{w}_i = n[P_1 \overline{\mathbf{w}}_1 - P_0 \overline{\mathbf{w}}_0]$, where $\overline{\mathbf{w}}_1$ is the sample mean of the n_1 observations with d_i equal to one and $\overline{\mathbf{w}}_0$ is the mean of the n_0 remaining observations. Note that the constant f^0 falls out of the resulting statistic, and we are left with the LM statistic for testing this null hypothesis:

$$\lambda_{\text{LM}} = n^2 [P_1 \overline{\mathbf{w}}_1 - P_0 \overline{\mathbf{w}}_0]' (\mathbf{W}'\mathbf{W})^{-1} [P_1 \overline{\mathbf{w}}_1 - P_0 \overline{\mathbf{w}}_0],$$

where $\mathbf{W}$ is the data matrix with ith row equal to $\mathbf{w}_i'$. As in the case of the likelihood ratio (LR) statistic, the same computation is used for both the probit and logit models.

11.3.2.5 Specification tests

Two specification issues are typically addressed in the context of these parametric models, heteroskedasticity and the distributional assumption. For the former, since there are no useful "residuals" whose squares will reveal anything about scaling in the model, general approaches such as the Breusch and Pagan (1979, 1980) LM test or the White (1980) test are not available. Heteroskedasticity must be built into the model and tested parametrically. Moreover, there is no robust approach to estimation and inference that will accommodate heteroskedasticity without specifically making it part of the model. (In linear regression, the ordinary least squares (OLS) estimator and White's (1980) heteroskedasticity robust covariance matrix serve that purpose.) A common approach to modeling heteroskedasticity in parametric binary choice models is based on Harvey's (1976) exponential model:

$$d_i^* = \mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_i, \quad E[\varepsilon_i | \mathbf{x}_i, \mathbf{z}_i, \mathbf{v}_i] = 0, \quad \text{Var}[\varepsilon_i | \mathbf{x}_i, \mathbf{z}_i, \mathbf{v}_i] = [\exp(\mathbf{v}_i'\boldsymbol{\tau})]^2$$
$$d_i = 1 \text{ if } d_i^* > 0, \text{ and } d_i = 0 \text{ otherwise,}$$

where $\mathbf{v}_i$ is a known set of variables (that does not include a constant term) and τ is a new parameter vector to be estimated. The adjustment of the log-likelihood is fairly straightforward; the terms are changed to accommodate

$$\text{Prob}(d_i = 1 | \mathbf{x}_i, \mathbf{z}_i, \mathbf{v}_i) = F[\mathbf{w}_i'\boldsymbol{\theta} / \exp(\mathbf{v}_i'\boldsymbol{\tau})].$$

Maximization of the likelihood function with respect to all the parameters is somewhat more complicated, as the function is no longer globally concave. The

complication arises in interpretation of the model. The partial effects in this augmented model are:

$$\boldsymbol{\delta}_i = \frac{\partial \text{Prob}(d_i = 1|\mathbf{w}_i, \mathbf{v}_i)}{\partial \begin{pmatrix} \mathbf{w}_i \\ \mathbf{v}_i \end{pmatrix}} = f\left(\frac{\mathbf{w}_i'\boldsymbol{\theta}}{\exp(\mathbf{v}_i'\boldsymbol{\tau})}\right)\begin{pmatrix} \boldsymbol{\theta} \\ [-(\mathbf{w}_i'\boldsymbol{\theta})/\exp(\mathbf{v}_i'\boldsymbol{\tau})]\boldsymbol{\tau} \end{pmatrix}.$$

If $\mathbf{w}_i$ and $\mathbf{v}_i$ have variables in common, then the two effects are added. Whether they do or not, this calls into question the interpretation of the original coefficients in the model. If $\mathbf{w}_i$ and $\mathbf{v}_i$ do share variables, then the partial effect may have sign and magnitude that both differ from those of the coefficients, $\boldsymbol{\theta}$. At a minimum, as before, the scales of the partial effects are different from those of the coefficients.

For testing for homoskedasticity, the same three statistics as before are useable. (This is a parametric restriction on the model; $H_0 : \boldsymbol{\tau} = \mathbf{0}$.) The derivatives of the log-likelihood function are presented in Greene (2008, Ch. 23). As usual, the LM test is the simplest to carry out. The term necessary to compute the LM statistic under the null hypothesis is:

$$\mathbf{g}_i = q_i f_i \begin{pmatrix} \mathbf{w}_i \\ (-\mathbf{w}_i'\boldsymbol{\theta})\mathbf{v}_i \end{pmatrix}.$$

A second specification test of interest concerns the distribution. Silva (2001) has suggested a score (LM) test that is based on adding a constructed variable to the logit or probit model. An alternative way of testing the two competing models could be based on Vuong's (1989) statistic. Vuong's test is computed using:

$$\lambda_{\text{Vuong}} = \frac{\sqrt{n}\overline{m}}{s_m}, \text{ where } \overline{m} = \frac{1}{n}\Sigma_{i=1}^{n}[\ln L_i(\text{probit}) - \ln L_i(\text{logit})],$$

and s_m is the sample standard deviation. Vuong shows that, under certain assumptions (likely to be met here for these two models), λ_{Vuong} has a limiting standard normal distribution. Large positive values (larger than +1.96) favor the probit model, while large negative values (less than −1.96) favor the logit model. The power of these two statistics for this setting remains to be investigated. As with all specification tests, the power depends crucially on the true but unknown underlying model, which may be unlike either candidate model.

11.3.2.6 The fit of the model

As noted earlier, in modeling binary (or other discrete) choices, there is no direct counterpart to the R^2 goodness-of-fit statistic. A common computation which, unfortunately in spite of its name, does not provide such a measure is the *likelihood ratio index*, which is also called the

$$\text{pseudo } R^2 = 1 - \ln L/\ln L_0,$$

where $\ln L$ is the log-likelihood for the estimated model (which must include a constant term) and $\ln L_0$ is the log-likelihood function for a model that only has a

constant. It is tempting to suggest that this measure measures the "contribution" of the variables to the fit of the model. It is a statistic that lies between zero and one, and it does rise unambiguously as variables are added to the model. However, the "fit" aspect of the statistic is ambiguous, since the likelihood function is not a fit measure. As a consequence, this measure can be distressingly small in a model that contains numerous precisely measured (highly significant) coefficients (see Wooldridge, 2002a, for discussion).

This does leave open the issue of how to assess the fit of the estimated model to the data. In order to address this question, the analyst must first decide what rule will be used to predict the observed outcome using the model, then determine how successful the model (and rule) are. A natural approach, since the model predicts probabilities of events, is to use the estimated probability, $F(\mathbf{w}_i'\boldsymbol{\theta})$. The prediction is based on the rule:

$$\text{Predict } d_i = 1 \text{ if the estimated Prob}(d_i = 1|\mathbf{w}_i) \text{ is greater than } P, \tag{11.3}$$

where P^* is to be chosen by the analyst. The usual choice of P^* is 0.5, reasoning that if the model predicts that the event is more likely to occur than not, we should predict that it will.[9] A summary 2×2 table of the number of cases in which the rule predicts correctly and incorrectly can be used to assess the fit of the model. Numerous single-valued functions of this tally have been suggested as counterparts to R^2. For example, Cramer (1999) proposed:

$$\lambda_C = (\text{average } \hat{P}_i|d_i = 1) - (\text{average } \hat{P}_i|d_i = 0).$$

This measure counts the correct predictions, and adds a penalty for incorrect predictions. Other modifications and similar alternatives have been suggested by Efron (1978), Kay and Little (1986), Ben-Akiva and Lerman (1985) and Zavoina and McKelvey (1975).

11.3.3 A Bayesian estimator

The preceding section has developed the classical MLE for binomial choice models. A Bayesian estimator for the probit model illustrates an intriguing technique for censored data models. The model framework is, as before:

$$d_i^* = \mathbf{w}_i'\boldsymbol{\theta} + \varepsilon_i, \varepsilon_i \sim N[0, 1] \tag{11.4}$$

$$d_i = 1 \text{ if } d_i^* > 0, \quad \text{otherwise } d_i = 0. \tag{11.5}$$

The data consist of $(\mathbf{d},\mathbf{W}) = (d_i,\mathbf{w}_i)$, $i = 1, \ldots, n$. The random variable d_i has a Bernoulli distribution with probabilities:

$$\text{Prob}[d_i = 1|\mathbf{w}_i] = \Phi(\mathbf{w}_i'\boldsymbol{\theta})$$

$$\text{Prob}[d_i = 0|\mathbf{w}_i] = 1 - \Phi(\mathbf{w}_i'\boldsymbol{\theta}).$$

The likelihood function for the observed data, $\mathbf{d}$, conditioned on $\mathbf{W}$ and $\boldsymbol{\theta}$, is:

$$L(\mathbf{d}|\mathbf{W}, \boldsymbol{\theta}) = \prod_{i=1}^{n} [\boldsymbol{\Phi}(\mathbf{w}_i'\boldsymbol{\theta})]^{d_i}[1 - \boldsymbol{\Phi}(\mathbf{w}_i'\boldsymbol{\theta})]^{1-d_i}.$$

To obtain the posterior mean (Bayesian estimator), we assume a non-informative, flat (improper) prior for $\boldsymbol{\theta}$:

$$p(\boldsymbol{\theta}) \propto 1.$$

By Bayes' theorem, the posterior density would be:

$$\begin{aligned} p(\boldsymbol{\theta}|\mathbf{d}, \mathbf{W}) &= \frac{p(\mathbf{d}|\mathbf{W}, \boldsymbol{\theta})p(\boldsymbol{\theta})}{\int_{\boldsymbol{\theta}} p(\mathbf{d}|\mathbf{W}, \boldsymbol{\theta})p(\boldsymbol{\theta})d\boldsymbol{\theta}} \\ &= \frac{\prod_{i=1}^{n}[\Phi(\mathbf{w}_i'\boldsymbol{\theta})]^{d_i}[1-\Phi(\mathbf{w}_i'\boldsymbol{\theta})]^{1-d_i}(1)}{\int_{\boldsymbol{\theta}} \prod_{i=1}^{n}[\Phi(\mathbf{w}_i'\boldsymbol{\theta})]^{d_i}[1-\Phi(\mathbf{w}_i'\boldsymbol{\theta})]^{1-d_i}(1)d\boldsymbol{\theta}}, \end{aligned}$$

and the estimator would be the posterior mean:

$$\hat{\boldsymbol{\theta}}_{BAYESIAN} = E[\boldsymbol{\theta}|\mathbf{d}, \mathbf{W}] = \frac{\int_{\boldsymbol{\theta}} \boldsymbol{\theta} \prod_{i=1}^{n}[\Phi(\mathbf{w}_i'\boldsymbol{\theta})]^{d_i}[1-\Phi(\mathbf{w}_i'\boldsymbol{\theta})]^{1-d_i}d\boldsymbol{\theta}}{\int_{\boldsymbol{\theta}} \prod_{i=1}^{n}[\Phi(\mathbf{w}_i'\boldsymbol{\theta})]^{d_i}[1-\Phi(\mathbf{w}_i'\boldsymbol{\theta})]^{1-d_i}\, d\boldsymbol{\theta}}.$$

Evaluation of the integrals in $\hat{\boldsymbol{\theta}}_{\text{BAYESIAN}}$ is hopelessly complicated, but a solution using the Gibbs sampler and the technique of *data augmentation*, pioneered by Albert and Chib (1993), is surprisingly simple. We begin by treating the unobserved d_i^*s as unknowns to be estimated, along with $\boldsymbol{\theta}$. Thus, the $(K+n)\times 1$ parameter vector is $\boldsymbol{\alpha} = (\boldsymbol{\theta}, \mathbf{d}^*)$. We now construct a Gibbs sampler. Consider, first, $p(\boldsymbol{\theta}|\, \mathbf{d}^*,\mathbf{d},\mathbf{W})$. If d_i^* is known, then d_i is known. It follows that:

$$p(\boldsymbol{\theta}|\mathbf{d}^*, \mathbf{d}, \mathbf{W}) = p(\boldsymbol{\theta}|\mathbf{d}^*, \mathbf{W}).$$

This posterior comes from a linear regression model with normally distributed disturbances and known $\sigma^2 = 1$ (see equation (11.4) above). This is the standard case for Bayesian analysis of the normal linear model with an uninformative prior for the slopes and known σ^2 (see, e.g., Koop, 2003; Greene, 2008a, sec. 18.3.1), with the additional simplification that $\sigma^2 = 1$. It follows that:

$$p(\boldsymbol{\theta}|\mathbf{d}^*, \mathbf{d}, \mathbf{W}) = N[\mathbf{q}^*, (\mathbf{W}'\mathbf{W})^{-1}],$$

where:

$$\mathbf{q}^* = (\mathbf{W}'\mathbf{W})^{-1}\mathbf{W}'\mathbf{d}^*.$$

For d_i^*, ignoring d_i for the moment, it would follow immediately from equation (11.4) that:

$$p(d_i^*|\boldsymbol{\theta}, \mathbf{W}) = N[\mathbf{w}_i'\boldsymbol{\theta}, 1].$$

However, d_i is informative about d_i^*. If d_i equals one, we know that $d_i^* > 0$ and, if d_i equals zero, then $d_i^* \leq 0$. The implication is that, conditioned on θ, $\mathbf{W}$, and $\mathbf{d}$, d_i^* has a truncated (above or below zero) normal distribution. The standard notation for this is:

$$p(d_i^*|\boldsymbol{\theta}, d_i = 1, \mathbf{w}_i) = N^+[\mathbf{w}_i'\boldsymbol{\theta}, 1]$$

$$p(d_i^*|\boldsymbol{\theta}, d_i = 0, \mathbf{w}_i) = N^-[\mathbf{w}_i'\boldsymbol{\theta}, 1].$$

These results set up the components for a Gibbs sampler that we can use to estimate the posterior means E[$\boldsymbol{\theta}$|**d**,**W**] and E[$\mathbf{d}^*$|**d**, **W**].

11.3.3.1 Gibbs sampler for the binomial probit model

1. Compute $\mathbf{W}'\mathbf{W}$ once at the outset and obtain $\mathbf{L}$ such that $\mathbf{L}\mathbf{L}' = (\mathbf{W}'\mathbf{W})^{-1}$.
2. Start $\boldsymbol{\theta}$ at any value such as $\mathbf{0}$.
3. Obtain draws $U_{i,r}$ from the standard uniform distribution. Greene (2008a, p. 575, result (17–1)) shows how to transform a draw from $U[0,1]$ to a draw from the truncated normal with underlying mean μ and standard deviation σ. For this application, $\mu = \mathbf{w}_i'\boldsymbol{\theta}$ and $\sigma = 1$, so the draws from $p(\mathbf{d}^*|\boldsymbol{\theta},\mathbf{d},\mathbf{W})$ are obtained as:
$$d_{i,r}^*(r) = \mathbf{w}_i'\boldsymbol{\theta}_{r-1} + \boldsymbol{\Phi}^{-1}\left[1 - (1 - U_{i,r})\boldsymbol{\Phi}(\mathbf{w}_i'\boldsymbol{\theta}_{r-1})\right] \text{ if } d_i = 1$$
$$d_{i,r}^*(r) = \mathbf{w}_i'\boldsymbol{\theta}_{r-1} + \boldsymbol{\Phi}^{-1}\left[U_{i,r}\boldsymbol{\Phi}(-\mathbf{w}_i'\boldsymbol{\theta}_{r-1})\right] \text{ if } d_i = 0.$$
This step is used to draw the n observations on $d_{i,r}^*(r)$.
4. To draw an observation from the multivariate normal population of $p(\boldsymbol{\theta}|\mathbf{d}^*, \mathbf{d}, \mathbf{W}]$, we need to draw from the normal population with mean q_{r-1}^* and variance $(\mathbf{W}'\mathbf{W})^{-1}$. For this application, we use the results at step 3 to compute $\mathbf{q}^* = (\mathbf{W}'\mathbf{W})^{-1}\mathbf{W}'\mathbf{d}^*(r)$. We obtain a vector, $\mathbf{v}$, of K draws from the $N[0,1]$ population, and then compute $\boldsymbol{\theta}(r) = \mathbf{q}^* + \mathbf{L}\mathbf{v}$.

The iteration cycles between steps 3 and 4. This should be repeated several thousand times, discarding the burn-in draws, and then the estimator of $\boldsymbol{\theta}$ is the sample mean of the retained draws. The posterior variance is computed with the variance of the retained draws. Posterior estimates of d_i^* would typically not be useful.

This application of the Gibbs sampler demonstrates, in an uncomplicated case, how the algorithm can provide an alternative to actually maximizing the log-likelihood. The similarity of the method to the EM algorithm (Dempster, Laird and Rubin, 1977) is not coincidental. Both procedures use an estimate of the unobserved, censored data, and both estimate $\boldsymbol{\theta}$ by using OLS using the predicted data.

11.3.4 Semiparametric models

The fully parametric probit and logit models remain by far the mainstays of empirical research on binary choice. Fully nonparametric discrete choice models are fairly exotic and have made only limited inroads in the literature, most of which is theoretical (e.g., Matzkin, 1993). The middle ground is occupied by a few semiparametric models that have been proposed to relax the detailed assumptions of the probit and logit specifications. The single index model of Klein and Spady (1993) has been used in several applications, including Gerfin (1996), Horowitz (1993) and Fernandez and Rodriguez-Poo (1997), and provides the theoretical platform for a number of extensions.[10]

The single index formulation departs from a regression formulation:

$$E[d_i|\mathbf{w}_i] = E[d_i|\mathbf{w}_i'\boldsymbol{\theta}].$$

Then:

$$\text{Prob}(d_i = 1|\mathbf{w}_i) = F(\mathbf{w}_i'\boldsymbol{\theta}|\mathbf{w}_i) = G(\mathbf{w}_i'\boldsymbol{\theta}),$$

where G is an unknown continuous distribution function whose range is [0,1]. The function G is not specified *a priori*; it is estimated (pointwise) along with the parameters. (Since G as well as $\boldsymbol{\theta}$ is to be estimated, a constant term is not identified; essentially, G provides the location for the index that would otherwise be provided by a constant.) The criterion function for estimation, in which n subscripts denote estimators based on the sample of n observations of their unsubscripted counterparts, is:

$$\ln L_n = \frac{1}{n}\sum_{i=1}^{n}\{d_i \ln G_n(\mathbf{w}_i'\boldsymbol{\theta}_n) + (1-d_i)\ln[1-G_n(\mathbf{w}_i'\boldsymbol{\theta}_n)]\}.$$

The estimator of the probability function, G_n, is computed at each iteration using a nonparametric kernel estimator of the density of $\mathbf{w}_i'\boldsymbol{\theta}_n$. For the Klein and Spady estimator, the nonparametric regression estimator is:

$$G_n(z_i) = \frac{\overline{d}\,g_n(z_i|d_i=1)}{\overline{d}\,g_n(z_i|d_i=1) + (1-\overline{d})\,g_n(z_i|d_i=0)},$$

where $g_n(z_i|d_i)$ is the *kernel estimate of the density* of $z_i = \mathbf{w}_i'\boldsymbol{\theta}_n$. This result is:

$$g_n(z_i|d_i=1) = \frac{1}{n\overline{d}h_n}\sum_{j=1}^{n} d_j K\left(\frac{z_i - \mathbf{w}_j'\boldsymbol{\theta}_n}{h_n}\right);$$

$g_n(z_i|d_i=0)$ is obtained by replacing $\overline{d}$ with $1-\overline{d}$ in the leading scalar and d_j with $1-d_j$ in the summation. The scalar h_n is the bandwidth. There is no firm theory for choosing the kernel function or the bandwidth. Both Horowitz and Gerfin used the standard normal density. Two different methods for choosing the bandwidth are suggested by them. Klein and Spady provide theoretical background for computing asymptotic standard errors.

Manski's (1975, 1985, 1986, 1987) maximum score estimator is even less parameterized than Klein and Spady's model. The estimator is based on the fitting rule:

$$\text{Maximize}_{\theta} S_{N\alpha}(\theta) = \frac{1}{n}\sum_{i=1}^{n}[q_i - (1-2\alpha)]\text{sign}(\mathbf{w}_i'\boldsymbol{\theta}).^{11}$$

The parameter α is a preset quantile, and $q_i = 2d_i - 1$ as before. If α is set to 0.5, then the maximum score estimator chooses the $\boldsymbol{\theta}$ to maximize the number of times that the prediction has the same sign as z. This result matches our prediction rule in equation (11.3) with $P^* = 0.5$. So for $\alpha = 0.5$, the maximum score attempts to maximize the number of correct predictions. Since the sign of $\mathbf{w}'\boldsymbol{\theta}$ is the same for all positive multiples of $\boldsymbol{\theta}$, the estimator is computed subject to the constraint that $\boldsymbol{\theta}'\boldsymbol{\theta} = 1$. Variants of semiparametric estimators are discussed in Li and Racine (2007), including a modification by Horowitz (1992) and an estimator suggested by Lewbel (2000).

The semiparametric estimators of $\boldsymbol{\theta}$ are robust to variation in the distribution of the random elements in the model, and even to heteroskedasticity. Robustness

is an ambiguous virtue in this context. As we have seen, the raw coefficients are of questionable value in interpreting the model – in order to translate them into useful quantities we have computed partial effects and predicted probabilities. But the semiparametric models specifically program around the assumption of a fixed distribution and thus sacrifice the ability to compute partial effects or probabilities. What remains is the estimator of $\boldsymbol{\theta}$ and, in some cases, a covariance matrix that can be used to test the significance of coefficients or to test hypotheses about restrictions on structural coefficients.[12] Perhaps for these reasons, applied work in binary choice remains overwhelmingly dominated by the parametric models.

11.3.5 Endogenous right-hand-side variables

The presence of endogenous right-hand-side variables in a binary choice model presents familiar problems for estimation. The problem is made worse in nonlinear models because, even if one has an instrumental variable readily at hand, it may not be immediately clear what is to be done with it. The instrumental variable estimator for the linear model is based on moments of the data, the variances and covariances. In a binary choice setting, we are not using any form of least squares to estimate the parameters, so the instrumental variable (IV) method would appear not to apply. Generalized method of moments is a possibility. Consider the model:

$$
\begin{aligned}
d_i^* &= \mathbf{x}_i'\boldsymbol{\beta} + \gamma z_i + \varepsilon_i \\
d_i &= 1(d_i^* > 0) \\
E[\varepsilon_i | z_i] &= g(z_i) \neq 0.
\end{aligned}
$$

Thus z_i is endogenous in this model. The MLEs considered earlier will not consistently estimate $(\boldsymbol{\beta}, \gamma)$. (Without an additional specification that allows us to formalize $\text{Prob}(d_i = 1|\mathbf{x}_i, z_i)$, we cannot state what the MLE will, in fact, estimate.) Suppose that we have a relevant (not "weak") instrumental variable, w_i, such that:

$$
\begin{aligned}
E[\varepsilon_i | w_i, \mathbf{x}_i] &= 0 \\
E[w_i z_i] &\neq 0.
\end{aligned}
$$

A natural instrumental variable estimator would be based on the "moment" condition:

$$
E\left[(d_i^* - \mathbf{x}_i'\boldsymbol{\beta} - \gamma z_i) \begin{pmatrix} \mathbf{x}_i \\ w_i \end{pmatrix} \right] = \mathbf{0}.
$$

However, d_i^* is not observed: d_i is, but the "residual," $d_i - \mathbf{x}_i'\boldsymbol{\beta} - \gamma z_i$, would have no meaning even if the true parameters were known.[13] One approach that was used in Avery, Hansen and Hotz (1983), Butler and Chatterjee (1997) and Bertschek and Lechner (1998) is to assume that the instrumental variable is orthogonal to the residual $[d_i - \Phi(\mathbf{x}_i'\boldsymbol{\beta} + \gamma z_i)]$, i.e.:

$$
E\left[[d_i - \Phi(\mathbf{x}_i'\boldsymbol{\beta} - \gamma z_i)] \begin{pmatrix} \mathbf{x}_i \\ w_i \end{pmatrix} \right] = \mathbf{0}.
$$

This form of the moment equation, based on observables, can form the basis of a straightforward two-step generalized method of moments (GMM) estimator.

The GMM estimator is not less parametric than the full information MLE described below, because the probit model based on the normal distribution is still invoked to specify the moment equation.[14] Nothing is gained in simplicity or robustness compared to full information maximum likelihood estimation, which we now consider. (As Bertschek and Lechner, 1998, argue, however, the gains might come in terms of practical implementation and computation time. The same considerations motivated Avery, Hansen and Hotz, 1983.)

The MLE requires a full specification of the model, including the assumption that underlies the endogeneity of z_i. This becomes essentially a simultaneous equations model. The model equations are:

$$\begin{aligned} &d_i^* = \mathbf{x}_i'\beta + \gamma z_i + \varepsilon_i,\ d_i = 1[d_i^* > 0], \\ &z_i = \mathbf{w}_i'\alpha + u_i, \\ &(\varepsilon_i, u_i) \sim N\left[\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & \rho\sigma_u \\ \rho\sigma_u & \sigma_u^2 \end{pmatrix}\right]. \end{aligned} \tag{11.6}$$

(We are assuming that there is a vector of instrumental variables, $\mathbf{w}_i$.) Probit estimation based on d_i and $(\mathbf{x}_i, z_i)$ will not consistently estimate $(\boldsymbol{\beta},\gamma)$ because of the correlation between z_i and ε_i induced by the correlation between u_i and ε_i. Several methods have been proposed for estimation of this model. One possibility is to use the partial reduced form obtained by inserting the second equation into the first. This becomes a probit model with probability $\text{Prob}(d_i = 1|\mathbf{x}_i, \mathbf{w}_i) = \Phi(\mathbf{x}_i'\boldsymbol{\beta}^* + \mathbf{w}_i'\boldsymbol{\alpha}^*)$. This will produce consistent estimates of $\boldsymbol{\beta}^* = \boldsymbol{\beta}/(1 + \gamma^2\sigma^2 + 2\gamma\sigma\rho)^{1/2}$ and $\boldsymbol{\alpha}^* = \gamma\boldsymbol{\alpha}/(1 + \gamma^2\sigma^2 + 2\gamma\sigma\rho)^{1/2}$ as the coefficients on $\mathbf{x}_i$ and $\mathbf{w}_i$, respectively. (The procedure will estimate a mixture of $\boldsymbol{\beta}^*$ and $\boldsymbol{\alpha}^*$ for any variable that appears in both $\mathbf{x}_i$ and $\mathbf{w}_i$.) In addition, linear regression of z_i on $\mathbf{w}_i$ produces estimates of $\boldsymbol{\alpha}$ and σ^2, but there is no method of moments estimator of ρ or γ produced by this procedure, so this estimator is incomplete. Newey (1987) suggested a "minimum chi-squared" estimator that does estimate all parameters. A more direct, and actually simpler, approach is full information maximum likelihood.

The log-likelihood is built up from the joint density of d_i and z_i, which we write as the product of the conditional and the marginal densities:

$$f(d_i, z_i) = f(d_i|z_i)f(z_i).$$

To derive the conditional distribution, we use results for the bivariate normal, and write:

$$\varepsilon_i|u_i = [(\rho\sigma)/\sigma^2]u_i + v_i,$$

where v_i is normally distributed with $\text{Var}[v_i] = (1 - \rho^2)$. Inserting this in the first equation of equation (11.6), we have:

$$d_i^*|z_i = \mathbf{x}_i'\boldsymbol{\beta} + \gamma z_i + (\rho/\sigma)u_i + v_i.$$

Therefore:

$$\text{Prob}[d_i = 1|\mathbf{x}_i, z_i] = \Phi\left[\frac{\mathbf{x}_i'\boldsymbol{\beta} + \gamma z_i + (\rho/\sigma)u_i}{\sqrt{1-\rho^2}}\right].$$

Inserting the expression for $u_i = (z_i - \mathbf{w}_i'\boldsymbol{\alpha})$, and using the normal density for the marginal distribution of z_i in the second equation of (11.6), we obtain the log-likelihood function for the sample:

$$\ln L = \sum_{i=1}^{n} \ln \Phi\left[(2d_i - 1)\left(\frac{\mathbf{x}_i'\boldsymbol{\beta} + \gamma w_i + (\rho/\sigma_u)(z_i - \mathbf{w}_i'\boldsymbol{\alpha})}{\sqrt{1-\rho^2}}\right)\right] + \ln\left[\frac{1}{\sigma_u}\phi\left(\frac{z_i - \mathbf{w}_i'\boldsymbol{\alpha}}{\sigma_u}\right)\right].$$

11.3.6 Panel data models

The ongoing development of large, rich panel data sets on individual and family market experiences, such as the GSOEP data we are using here, has brought attention to panel data approaches for discrete choice modeling. The extensions of familiar fixed and random effects models are not direct and bring statistical and computational issues that are not present in linear regression modeling. This section will detail the most widely used techniques. This area of research is one of the most active theoretical arenas as well. We will only have space to note the theoretical frontiers briefly in the conclusions.

11.3.6.1 Panel data modeling frameworks

The natural departure point for panel data analysis of binary choice is the extension of the familiar fixed and random effects linear regression models. Since the models considered here are nonlinear, however, the convenient least squares and feasible generalized least squares methods are unavailable. This proves to be more than an inconvenience in this setting, as it mandates consideration of some specification issues. We will begin by considering extensions of the fixed and random effects models, then turn to more general models of individual heterogeneity, the random parameters and latent class models. The various models described here all carry over to a range of specifications. However, in the applied literature, the binary choice model is the leading case.

11.3.6.2 Fixed effects model

The fixed effects model is:

$$d_{it}^* = \alpha_i + \mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_{it}, \quad t = 1, \ldots, T_i,\ i = 1, \ldots, n$$
$$d_{it} = 1 \text{ if } d_{it}^* > 0, \text{ and } d_{it} = 0 \text{ otherwise.}$$

We have made the distinction between time varying attributes and characteristics, $\mathbf{x}_{it}$, and time invariant characteristics, $\mathbf{z}_i$. The common effects, α_i, may be

correlated with the included variables, $\mathbf{x}_{it}$. Since the model is nonlinear, the least squares estimator is unuseable. The log-likelihood is:

$$\ln L = \sum_{i=1}^{n} \sum_{t=1}^{T_i} \ln F[q_{it}(\alpha_i + \mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})].$$

In principle, direct (brute force) maximization of the function with respect to $(\alpha_1, \ldots, \alpha_n, \boldsymbol{\beta}, \boldsymbol{\gamma})$ can be used to obtain estimates of the parameters and of their asymptotic standard errors. However, several issues arise.

1. The number of individual intercept parameters may be excessive. In our application, e.g., there are 7,293 families. Direct maximization of the log-likelihood function for this many parameters is likely to be difficult. This purely practical issue does have a straightforward solution and is, in fact, not an obstacle to estimation (see Greene, 2001, 2008a, Ch. 23).
2. As in the case of the linear model, it is not possible to estimate the parameters that apply to time invariant variables, $\mathbf{z}_i$. In the linear case, the transformation to group mean deviations turns these variables into columns of zeros. A similar problem arises in this nonlinear model.
3. Groups of observations in which the outcome variable, d_{it}, is always one or always zero for $t = 1, \ldots, T_i$ must be dropped from the sample.
4. The full MLE for this model is inconsistent, a consequence of the *incidental parameters problem* (see Neyman and Scott, 1948; Lancaster, 2000). The problem arises because the number of α_i parameters in the model rises with n. With small T or T_i this produces a bias in the estimator of $\boldsymbol{\beta}$ that does not diminish with increases in n. The best known case, that of the logit model with $T = 2$, was documented by Andersen (1970), Hsiao (1986) and Abrevaya (1997), who showed analytically that, with $T = 2$, the MLE of $\boldsymbol{\theta}$ for the binary logit model in the presence of the fixed effects will converge to $2\boldsymbol{\theta}$. Results for other distributions and other values of T have not been obtained analytically, and are based on Monte Carlo studies. Table 11.1, extracted from Greene (2001, 2004a, 2004b), demonstrates the effect in the probit, logit, and ordered probit model discussed in section 11.5. (The conditional estimator is discussed below.) The model contains a continuous variable, x_{it1}, and a dummy variable, x_{it2}. The

[a] Estimates obtained using the conditional likelihood function – fixed effects not estimated.

population values of both coefficients are 1.0. The results, which are consistent with other studies, e.g., Katz (2001), suggest the persistence of the "small T bias" out to fairly large T.

These problems, particularly the last, have made the full fixed effects approach unattractive. The specification, however, remains an attractive alternative to the random effects approach considered next. Two approaches have been taken to work around the incidental parameters problem in the fixed effects model. A variety of semiparametric models have been suggested, such as Honore and Kyriazidou (2000a, 2000b) and Honore (2002).[15] In a few cases, including the binomial logit (but not the probit), it is possible to condition the fixed effects out of the model. The operation is similar to the group mean deviations transformation in the linear regression model. For the binary logit model (omitting the time invariant variables), we have:

$$\text{Prob}(d_{it} = j_{it}|\mathbf{x}_{it}) = \frac{\exp[j_{it}(\alpha_i + \mathbf{x}_{it}'\boldsymbol{\beta})]}{1 + \exp(\alpha_i + \mathbf{x}_{it}'\boldsymbol{\beta})} \quad \text{where } j_{it} \text{ is the observed value.}$$

This is the term that enters the unconditional log-likelihood function. However, conditioning on $\Sigma_{t=1}^{T_i} j_{it} = S_i$, we have the joint probability:

$$\text{Prob}(d_{i1} = j_{i1},\ d_{i2} = j_{i2}, \ldots |\mathbf{x}_{it}, \Sigma_{t=1}^{T_i} d_{it} = S_i) = \frac{\exp(\Sigma_{t=1}^{T_i} j_{it}\mathbf{x}_{it}'\boldsymbol{\beta})}{\sum_{\Sigma_t d_{it}=S_i} \exp(\Sigma_{t=1}^{T_i} d_{it}\mathbf{x}_{it}'\boldsymbol{\beta})}.$$

(See Rasch, 1960; Andersen, 1970; Chamberlain, 1980.) The denominator of the conditional probability is the summation over the different realizations of $(d_{i1}, \ldots, d_{i,Ti})$ that can sum to S_i. Note that, in this formulation, if $S_i = 0$ or T_i, there is only one way for the realizations to sum to S_i, and the one term in the denominator equals the observed result in the numerator. The probability equals one and, as noted in point 3 above, this group falls out of the estimator. The conditional log-likelihood is the sum of the logs of the joint probabilities. The log-likelihood is free of the fixed effects, so the estimator has the usual properties, including consistency. This estimator was used by Cecchetti (1986) and Willis (2006) to analyze magazine price changes.

The conditional estimator is consistent, so it bypasses the incidental parameter problem. However, it does have a major shortcoming. By avoiding the estimation of the fixed effects, we have precluded computation of the partial effects or estimates of the probabilities for the outcomes. So, like the robust semiparametric estimators, this approach limits the analyst to simple inference about $\boldsymbol{\beta}$ itself. One approach that might provide some headway out of this constraint is to compute second-step estimates of α_i. Since we have in hand a consistent estimator of $\boldsymbol{\beta}$, we treat that as known, and return to the unconditional log-likelihood function. For individual i, the contribution to the log-likelihood is:

$$\ln L_i = \sum_{t=1}^{T_i} \ln F[q_{it}(\alpha_i + \mathbf{x}_{it}'\boldsymbol{\beta})].$$

For convenience, denote the "known" $\mathbf{x}_{it}'\boldsymbol{\beta}$ as b_{it}. The first-order condition for maximizing ln$L$ with respect to α_i, given known $\boldsymbol{\beta}$, is:

$$\partial \ln L_i/\partial b_{it} = \sum_{t=1}^{T_i}[d_{it} - F(\alpha_i + b_{it})] = 0.$$

This is one equation in one unknown that can be solved iteratively to provide an estimate of α_i. The resulting estimator is inconsistent, since T_i is fixed – the resulting estimates are also likely to be highly variable because of the small sample sizes. However, the inconsistency results not because it converges to something other than α_i. The estimator is inconsistent because its variance is $O(1/T_i)$. Consequently, an estimator of the average partial effects:

$$\bar{\hat{\boldsymbol{\delta}}} = \frac{1}{n}\sum_{i=1}^{n}\sum_{t=1}^{T_i} f(\hat{\alpha}_i + \mathbf{x}_{it}'\hat{\boldsymbol{\beta}})\hat{\boldsymbol{\beta}},$$

may yet provide a useful estimate of the partial effects. This estimator remains to be examined empirically or theoretically.

The fixed effects model has the attractive aspect that it is a robust specification. The four shortcomings listed above, especially items 2 and 4, do reduce its appeal, however. The wisdom behind the linear model does not carry over to binary choice models because the estimation and inferential problems change substantively in nonlinear settings. The statistical aspects of the random effects model discussed next are more appealing. However, the model's assumption of orthogonality between the unobserved heterogeneity and the included variables is also unattractive. The Mundlak (1978) device is an intermediate step between these two that is sometimes used. This approach relies on a projection of the effects on the time invariant characteristics and group means of the time variables;

$$\alpha_i = \mathbf{z}_i'\boldsymbol{\gamma} + \pi_0 + \bar{\mathbf{x}}_i'\boldsymbol{\pi} + \sigma_u u_i, \quad \text{where } E[u_i|\bar{\mathbf{x}}_i] = 0 \text{ and } \text{Var}[u_i|\bar{\mathbf{x}}_i] = 1.$$

(The location parameter π_0 accommodates a non-zero mean while the scale parameter, σ_u, picks up the variance of the effects, so the assumptions of zero mean and unit variance for u_i are just normalizations.) Inserting this into the fixed effects model produces a type of random effects model:

$$d_{it}^* = \mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \pi_0 + \bar{\mathbf{x}}_i'\boldsymbol{\pi} + \sigma_u u_i + \varepsilon_{it}, \quad t = 1, \ldots, T_i, \quad i = 1, \ldots, n$$

$$d_{it} = 1 \text{ if } d_{it}^* > 0, \text{ and } d_{it} = 0 \text{ otherwise.}$$

If the presence of the projection on the group means successfully picks up the correlation between α_i and $\mathbf{x}_{it}$, then the parameters ($\boldsymbol{\beta}$, $\boldsymbol{\gamma}$, π_0, $\boldsymbol{\pi}$, σ_u) can be estimated by maximum likelihood (ML) as a random effects model. The remaining assumptions (functional form and distribution) are assumed to hold (at least approximately), so that the random effects treatment is appropriate.

11.3.6.3 Random effects models and estimation

As suggested in the preceding section, the counterpart to a random effects model for binary choice would be:

$$d_{it}^* = \mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \sigma_u u_i + \varepsilon_{it}, \quad t = 1, \ldots, T_i, \quad i = 1, \ldots, n,$$

where $E[u_i|\mathbf{x}_{it}] = 0$ and $\text{Var}[u_i|\mathbf{x}_{it}] = 1$ and:

$$d_{it} = 1 \text{ if } d_{it}^* > 0, \text{ and } d_{it} = 0 \text{ otherwise.}$$

(Since the random effects model can accommodate time invariant characteristics, we have reintroduced $\mathbf{z}_i$ into the model.) The random effects model is fitted by ML assuming normality for ε_{it} and u_i. (The most common application is the random effects probit model.)

To begin, suppose the common effect is ignored, and the "pooled" model is fitted by simple ML, ignoring the presence of the heterogeneity. The (incorrectly) assumed model is:

$$\text{Prob}(d_{it} = 1|\mathbf{x}_{it}) = F(\mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}).$$

In the presence of u_i, the correct model is:

$$\begin{aligned}\text{Prob}(d_{it} = 1|\mathbf{x}_{it}) &= \text{Prob}(\varepsilon_{it} + \sigma_u u_i < \mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}) \\ &= \text{Prob}\left(\frac{\varepsilon_{it} + \sigma_u u_i}{\sqrt{1+\sigma_u^2}} < \frac{\mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}}{\sqrt{1+\sigma_u^2}}\right) \\ &= \text{Prob}\left(v_{it} < \mathbf{x}_{it}'\boldsymbol{\beta}^u + \mathbf{z}_i'\boldsymbol{\gamma}^u\right), \quad v_{it} \sim N[0,1].\end{aligned}$$

Thus the marginal probability that d_{it} equals one obeys the assumptions of the familiar probit. However, the coefficient vector is not $\boldsymbol{\beta}$, but $\boldsymbol{\beta}^u = \boldsymbol{\beta}/(1+\sigma_u^2)^{1/2}$, and likewise for $\boldsymbol{\gamma}$. The upshot is that ignoring the heterogeneity (random effect) is not so benign here as in the linear regression model. In the regression case, ignoring a random effect that is uncorrelated with the included variables produces an inefficient, but consistent, estimator.

In spite of the preceding result, it has become common in the applied literature to report "robust," "cluster corrected" asymptotic covariance matrices for pooled estimators such as the MLE above. The underlying justification is that, while the MLE may be consistent (though it rarely is, as exemplified above), the asymptotic covariance matrix should account for the correlation across observations within a group. The corrected estimator is:

$$\begin{aligned}\text{Est.Asy.Var}\left[\hat{\boldsymbol{\theta}}_{MLE}\right] = &\left[\sum_{i=1}^{n}\sum_{t=1}^{T_i}\mathbf{H}_{it}\right]^{-1}\left[\sum_{i=1}^{n}\left(\sum_{t=1}^{T_i}\mathbf{g}_{it}\right)\left(\sum_{t=1}^{T_i}\mathbf{g}_{it}'\right)\right] \\ &\times\left[\sum_{i=1}^{n}\sum_{t=1}^{T_i}\mathbf{H}_{it}\right]^{-1},\end{aligned}$$

where $\mathbf{H}_{it} = \partial^2 \ln F(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}))/\partial\boldsymbol{\theta}\partial\boldsymbol{\theta}'$ and $\mathbf{g}_{it} = \partial \ln F(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}))/\partial\boldsymbol{\theta}$ and all terms are computed at the pooled MLE. The estimator has a passing resemblance to the White (1980) covariance estimator for the least squares coefficient estimator. However, the usefulness of this estimator rests on the assumption that the pooled estimator is consistent, which will generally not be the case.

Efficiency is a moot point for this estimator, since the probit MLE estimates $\boldsymbol{\beta}$ with a bias toward zero:

$$\begin{aligned}\text{plim } \hat{\boldsymbol{\beta}}_{MLE} &= \boldsymbol{\beta}^{u} \\ &= \boldsymbol{\beta}/(1+\sigma_u^2)^{1/2} \\ &= \boldsymbol{\beta}(1-\rho^2)^{1/2},\end{aligned}$$

where $\rho^2 = \text{Corr}^2[\varepsilon_{it}+u_i, \varepsilon_{is}+u_i]$ for $t \neq s$. Wooldridge (2002a) suggests that this may not be an issue here, since the real interest is in the partial effects, which are, for the correct model:

$$\boldsymbol{\delta}_{it} = \partial \text{Prob}[d_{it}=1|\mathbf{x}_{it}, \mathbf{z}_i]/\partial \mathbf{x}_{it} = \boldsymbol{\beta}^{u}\phi(\mathbf{x}_{it}'\boldsymbol{\beta}^{u} + \mathbf{z}_i'\boldsymbol{\gamma}^{u}).$$

These would then be averaged over the individuals in the sample. It follows, then, that the "pooled" estimator, which ignores the heterogeneity, does not estimate the structural parameters of the model correctly, but it does produce an appropriate estimator of the average partial effects.

In the random effects model, the observations are not statistically independent – because of the common u_i, the observations $(d_{i1}, \ldots, d_i, T_i, u_i)$ constitute a T_i+1 variate random vector. The contribution of observation i to the log-likelihood is the joint density:

$$f(d_{i1}, \ldots, d_{i,Ti}, u_i|\mathbf{X}_i) = f(d_{i1}, \ldots, d_{i,Ti}|\mathbf{X}_i, \mathbf{z}_i, u_i)f(u_i).$$

Conditioned on u_i, the T_i random outcomes, $d_{i1},\ldots,d_{i,Ti}$, are independent. This implies that (with the normality assumption now incorporated in the model) the contribution to the log-likelihood is:

$$\ln L_i = \ln\left\{\left[\prod_{t=1}^{T_i}\Phi\left(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \sigma_u u_i)\right)\right]\phi(u_i)\right\},$$

where $\phi(u_i)$ is the standard normal density. This joint density contains the unobserved u_i, which must be integrated out of the function to obtain the appropriate log-likelihood function in terms of the observed data. Combining all terms, we have the log-likelihood for the observed sample:

$$\ln L = \sum_{i=1}^{n}\ln\left[\int_{-\infty}^{\infty}\left(\prod_{t=1}^{T_i}\Phi\left(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \sigma_u u_i)\right)\right)\phi(u_i)du_i\right]. \tag{11.7}$$

Maximization of the log-likelihood with respect to $(\boldsymbol{\beta}, \sigma_u)$ requires evaluation of the integrals in equation (11.7). Since these do not exist in closed form, some method of approximation must be used. The most common approach is the Hermite quadrature method suggested by Butler and Moffitt (1982). The approximation is written:

$$\begin{aligned}&\int_{-\infty}^{\infty}\left(\prod_{t=1}^{T_i}\Phi\left(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \sigma_u u_i)\right)\right)\phi(u_i)du_i \approx \frac{1}{\sqrt{\pi}}\sum_{h=1}^{H} w_h \prod_{t=1}^{T_i} \\ &\quad \Phi\left(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \sqrt{2}\sigma_u z_h)\right),\end{aligned}$$

where w_h and z_h are the weights and nodes of the quadrature (see Abramovitz and Stegun, 1971) and H is the number of nodes chosen (typically 20, 32 or 64). An alternative approach to the approximation is suggested by noting that:

$$\left[\int_{-\infty}^{\infty}\left(\prod_{t=1}^{T_i}\Phi\left(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta}+\mathbf{z}_i'\boldsymbol{\gamma}+\sigma_u u_i)\right)\right)\phi(u_i)du_i\right]$$
$$=E_{u_i}\left[\prod_{t=1}^{T_i}\Phi\left(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta}+\mathbf{z}_i'\boldsymbol{\gamma}+\sigma_u u_i)\right)\right].$$

The expected value can be approximated satisfactorily by simulation by using a sufficiently large sample of random draws from the population of u_i:

$$\left[\int_{-\infty}^{\infty}\left(\prod_{t=1}^{T_i}\Phi\left(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta}+\mathbf{z}_i'\boldsymbol{\gamma}+\sigma_u u_i)\right)\right)\phi(u_i)du_i\right]$$
$$\approx\frac{1}{R}\sum_{r=1}^{R}\prod_{t=1}^{T_i}\Phi\left(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta}+\mathbf{z}_i'\boldsymbol{\gamma}+\sigma_u u_{ir})\right).$$

Sampling from the standard normal population is straightforward using modern software (see Greene, 2008a, Ch. 17). The right-hand side converges to the left-hand side as R increases (so long as $\sqrt{n}/R\rightarrow 0$; see Gourieroux and Monfort, 1996).[16] The *simulated log-likelihood* to be maximized is:

$$\ln L_S=\sum_{i=1}^{n}\ln\frac{1}{R}\sum_{r=1}^{R}\prod_{t=1}^{T_i}\Phi\left(q_{it}(\mathbf{x}_{it}'\boldsymbol{\beta}+\mathbf{z}_i'\boldsymbol{\gamma}+\sigma_u u_{ir})\right).$$

Recent research in numerical methods has revealed alternative approaches to random sampling to speed up the rate of convergence in the integration. Halton sequences (see Bhat, 1999) are often used to produce approximations which provide comparable accuracy with far fewer draws than the simulation approach.

11.3.6.4 Dynamic models

An important extension of the panel data treatment in the previous section is the dynamic model:

$$d_{it}^{*}=\mathbf{x}_{it}'\boldsymbol{\beta}+\mathbf{z}_i'\boldsymbol{\gamma}+\lambda d_{i,t-1}+\alpha_i+\varepsilon_{it}$$
$$d_{it}=1\text{ if }d_{it}^{*}>0\text{ and 0 otherwise.}\qquad(11.8)$$

Recent applications include Hyslop's (1999) analysis of labor force participation, Wooldridge's (2005) study of union membership and Contoyannis, Jones and Rice's (2004) analysis of self-reported health status in the BHPS.[17] In these and other applications, the central feature is *state dependence*, or the *initial conditions problem*: individuals tend to "stick" with their previous position. Wooldridge (2002b) lays out conditions under which an appropriate treatment is to model the individual effect as being determined by the initial value in:

$$\alpha_i=\alpha_0+\alpha_1 d_{i0}+\overline{\mathbf{x}}_i'\boldsymbol{\pi}+\sigma_u u_i,\quad u_i\sim N[0,1].\qquad(11.9)$$

This is the Mundlak treatment suggested earlier with the addition of the initial state in the projection.[18] Inserting equation (11.9) in (11.8) produces an augmented

random effects model that can be estimated, as in the static case, by Hermite quadrature of maximum simulated likelihood (MSL).

Much of the contemporary literature has focused on methods of avoiding the strong parametric assumptions of the probit and logit models. Manski (1987) and Honore and Kyriadizou (2000a) show that Manski's (1986) maximum score estimator can be applied to the differences of unequal pairs of observations in a two-period panel with fixed effects. An extension of lagged effects to a parametric model is Chamberlain (1980), Jones and Landwehr (1988) and Magnac (1997), who added state dependence to Chamberlain's fixed effects logit estimator. Unfortunately, once the identification issues are settled, the model is only operational if there are no other exogenous variables in it, which limits its usefulness for practical application. Lewbel (2000) has extended his fixed effects estimator to dynamic models as well. In this framework, the narrow assumptions about the independent variables once again limit its practical applicability. Honore and Kyriazidou (2000b) have combined the logic of the conditional logit model and Manski's maximum score estimator. They specify:

$$\begin{aligned}
&\text{Prob}(d_{i0} = 1|\mathbf{X}_i, \mathbf{z}_i, \alpha_i) = F_0(\mathbf{X}_i, \mathbf{z}_i, \alpha_i), \text{ where } \mathbf{X}_i = (\mathbf{x}_{i1}, \mathbf{x}_{i2}, \ldots, \mathbf{x}_{iT}),\\
&\text{Prob}(d_{it} = 1|\mathbf{X}_i, \mathbf{z}_i, \alpha_i, d_{i0}, d_{i1}, \ldots, d_{i,t-1})\\
&\qquad = F(\mathbf{x}_{it}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \alpha_i + \lambda d_{i,t-1})\ t = 1, \ldots, T.
\end{aligned}$$

The analysis assumes a single regressor and focuses on the case of $T = 3$. The resulting estimator resembles Chamberlain's but relies on observations for which $\mathbf{x}_{it} = \mathbf{x}_{i,t-1}$, which rules out direct time effects as well as, for practical purposes, any continuous variable. The restriction to a single regressor limits the generality of the technique as well. The need for observations with equal values of $\mathbf{x}_{it}$ is a considerable restriction, and the authors propose a kernel density estimator for the difference, $\mathbf{x}_{it} - \mathbf{x}_{i,t-1}$, instead, which does relax that restriction a bit. The end result is an estimator which converges (they conjecture) but to a non-normal distribution and at a rate slower than $n^{-1/3}$.

Semiparametric estimators for dynamic models at this point in the development are still primarily of theoretical interest. Models that extend the parametric formulations to include state dependence have a much longer history, including Heckman (1978, 1981a, 1981b), Heckman and Macurdy (1981), Jakubson (1988), Keane (1993) and Beck, Epstein and Jackman (2001), to name just a few.[19]

11.3.6.5 Parameter heterogeneity: random parameters and latent class models

Among the central features of panel data treatments of individual data is the opportunity to model individual heterogeneity, both observed and unobserved. The preceding discussion develops a set of models in which latent heterogeneity is embodied in the additive effect, α_i. We can extend the model to allow heterogeneity in the other model parameters as well,. The resulting specification is:

$$d_{it}^* = \mathbf{w}_{it}'\boldsymbol{\theta}_i + \alpha_i + \varepsilon_i, \quad d_{it} = 1(d_{it}^* > 0). \tag{11.10}$$

The specification is completed by the assumptions about the process that generates the individual specific parameters. Note that, in this formulation, the "effect" α_i is now merely an individual specific constant term. It is thus convenient to absorb it into the rest of the parameter vector, $\boldsymbol{\theta}_i$, and assume that $\mathbf{w}_{it}$ contains a constant.

A random parameters model (or mixed model or hierarchical model), in which parameters are continuously distributed across individuals, can be written:

$$\boldsymbol{\theta}_i = \boldsymbol{\theta}_0 + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{u}_i,$$

where $\mathbf{u}_i$ is a set of uncorrelated random variables with zero means (means are absorbed in $\boldsymbol{\theta}_0$) and unit variances (non-unit variances are contained in the parameter matrix $\boldsymbol{\Gamma}$). The random effects model examined earlier emerges if $\boldsymbol{\Delta} = \mathbf{0}$ and the only random component in $\boldsymbol{\theta}_i$ is the constant term, in which case $\boldsymbol{\Gamma}$ would have a single nonzero diagonal element equal to σ_u. For the more general case, we have a random parameters formulation in which:

$$E[\boldsymbol{\theta}_i|\mathbf{z}_i] = \boldsymbol{\theta}_0 + \boldsymbol{\Delta}\mathbf{z}_i$$
$$\text{Var}[\boldsymbol{\theta}_i|\mathbf{z}_i] = \boldsymbol{\Gamma}\boldsymbol{\Gamma}'.$$

A random parameters model of this sort can be estimated by Hermite quadrature (see Rabe-Hesketh, Skrondal and Pickles, 2005) or by MSL (see Train, 2003; Greene, 2008a, Ch. 17, 23). The simulated log-likelihood function for this model will be:

$$\ln L_S = \sum_{i=1}^{n} \ln \frac{1}{R} \sum_{r=1}^{R} \prod_{t=1}^{T_i} \Phi\left(q_{it}(\mathbf{w}_{it}'(\boldsymbol{\theta}_0 + \Delta\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{u}_{ir}))\right).$$

Partial effects in this model can be computed by averaging the partial effects at the population conditional means of the parameters, $E[\boldsymbol{\theta}_i|\mathbf{z}_i] = \boldsymbol{\theta}_0 + \boldsymbol{\Delta}\mathbf{z}_i$.

11.3.7 Application

Riphahn, Wambach and Million (2003) were interested in counts of physician and hospital visits. In this application, they were particularly interested in the impact that the presence of private insurance had on utilization counts, i.e., whether the data contain evidence of moral hazard. The sample is an unbalanced panel of 7,293 households. The number of households varies over seven periods (1,525; 1,079; 825; 926; 1,051; 1,000; 887) with a total number of 27,326 observations. The variables in the data file are listed in Table 11.2. (Only a few of these were used in the applications.)

The model to be examined here (not the specification used in the original study) is:

$$\text{Prob}(Doctor_{it} = 1|\mathbf{x}_{it}) = F(\beta_1 + \beta_2 Age_{it} + \beta_3 Income_{it} + \beta_4 Kids_{it} + \beta_5 Education_{it} + \beta_6 Married_{it}).$$

(In order to examine fixed effects models, we have not used any of the time invariant variables, such as gender.) Table 11.3 lists the maximum likelihood estimates and estimated asymptotic standard errors for several model specifications. Estimates of the logit model are shown first, followed by the probit estimates. There is a surprising amount of variation across the estimators. The coefficients are in bold to facilitate reading the table. The empirical regularity that the MLEs of the coefficients in the logit model are typically about 1.6 times their probit counterparts is strikingly evident in these results (e.g., the ratios are 1.613 and 1.597 for the coefficients on age and income, respectively). The apparent differences between the logit and probit results are resolved by a comparison of the partial effects also shown in Table 11.3. As anticipated, the results are essentially the same for

[a] Unconditional fixed effects estimator.
[b] Conditional fixed effects estimator.
[c] Butler and Moffitt estimator.
[d] Maximum simulated likelihood estimator.
[e] Robust, "cluster" corrected standard error.

the two models. The first two rows of partial effects in Table 11.3 compare the partial effects computed at the means of the variables, shown in the first row, to the average partial effects, computed by averaging the individual partial effects, shown in the second row. As might be expected, the differences between them are inconsequential.

The log-likelihood for the probit model is slightly larger than for the logit: however, it is not possible to compare the two on this basis as the models are non-nested. The Vuong statistic, based on $v_i = \ln L_i(\text{logit}) - \ln L_i(\text{probit})$, equals -7.44, which favors the probit model. The aggregated prediction of the pooled logit model is shown in the following table, using the usual prediction rule, $P^* = 0.5$.

	Predicted	
Actual	0	1
0	378	9,757
1	394	16,797

Thus, we obtain correct prediction of $(378 + 16,797)/27,326 = 62.9\%$ of the observations. In spite of this apparently good model performance, the pseudo-R^2 is only $1 - (-17673.10)/(-18019.55) = 0.01923$. This suggests a disconnection between these two measures of model performance. As a final check on the model itself, we tested the null hypothesis that the five coefficients other than the constant term are zero in the probit specification. The likelihood ratio test is based on the statistic:

$$\lambda_{\text{LR}} = 2[-17670.94 - 27326(.37089 \ln .37089 + .62911 \ln .62911)] = 697.22.$$

The Wald statistic based on the full model is λ_{WALD} = 686.991. The LM statistic is computed as:

$$\lambda_{LM} = \mathbf{g}_0' \boldsymbol{X} (\mathbf{G}_0' \boldsymbol{G}_0)^{-1} \mathbf{X}' \mathbf{g}_0,$$

where $\mathbf{g}_0$ is the derivative of the log-likelihood when the model contains only a constant term. This is equal to $q_{it}\phi(q_{it}\beta_0)/\Phi(q_{it}\beta_0)$, where $\beta_0 = \Phi^{-1}(.62911) = .32949$. Then the ith row of $\mathbf{G}$ is $\mathbf{g}_{it,0}$ times the corresponding row of $\mathbf{X}$. The value of the LM statistic is 715.97. The 5% critical value from the chi-squared distribution with 5 degrees of freedom is 11.07 so, in all three cases, the null hypothesis that the slopes are zero is soundly rejected.

The second set of probit estimates was computed using the Gibbs sampler and a noninformative prior. We used only 500 replications, and discarded the first 100 for the burn-in. The similarity to the maximum likelihood estimates is what one would expect given the large sample size. We note, however, that, notwithstanding the striking similarity of the Gibbs sampler to the MLE, this is not an efficient method of estimating the parameters of a probit model. The estimator requires generation

of thousands of samples of potentially thousands of observations. We used only 500 replications to produce the results in Table 11.3. The computations took about five minutes. Using Newton's method to maximize the log-likelihood directly took less than five seconds. Unless one is wedded to the Bayesian paradigm then, on strictly practical grounds, the MLE would be the preferred estimator.

Table 11.3 also lists the probit and logit random and fixed effects estimators. The random effects estimators produce a reasonably large estimate of ρ^2, roughly 0.44. The high correlation across observations does cast some doubt on the validity of the pooled estimator. The pooled estimator is inconsistent in either the fixed or random effects cases. The logit results include two fixed effects estimators. The model marked "U" is the unconditional (inconsistent) estimator. The one marked "C" is Chamberlain's consistent estimator. Note that, for all three fixed effects estimators, it is necessary to drop from the sample any groups that have Doctor_{it} equal to zero or one for every period. There were 3,046 such groups, which is about 42% of the sample. We also computed the probit random effects model in two ways: first by using the Butler and Moffitt method, then by using MSL estimation. In this case, the estimators are very similar, as might be expected. The estimated squared correlation coefficient is computed as $\rho^2 = \sigma_u^2/(\sigma_\varepsilon^2 + \sigma_u^2)$. For the probit model, $\sigma_\varepsilon^2 = 1$. The MSL estimator computes $s_u = 0.9088376$, from which we obtained ρ^2. The estimated partial effects for the models are also shown in Table 11.3. The average of the fixed effects constant terms is used to obtain a constant term for the fixed effects case. Once again there is a considerable amount of variation across the different estimators. On average, the fixed effects models tend to produce much larger values than the pooled or random effects models.

Finally, we carried out two tests of the stability of the model. All of the estimators listed in Table 11.3 derive from a model in which it is assumed that the same coefficient vector applies in every period. To examine this assumption, we carried out a homogeneity test of the hypothesis:

$$H_0 : \boldsymbol{\beta}_1 = \boldsymbol{\beta}_2 = \ldots = \boldsymbol{\beta}_T,$$

for the $T = 7$ periods in the sample. The likelihood ratio statistic is:

$$\lambda = 2\left[\left(\Sigma_{t=1}^{T} \ln L_t\right) - \ln L_{POOLED}\right].$$

The first part of the statistic is obtained by dividing the sample into the seven years of data – the number of observations varies (3,874; 3,794; 3,792; 3,661; 4,483; 4,340; 3,377) – and then estimating the model separately for each year. The calculated statistic is 202.97. The 5% critical value from the chi squared distribution with $(T-1)6 = 36$ degrees of freedom is 50.998, so the homogeneity assumption is rejected by the data. As a second test, we separated the sample into men and women and once again tested for homogeneity. The likelihood ratio test statistic is:

$$\begin{aligned}\lambda &= 2[\ln L_{\text{FEMALE}} + \ln L_{\text{MALE}} - \ln L_{\text{POOLED}}] \\ &= 2[(-7855.219377) + (-9541.065897) - (-18019.55)] \\ &= 1246.529452.\end{aligned}$$

The 5% critical value from the chi-squared distribution with 6 degrees of freedom is 12.592, so this hypothesis is rejected as well.

11.4 Bivariate and multivariate binary choice

The health care data contain two binary variables, DOCTOR and HOSPITAL, which one would expect to be at least correlated if not jointly determined. The extension of the binary choice model to more than one choice is relatively uncomplicated, but does bring new statistical issues as well as new practical complications. We consider several two equation specifications first, as these are the leading cases, then consider the extension to an arbitrary number of binary choices.

11.4.1 Bivariate binary choice

A two-equation binary choice model would take the form of a seemingly unrelated regressions model:

$$d_{i,1}^* = \mathbf{w}_{i,1}'\boldsymbol{\theta}_1 + \varepsilon_{i,1}, \quad d_{i,1} = 1 \text{ if } d_{i,1}^* > 0,$$
$$d_{i,2}^* = \mathbf{w}_{i,2}'\boldsymbol{\theta}_2 + \varepsilon_{i,2}, \quad d_{i,2} = 1 \text{ if } d_{i,2}^* > 0,$$

where "1" and "2" distinguish the equations (and are distinct from the periods in a panel data case). The bivariate binary choice model arises when the two disturbances are correlated. There is no convenient approach for this model based on the logistic model, so we assume bivariate normality at the outset. The bivariate probit model has:

$$F(\varepsilon_{i,1}, \varepsilon_{i,2}) = N_2[(0,0),(1,1),\rho], \quad -1 < \rho < 1.$$

The probability associated with the joint event $d_{i,1} = d_{i,2} = 1$ is then:

$$\text{Prob}(d_{i,1} = 1, d_{i,2} = 1 | \mathbf{w}_{i,1}, \mathbf{w}_{i,2}) = \Phi_2\left[\mathbf{w}_{i,1}'\boldsymbol{\theta}_1, \mathbf{w}_{i,2}'\boldsymbol{\theta}_2, \rho\right],$$

where $\Phi_2[t_1, t_2, \rho]$ denotes the bivariate normal c.d.f. The log-likelihood function is the joint density for the observed outcomes. By extending the formulation of the univariate probit model in the preceding section, we obtain:

$$\ln L = \sum_{i=1}^{n} \ln \Phi_2\left[\left(q_{i,1}\mathbf{w}_{i,1}'\boldsymbol{\theta}_1\right), \left(q_{i,2}\mathbf{w}_{i,2}'\boldsymbol{\theta}_2\right), \left(q_{i,1}q_{i,2}\rho\right)\right].$$

The bivariate normal integral does not exist in closed form, and must be approximated, typically with Hermite quadrature.

The model is otherwise conventional and the standard conditions for MLEs are obtained. Interpretation of the model does bring some complications, however. First, $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$ are not the slopes of any recognizable conditional mean function and neither are the derivatives of the possibly interesting $\text{Prob}(d_{i,1} = 1, d_{i,2} = 1 | \mathbf{w}_{i,1}, \mathbf{w}_{i,2})$. Both of these are complicated functions of all the model parameters and both data vectors (see Greene, 2008a, sec. 23.8.3; Christofides, Stengos and Swidinsky, 1997; Christofides, Hardin and Stengos, 2000). Since this is a two-equation model, it is unclear what quantity should be analyzed when interpreting the coefficients in relation to partial effects. One possibility

is the joint probability, $\text{Prob}(d_{i,1} = 1, d_{i,2} = 1) = \Phi_2\left[\mathbf{w}_{i,1}'\boldsymbol{\theta}_1,\ \mathbf{w}_{i,2}'\boldsymbol{\theta}_2,\ \rho\right]$, that is analyzed by Christofides, Stengos and Swidinsky (1997). Greene (1996, 2008a) considers, instead, the conditional mean function $\text{E}[d_{i,1}|d_{i,2} = 1, \mathbf{w}_{i,1}, \mathbf{w}_{i,2}] = \Phi_2\left[\mathbf{w}_{i,1}'\boldsymbol{\theta}_1,\ \mathbf{w}_{i,2}'\boldsymbol{\theta}_2,\ \rho\right]/\Phi[\mathbf{w}_{i,2}'\boldsymbol{\theta}_2]$. In either case, the raw coefficients bear little resemblance to the partial effects.

For hypothesis testing about the coefficients, the standard results for Wald, LM and LR tests apply. The LM test is likely to be cumbersome because the derivatives of the log-likelihood function are complicated. The other two are straightforward. A hypothesis of interest is that the correlation is zero. For testing:

$$H_0 : \rho = 0,$$

all three likelihood-based procedures are straightforward, as the application below demonstrates. The LM statistic derived by Kiefer (1982) is:

$$\lambda_{\text{LM}} = \frac{\left\{\sum_{i=1}^{n}\left[q_i, 1q_i, 2\frac{\phi(\mathbf{w}_{i,1}'\boldsymbol{\theta}_1)\phi(\mathbf{w}_{i,2}'\boldsymbol{\theta}_2)}{\Phi(\mathbf{w}_{i,1}'\boldsymbol{\theta}_1)\Phi(\mathbf{w}_{i,2}'\boldsymbol{\theta}_2)}\right]\right\}^2}{\sum_{i=1}^{n}\left\{\frac{\left[\phi(\mathbf{w}_{i,1}'\boldsymbol{\theta}_1)\phi(\mathbf{w}_{i,2}'\boldsymbol{\theta}_2)\right]^2}{\Phi(\mathbf{w}_i', 1\boldsymbol{\theta}_1)\Phi(-\mathbf{w}_i', 1\boldsymbol{\theta}_1)\Phi(\mathbf{w}_i', 2\boldsymbol{\theta}_2)\Phi(-\mathbf{w}_i', 2\boldsymbol{\theta}_2)}\right\}},$$

where the two coefficient vectors are the MLEs from the univariate probit models estimated separately.

11.4.2 Recursive simultaneous equations

Section 11.3.5 considered a type of simultaneous equations model in which an endogenous regressor appears on the right-hand side of a probit model. Two other simultaneous equations specifications have attracted interest. Amemiya (1985) demonstrates that a fully simultaneous bivariate probit model,

$$\begin{aligned} d_{i,1}^* &= \mathbf{w}_{i,1}'\boldsymbol{\theta}_1 + \gamma_1 d_{i,2} + \varepsilon_{i,1}, \quad d_{i,1} = 1 \text{ if } d_{i,1}^* > 0, \\ d_{i,2}^* &= \mathbf{w}_{i,2}'\boldsymbol{\theta}_2 + \gamma_2 d_{i,1} + \varepsilon_{i,2}, \quad d_{i,2} = 1 \text{ if } d_{i,2}^* > 0, \end{aligned}$$

is internally inconsistent and unidentified. However, a recursive model:

$$\begin{aligned} d_{i,1}^* &= \mathbf{w}_{i,1}'\boldsymbol{\theta}_1 + \varepsilon_{i,1}, \qquad\qquad d_{i,1} = 1 \text{ if } d_{i,1}^* > 0, \\ d_{i,2}^* &= \mathbf{w}_{i,2}'\boldsymbol{\theta}_2 + \gamma_2 d_{i,1} + \varepsilon_{i,2}, \quad d_{i,2} = 1 \text{ if } d_{i,2}^* > 0, \\ (\varepsilon_{i,1}&\varepsilon_{i,2}) \sim N_2[(0,0),(1,1),\rho], \end{aligned}$$

is a straightforward extension of the bivariate model. For estimation of this model, we have the counterintuitive result that it can be fitted as an ordinary bivariate probit model with the additional right-hand-side variable in the second equation, ignoring the simultaneity. The recent literature provides a variety of applications of this model, including Greene (1998), Fabbri, Monfardini and Radice (2004), Kassouf and Hoffman (2006), White and Wolaver (2003), Gandelman (2005) and Greene, Rhine and Toussaint-Comeau (2006).

Interpretation of the components of this model is particularly complicated. Typically, interest will center on the second equation. In Greene (1998), the second equation concerned the presence of a gender economics course in a college curriculum, while the first equation specified the presence of a women's studies program on the campus. In Kassouf and Hoffman (2006), the authors were interested in the occurrence of work-related injuries while the first conditioning equation specified the use or non-use of protective equipment. Fabbri, Monfardini and Radice (2004) analyzed the choice of Cesarean delivery conditioned on hospital type (public or private). In Greene, Rhine and Toussaint-Comeau (2003), the main equation concerned use of a check cashing facility while the conditioning event in the first equation was whether or not the individual participated in the banking system. In all of these cases, the margin of interest is the impact of the variables in the model on the probability that $d_{i,2}$ equals one. Because $d_{i,1}$ appears in the second equation, there is (potentially) a direct effect (in $\mathbf{w}_{i,2}$) and an indirect effect transmitted to $d_{i,2}$ through the impact of the variable in question on the probability that $d_{i,1}$ equals one. Details on these computations appear in Greene (2008a) and Kassouf and Hoffmann (2006).

11.4.3 Sample selection in a bivariate probit model

Another bivariate probit model that is related to the recursive model of the preceding section is the *bivariate probit with sample selection*. The structural equations are

$$d_{i,1}^{*} = \mathbf{w}_{i,1}'\boldsymbol{\theta}_1 + \varepsilon_{i,1}, \quad d_{i,1} = 1 \text{ if } d_{i,1}^{*} > 0, \text{ 0 otherwise,}$$

$$d_{i,2}^{*} = \mathbf{w}_{i,2}'\boldsymbol{\theta}_2 + \varepsilon_{i,2}, \quad d_{i,2} = 1 \text{ if } d_{i,2}^{*} > 0, \text{ 0 otherwise, and if } d_{i,1} = 1,$$

$$d_{i,2}, \mathbf{w}_{i,2} \text{ are unobserved when } d_{i,1} = 0,$$

$$(\varepsilon_{i,1}\varepsilon_{i,2}) \sim N_2[(0,0),(1,1),\rho].$$

The first equation is a "selection equation." Presence in the sample of observations for the second equation is determined by the first. Like the recursive model, this framework has been used in a variety of applications. The first was a study of the choice of deductibles in insurance coverage by Wynand and van Praag (1981). Boyes, Hoffman and Low (1989) and Greene (1992) studied loan default in which the application is the selection rule. More recently, McQuestion (2000) has used the model to analyze health status (selection) and health behavior, and Lee, Lee and Eastwood (2003) have studied consumer adoption of computer banking technology.

Estimation of this sample selection model is done by maximum likelihood in one step.[20] The log-likelihood is:

$$\ln L = \sum_{d_{i,a}=0} \ln \Phi(-\mathbf{w}_{i,1}'\boldsymbol{\theta}_1) + \sum_{i=1,d_{i,1}=1}^{n} \ln \Phi_2\left[\mathbf{w}_{i,1}'\boldsymbol{\theta}_1, q_{i,2}\mathbf{w}_{i,2}'\boldsymbol{\theta}_2, q_{i,2}\rho\right].$$

As before, estimation and inference in this model follows the standard procedures.

11.4.4 Multivariate binary choice and the panel probit model

In principle, the bivariate probit model can be extended to an arbitrary number of equations, as:

$$
\begin{aligned}
&d_{i,1}^{*} = \mathbf{w}_{i,1}'\boldsymbol{\theta}_1 + \varepsilon_{i,1}, \quad d_{i,1} = 1 \text{ if } d_{i,1}^{*} > 0,\\
&d_{i,2}^{*} = \mathbf{w}_{i,2}'\boldsymbol{\theta}_2 + \varepsilon_{i,2}, \quad d_{i,2} = 1 \text{ if } d_{i,2}^{*} > 0\\
&\cdots\\
&d_{i,M}^{*} = \mathbf{w}_{i,M}'\boldsymbol{\theta}_M + \varepsilon_{i,M}, d_{i,M} = 1 \text{ if } d_{i,M}^{*} > 0,\\
&\begin{pmatrix} \varepsilon_{i,1} \\ \varepsilon_{i,2} \\ \cdots \\ \varepsilon_{i,M} \end{pmatrix} \sim N\left[\begin{pmatrix} 0 \\ 0 \\ \cdots \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & \rho_{12} & \cdots & \rho_{1M} \\ \rho_{12} & 1 & \cdots & \rho_{2M} \\ \cdots & \cdots & \cdots & \cdots \\ \rho_{1M} & \rho_{2M} & \cdots & 1 \end{pmatrix}\right] \quad = \quad N_2[\mathbf{0}, \mathbf{R}].
\end{aligned}
$$

The obstacle to the use of this model is its computational burden. The log-likelihood is computed as follows. Let:

$$
\begin{aligned}
&\mathbf{Q}_i = \text{diag}(q_{i,1}, q_{i,2}, \ldots, q_{i,M})\\
&\mathbf{b}_i = (\mathbf{w}_{i,1}'\boldsymbol{\theta}_1, \mathbf{w}_{i,2}'\boldsymbol{\theta}_2, \ldots, \mathbf{w}_{i,M}'\boldsymbol{\theta}_M)'\\
&\mathbf{c}_i = \mathbf{Q}_i\mathbf{b}_i\\
&\mathbf{D}_i = \mathbf{Q}_i\mathbf{R}\mathbf{Q}_i.
\end{aligned}
$$

Then:

$$\ln L = \sum_{i=1}^{n} \ln \Phi_M[\mathbf{c}_i, \mathbf{D}_i].$$

Evaluation of the M-variate normal c.d.f. cannot be done analytically or with quadrature. It is done with simulation, typically using the GHK (Geweke, Hajivassilou and Keane) simulator.

This form of the model also generalizes the random effects probit model examined earlier. We can relax the assumption of equal cross-period correlations by writing:

$$
\begin{aligned}
&d_{it}^{*} = \mathbf{w}_{it}'\boldsymbol{\theta} + \varepsilon_{it}, \quad d_{it} = 1 \text{ if } d_{it}^{*} > 0, \ 0 \text{ otherwise},\\
&(\varepsilon_{i1}, \ldots, \varepsilon_{iT}) \sim N[\mathbf{0}, \mathbf{R}].
\end{aligned}
$$

This is precisely the model immediately above with the constraint that the coefficients in the equations are all the same. In this form, it is conventionally labeled the *panel probit model*.[21] Bertschek and Lechner (1998) devised a GMM estimator to circumvent the computational burden of this model. Greene (2004a) examined the same model, and considered alternative computational procedures as well as some variations of the model specification.

11.4.5 Application

Riphahn, Wambach and Million (2003) studied the joint determination of two counts, doctor visits and hospital visits. One would expect these to be highly correlated, so a bivariate probit model should apply to DOCTOR = 1 (DocVis > 0) and HOSPITAL = 1(HospVis > 0). The simple product moment correlation coefficient is inappropriate for binary variables. The tetrachoric correlation is used instead; this turns out to be the estimate of ρ in a bivariate probit model in which both equations contain only a constant term. The first estimated model in Table 11.4 reports a value of 0.311 with a standard error of only 0.0136, so the results are consistent with the conjecture. The second set of estimates assume $\rho = 0$; the estimates for the "Doctor" equation are reproduced from Table 11.3. As noted, there is evidence that ρ is positive. Kiefer's (1982) LM statistic equals 399.20. The limiting distribution is chi-squared with one degree of freedom – the 5% critical value is 3.84, so the hypothesis that the outcomes are uncorrelated is rejected. The Wald and likelihood ratio statistics based on the unrestricted model are $21.496^2 = 462.08$ and $2[17670.94 + 8084.465 - 25534.46] = 441.998$, respectively, so the hypothesis is rejected by all three tests. The third model shown in Table 11.4 is the unrestricted bivariate probit model, while the fourth is the recursive bivariate probit model with DOCTOR added to the right-hand side of the HOSPITAL equation. The results do not support this specification; the log-likelihood is almost unchanged. It is noteworthy that in this expanded specification, the estimate of ρ is no longer significant, as might have been expected.

Table 11.4 Estimated bivariate probit models (standard errors in parentheses)

11.5 Ordered choice

In the preceding sections, the consumer is assumed to maximize utility over a pair of alternatives. Models of ordered choice describe settings in which individuals reveal the strength of their utility with respect to a single outcome. For example, in a survey of voter preferences over a single issue (a new public facility or project, a political candidate, etc.), random utility is, as before:

$$U_i^* = \mathbf{x}_i'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_i.$$

The individual reveals a censored version of U_i^* through a discrete response, e.g.,

$$\begin{aligned} y_i = 0 &: \text{strongly dislike} \\ 1 &: \text{mildly dislike} \\ 2 &: \text{indifferent} \\ 3 &: \text{mildly prefer} \\ 4 &: \text{strongly prefer.} \end{aligned}$$

The translation between the underlying U_i^* and the observed y_i produces the ordered choice model:

$$\begin{aligned} y_i = 0 \quad & \text{if } U_i^* \le \mu_0 \\ 1 \quad & \text{if } \mu_0 < U_i^* \le \mu_1 \\ 2 \quad & \text{if } \mu_1 < U_i^* \le \mu_2 \\ & \cdots \\ J \quad & \text{if } \mu_{J-1} < U_i^* \le \mu_J, \end{aligned}$$

where $\mu_0, \ldots, \mu_J$ are threshold parameters that are to be estimated with the other model parameters subject to $\mu_j > \mu_{j-1}$ for all j. Assuming $\boldsymbol{\beta}$ contains a constant term, the distribution is located by the normalization $\mu_0 = 0$. At the upper tail, $\mu_J = +\infty$. Probabilities for the observed outcomes are derived from the laws of probability:

$$\text{Prob}(y_i = j | x_i, z_i) = \text{Prob}(\mu_{j-1} < U_i^* \le \mu_j), \text{ where } \mu_{-1} = -\infty.$$

As before, the observed data do not reveal information about the scaling of ε_i, so the variance is normalized to one. Two standard cases appear in the literature; if ε_i has a normal distribution, then the ordered probit model emerges, while if it has the standardized logistic distribution, the ordered logit model is produced. (Other distributions have been suggested as the model is internally consistent with any continuous distribution over the real line. However, these two overwhelmingly dominate the received applications.)

By the laws of probability:

$$\begin{aligned}\text{Prob}(y_i = j|\mathbf{x}_{i,},\ \mathbf{z}_i) &= \text{Prob}(U_i^* \le \mu_j) - \text{Prob}(U_i^* \le \mu_{j-1}) \\ &= F(\mu_j - \mathbf{x}_i'\boldsymbol{\beta} - \mathbf{z}_i'\boldsymbol{\gamma}) - F(\mu_{j-1} - \mathbf{x}_i'\boldsymbol{\beta} - \mathbf{z}_i'\boldsymbol{\gamma}),\end{aligned}$$

where $F(t)$ is the assumed c.d.f., either normal or logistic. These are the terms that enter the log-likelihood for a sample of n observations. The standard conditions for maximum likelihood estimation apply here. The results in Table 11.1 suggest that the force of the incidental parameters problem in the fixed effects case is similar to that for the binomial probit model.

As usual in discrete choice models, partial effects in this model differ substantively from the coefficients. Note, first, that there is no obvious regression at work. Since y_i is merely a labeling with no implicit scale, there is no conditional mean function to analyze. In order to analyze the impact of changes in a variable, say income, one can decompose the set of probabilities. For a continuous variable $x_{i,k}$, e.g.:

$$\begin{aligned}\delta_{i,k}(j) &= \partial\text{Prob}(y_i = j|x_i, z_i)/\partial x_{i,k} \\ &= -\boldsymbol{\beta}_k[f(\mu_j - \mathbf{x}_i'\boldsymbol{\beta} - \mathbf{z}_i'\boldsymbol{\gamma}) - f(\mu_{j-1} - \mathbf{x}_i'\boldsymbol{\beta} - \mathbf{z}_i'\boldsymbol{\gamma})], \quad j = 0, \ldots, J,\end{aligned}$$

where $f(t)$ is the density, $\text{d}F(t)/\text{d}t$. The sign of the partial effect is ambiguous, since the difference of the two densities can have either sign. Moreover, since $\Sigma_{j=0}^{J}\text{Prob}(y_i = 1|x_i, z_i) = 1$, it follows that $\Sigma_{j=1}^{J}\delta_{i,k}(j) = 0$. Since the c.d.f. is monotonic, there is one sign change in the set of partial effects as the example below demonstrates. For purposes of using and interpreting the model, it seems that the coefficients are of relatively little utility – neither the sign nor the magnitude directly indicates the effect of changes in a variable on the observed outcome.

Terza (1985) and Pudney and Shields (2000) suggested an extension of the ordered choice model that would accommodate heterogeneity in the threshold parameters. The extended model is:

$$\text{Prob}(y_i = j|x_i, z_i) = F(\mu_{i,j} - \mathbf{x}_i'\boldsymbol{\beta} - \mathbf{z}_i'\boldsymbol{\gamma}) - F(\mu_{i,j-1} - \mathbf{x}_i'\boldsymbol{\beta} - \mathbf{z}_i'\boldsymbol{\gamma}),$$

where:

$$\mu_{i,j} = \mathbf{v}_i'\boldsymbol{\pi}_j, \quad \text{where } \pi_0 = 0,$$

for a set of variables $\mathbf{v}_i$. The model as shown has two complications First, it is straightforward to constrain the fixed threshold parameters to preserve the ordering needed to ensure that all probabilities are positive.[22] When there are variables v_i in the construction, it is no longer possible to produce this result parametrically. The authors (apparently) did not find it necessary to confront this constraint. A second feature of the model (which was examined at length by the authors) is the unidentifiability of elements of $\boldsymbol{\pi}_j$ when v_i and $(\mathbf{x}_i, \mathbf{z}_i)$ contain the same variables. This is a result of the linear functional form assumed for $\mu_{i,j}$. Greene (2007a) and

Harris and Zhao (2007) suggested alternative parameterizations that circumvent these problems – a restricted version:

$$\mu_{i,j} = \exp(\mu_j + \mathbf{v}_i'\boldsymbol{\pi}_j),$$

and a counterpart to Pudney and Shields' (2000) formulation:

$$\mu_{i,j} = \exp(\mathbf{v}_i'\boldsymbol{\pi}_j).^{23}$$

11.5.1 Specification analysis

As in the binary choice case, the analysis of micro-level data is likely to encounter individual heterogeneity, not only in the means of utilities ($\mathbf{x}_i$,$\mathbf{z}_i$), but also in the scaling of U_i^*, i.e., in the variance of ε_i. Building heteroskedasticity into the model, as in the binary choice model shown earlier, is straightforward. If:

$$E[\varepsilon_i^2|\mathbf{v}_i] = [\exp(\mathbf{v}_i'\boldsymbol{\tau})]^2,$$

then the log-likelihood would become:

$$\ln L = \sum_{i=1}^{j} \ln\left[F\left(\frac{\mu_{y_i-1} - x_i'\boldsymbol{\beta} - z_i'\boldsymbol{\gamma}}{\exp(v_i'\boldsymbol{\tau})}\right) - F\left(\frac{\mu_{y_i} - x_i'\boldsymbol{\beta} - z_i'\boldsymbol{\gamma}}{\exp(v_i'\boldsymbol{\tau})}\right)\right].$$

As before, this complicates (even further) the interpretation of the model components and the partial effects.

There is no direct test for the distribution, since the alternatives are not nested. The Vuong test is a possibility, although the power of this test and its characteristics remain to be examined both analytically and empirically.

11.5.2 Bivariate ordered probit models

There are several extensions of the ordered probit model that follow the logic of the bivariate probit model we examined in Section 11.4. A direct analog to the base case two-equation model was used by Butler, Finegan and Siegfried (1998), who analyzed the relationship between the level of calculus attained and grades in intermediate economics courses for a sample of Vanderbilt students. The two-step estimation approach involved the following strategy. (We are stylizing the precise formulation a bit in order to compress the description.) Step 1 involved a direct application of the ordered probit model to the level of calculus achievement, which is coded 0, 1, . . . , 6:

$$\begin{aligned} m_i^* &= \mathbf{x}_i'\boldsymbol{\beta} + \varepsilon_i, \varepsilon_i|\mathbf{x}_i \sim N[0,1], \\ m_i &= 0 \text{ if } -\infty < m_i^* \leq 0, \\ &\quad 1 \text{ if } 0 < m_i^* \leq \mu_1, \\ &\quad \cdots \\ &\quad 6 \text{ if } \mu_5 < m_i^* < +\infty. \end{aligned}$$

The authors argued that, although the various calculus courses can be ordered discretely by the material covered, the differences between the levels cannot be measured directly. Thus, this is an application of the ordered probit model. The independent variables in this first-step model included SAT (scholastic aptitude test) scores, foreign language proficiency, indicators of intended major, and several other variables related to areas of study.

The second step of the estimator involves regression analysis of the grade in the intermediate microeconomics or macroeconomics course. Grades in these courses were translated to a granular continuous scale (A = 4.0, A− = 3.7, etc.). A linear regression is then specified:

$$Grade_i = \mathbf{z}_i'\boldsymbol{\delta} + u_i, \quad \text{where } u_i|\mathbf{z}_i \sim N[0, \sigma_u^2].$$

Independent variables in this regression include, among others, (1) dummy variables for which the outcome in the ordered probit model applies to the student (with the zero reference case omitted), (2) grade in the last calculus course, (3) several other variables related to prior courses, (4) class size, (5) freshman grade point average, etc. The unobservables in the *Grade* equation and the math attainment are clearly correlated, a feature captured by the additional assumption that $(\varepsilon_i, u_i|\mathbf{x}_i,\mathbf{z}_i) \sim N_2[(0,0),(1,\sigma_u^2),\rho\sigma_u]$. A non-zero ρ captures this "selection" effect. With this in place, the dummy variables now become endogenous. The solution is a "selection" correction where the modified equation becomes:

$$\begin{aligned} Grade_i|m_i &= \mathbf{z}_i'\boldsymbol{\delta} + E[u_i|m_i] + v_i \\ &= \mathbf{z}_i'\boldsymbol{\delta} + (\rho\sigma_u)[\lambda(\mathbf{x}_i'\boldsymbol{\beta}, \mu_1, \ldots, \mu_5)] + v_i. \end{aligned}$$

They thus adopt a "control function" approach to accommodate the endogeneity of the math attainment dummy variables. The term $\lambda(\mathbf{x}_i'\boldsymbol{\beta}, \mu_1, \ldots, \mu_5)$ is a generalized residual that is constructed using the estimates from the first-stage ordered probit model (a precise statement of the form of this variable is given in Tobias and Li, 2006). Linear regression of the course grade on $\mathbf{z}_i$ and this constructed regressor is computed at the second step. The standard errors at the second step must be corrected for the use of the estimated regressor using what amounts to a Murphy and Topel (1985) correction.

Tobias and Li (2006), in a replication of and comment on Butler, Finegan and Siegfried (1998), after roughly replicating the classical estimation results with a Bayesian estimator, observe that the *Grade* equation above could also be treated as an ordered probit model. The resulting bivariate ordered probit model would be:

$$\begin{array}{rlcrl} m_i^* = & \mathbf{x}_i'\boldsymbol{\beta} + \varepsilon_i, & \text{and} & g_i^* & = \mathbf{z}_i'\boldsymbol{\delta} + u_i, \\ m_i = & 0 \text{ if } -\infty < m_i^* \le 0, & & g_i & = 0 \text{ if } -\infty < g_i^* \le 0, \\ & 1 \text{ if } 0 < m_i^* \le \mu_1, & & & 1 \text{ if } 0 < g_i^* \le \alpha_1, \\ & \ldots & & & \ldots \\ & 6 \text{ if } \mu_5 < m_i^* < +\infty & & & 11 \text{ if } \mu_9 < g_i^* < +\infty, \end{array}$$

where $(\varepsilon_i,u_i|\mathbf{x}_i,\mathbf{z}_i) \sim N_2[(0,0),(1,\sigma_u^2),\rho\sigma_u]$.

Tobias and Li extended their analysis to this case simply by "transforming" the dependent variable in Butler, Finegan and Siegfried's second equation. Computing the log-likelihood using sets of bivariate normal probabilities is fairly straightforward for the bivariate ordered probit model (see Greene, 2007b). However, the classical study of these data using the bivariate ordered approach remains to be done, so a side-by-side comparison to Tobias and Li's Bayesian alternative estimator is not possible. The endogeneity of the calculus dummy variables remains a feature of the model, so both the MLE and the Bayesian posterior are less straightforward than they might appear.

The bivariate ordered probit model has been applied in a number of settings in the recent empirical literature, including husband and wife's education levels (Magee, Burbidge and Robb, 2000), family size (Calhoun, 1991) and many others. In two early contributions to the field of pet econometrics, Butler and Chatterjee analyze ownership of cats and dogs (1995) and dogs and televisions (1997).

11.5.3 Panel data applications

11.5.3.1 Fixed effects

D'Addio, Eriksson and Frijters (2003), using methodology developed by Frijters, Haisken-DeNew and Shields (2004) and Ferrer-i-Carbonel and Frijters (2004), analyzed survey data on job satisfaction using the Danish component of the European Community Household Panel. Their estimator for an ordered logit model is built around the logic of Chamberlain's estimator for the binary logit model. The approach is robust to individual specific threshold parameters and allows time invariant variables, so it differs sharply from the fixed effects models we have considered thus far, as well as from the ordered probit model.[24] Unlike Chamberlain's estimator for the binary logit model, however, their conditional estimator is not a function of minimal sufficient statistics. As such, the incidental parameters problem remains an issue.

Das and van Soest (2000) proposed a somewhat simpler approach. (See, as well, Long's 1997 discussion of the "parallel regressions assumption," which employs this device in a cross-section framework.) Consider the base case ordered logit model with fixed effects:

$$y_{it}^* = \alpha_i + \mathbf{x}_{it}'\boldsymbol{\beta} + \varepsilon_{it}, \varepsilon_{it}|\mathbf{X}_i \sim N[0,1]$$

$$y_{it} = j \text{ if } \mu_{j-1} < y_{it}^* < \mu_j, j = 0, 1, \ldots, J \text{ and } \mu_{-1} = -\infty, \mu_0 = 0, \mu_J = +\infty.$$

The model assumptions imply that:

$$\text{Prob}(y_{it} = j|\mathbf{X}_i) = \Lambda(\mu_j - \alpha_i - \mathbf{x}_{it}'\boldsymbol{\beta}) - \Lambda(\mu_{j-1} - \alpha_i - \mathbf{x}_{it}'\boldsymbol{\beta}),$$

where $\Lambda(t)$ is the c.d.f. of the logistic distribution. Now, define a binary variable:

$$w_{it,j} = 1 \quad \text{if } y_{it} > j, \quad j = 0, \ldots, J-1.$$

It follows that:

$$\begin{aligned}\text{Prob}[w_{it,j} = 1|\mathbf{X}_i] &= \Lambda(\alpha_i - \mu_j + \mathbf{x}_{it}'\boldsymbol{\beta}) \\ &= \Lambda(\theta_i + \mathbf{x}_{it}'\boldsymbol{\beta}).\end{aligned}$$

The "j" specific constant, which is the same for all individuals, is absorbed in θ_i. Thus a fixed effects binary logit model applies to each of the $J-1$ binary random variables, $w_{it,j}$. The method in section 11.3 can now be applied to each of the $J-1$ random samples. This provides $J-1$ estimators of the parameter vector $\boldsymbol{\beta}$ (but no estimator of the threshold parameters). The authors propose to reconcile these different estimators by using a minimum distance estimator of the common true $\boldsymbol{\beta}$. The minimum distance estimator at the second step is chosen to minimize:

$$q = \sum_{j=0}^{J-1} \sum_{m=0}^{J-1} \left(\hat{\boldsymbol{\beta}}_j - \boldsymbol{\beta}\right)' \left[\mathbf{V}_{jm}^{-1}\right] \left(\hat{\boldsymbol{\beta}}_m - \boldsymbol{\beta}\right),$$

where $\left[\mathbf{V}_{jm}^{-1}\right]$ is the j,m block of the inverse of the $(J-1)K \times (J-1)K$ partitioned matrix $\mathbf{V}$ that contains Asy.Cov$\left[\hat{\boldsymbol{\beta}}_j, \hat{\boldsymbol{\beta}}_m\right]$. The appropriate form of this matrix for a set of cross-section estimators is given in Brant (1990). Das and van Soest (2000) used the counterpart of Chamberlain's fixed effects estimator, but do not provide the specifics for computing the off diagonal blocks in $\mathbf{V}$.

The full ordered probit model with fixed effects, including the individual specific constants, can be estimated by unconditional maximum likelihood using the results in Greene (2008a, sec. 16.9.6.c). The likelihood function is concave (see Pratt, 1981), so despite its superficial complexity, the estimation is straightforward. (In the application below, with over 27,000 observations and 7,293 individual effects, estimation of the full model required roughly five seconds of computation.) No theoretical counterpart to the Hsiao (1986, 2003) and Abrevaya (1997) results on the small T bias (incidental parameters problem) of the MLE in the presence of fixed effects has been derived for the ordered probit model. The Monte Carlo results in Table 11.1 suggest that biases comparable to those in the binary choice models persist in the ordered probit model as well. As in the binary choice case, the complication of the fixed effects model is the small sample bias, not the computation. The Das and van Soest (2000) approach finesses this problem, as their estimator is consistent, but at the cost of losing the information needed to compute partial effects or predicted probabilities.

11.5.3.2 Random effects

The random effects ordered probit model has been much more widely used than the fixed effects model. Applications include Groot and van den Brink (2003), who studied training levels of employees, with firm effects and gains to marriage, Winkelmann (2004), who examined subjective measures of well-being with individual and family effects, Contoyannis, Jones and Rice (2004), who analyzed self-reported measures of health status, and numerous others. In the simplest case, the quadrature method of Butler and Moffitt (1982) can be used.

11.5.4 Application

The GSOEP data that we have used earlier includes a self-reported measure of health satisfaction, *HSAT*, that takes values 0, 1, . . . , 10. This is a typical application

of a scale variable that reflects an underlying continuous variable, "health." The frequencies and sample proportions for the reported values are as follows:

NEWHSAT	0	1	2	3	4	5	6	7	8	9	10
Frequency	447	255	642	1173	1390	4233	2530	4231	6172	3061	3192
Proportion	1.6%	0.9%	2.3%	4.2%	5.0%	15.4%	9.2%	15.4%	22.5%	11.2%	11.6%

We have fitted pooled and panel data versions of the ordered probit model to these data. The model used is:

$$U_{it}^{*} = \beta_1 + \beta_2 Age_{it} + \beta_3\, Income_{it} + \beta_4\, Education_{it} + \beta_5\, Married_{it} + \beta_6\, Working_{it} + \varepsilon_{it} + c_i,$$

where c_i will be the common fixed or random effect. (We are interested in comparing the fixed and random effects estimators, so we have not included any time invariant variables such as gender in the equation.) Table 11.5 lists five estimated models. (Standard errors for the estimated threshold parameters are omitted.) The first is the pooled ordered probit model. The second and third are fixed effects. Column 2 shows the unconditional fixed effects estimates using the results in Greene (2008). Column 3 shows the Das and van Soest (2000) estimator. For the minimum distance estimator, we used an inefficient weighting matrix, the block diagonal matrix in which the *j*th block is the inverse of the *j*th asymptotic covariance matrix for the individual logit estimators. With this weighting matrix, the estimator is:

$$\hat{\beta}_{MDE} = \left[\sum_{j=0}^{9} \mathbf{V}_j^{-1}\right]^{-1} \sum_{j=0}^{9} \mathbf{V}_j^{-1} \hat{\beta}_j,$$

and the estimator of the asymptotic covariance matrix is approximately equal to the bracketed inverse matrix. The fourth set of results is the random effects estimator computed using the MSL method. This model can be estimated using Butler and Moffitt's quadrature method: however, we found that, even with a large number of nodes, the quadrature estimator converged to a point where the log-likelihood was far lower than the MSL estimator, and at parameter values that were implausibly different from the other estimates. Using different starting values and different numbers of quadrature points did not change this outcome. The MSL estimator for a random constant term is considerably slower, but produces more reasonable results. The fifth set of results is the Mundlak form of the random effects model, which includes the group means in the models as controls to accommodate possible correlation between the latent heterogeneity and the included variables. As noted earlier, the components of the ordered choice model must be interpreted with some care. By construction, the partial effects of the variables on the probabilities of the outcomes must change sign, so the simple coefficients do not show the complete picture implied by the estimated model. Table 11.6 shows the partial effects for the pooled model to illustrate the computations.

Winkelmann (2004) used the random effects approach to analyze the subjective well-being (SWB) question (also coded 0 to 10) in the GSOEP dataset. The ordered probit model in this study is based on the latent regression:

$$y^*_{imt} = \mathbf{x}'_{imt}\boldsymbol{\beta} + \varepsilon_{imt} + u_{im} + v_i.$$

The independent variables include age, gender, employment status, income, family size and an indicator for good health. An unusual feature of the model is the nested random effects, which include a family effect, v_i, as well as the individual family member (i in family m) effect, u_{im}. The MLE approach is unavailable in this nonlinear setting. Winkelmann instead employed a Hermite quadrature procedure to maximize the log-likelihood function.

Contoyannis, Jones and Rice (2004) analyzed a self-assessed health scale that ranged from 1 (very poor) to 5 (excellent) in the BHPS. Their model accommodated

Table 11.6 Estimated marginal effects: pooled model

10	−0.0035	0.0336	0.0114	0.0063	0.0047	0.0233

a variety of complications in survey data. The latent regression underlying their ordered probit model is:

$$h_{it}^{*} = \mathbf{x}_{it}^{\prime}\boldsymbol{\beta} + \mathbf{H}_{i,t-1}^{\prime}\boldsymbol{\gamma} + \alpha_i + \varepsilon_{it},$$

where $\mathbf{x}_{it}$ includes marital status, race, education, household size, age, income, and the number of children in the household. The lagged value, $\mathbf{H}_{i,t-1}$, is a set of binary variables for the observed health status in the previous period. In this case, the lagged values capture state dependence, as the assumption that the health outcome is redrawn randomly in each period is inconsistent with evident runs in the data. The initial formulation of the regression is a fixed effects model. To control for the possible correlation between the effects, α_i, and the regressors, and the initial conditions problem that helps to explain the state dependence, they use a hybrid of Mundlak's (1978) correction and a suggestion by Wooldridge (2002b) for modeling the initial conditions:

$$\alpha_i = \alpha_0 + \overline{\mathbf{x}}^{\prime}\alpha_1 + \mathbf{H}_{i,1}^{\prime}\boldsymbol{\delta} + u_i,$$

where u_i is exogenous. Inserting the second equation into the first produces a random effects model that can be fitted using Butler and Moffitt's (1982) quadrature method.

11.6 Models for counts

A model that is often used for interarrival times at such facilities as a telephone switch, an ATM machine, or at the service window of a bank or gasoline station, is the *exponential model*:

$$f(t) = \theta \exp(-\theta t), \quad t \geq 0, \theta > 0,$$

where the continuous variable, t, is the time between arrivals. The expected interarrival time in this distribution is $E[t] = 1/\theta$. Consider the number of arrivals, y,

that occur *per unit of time*. It can be shown that this discrete random variable has the *Poisson probability distribution*:

$$f(y) = \exp(-\lambda)\lambda^{y}/y!, \quad \lambda = 1/\theta > 0, y = 0, 1, \ldots$$

The expected value of this discrete random variable is $E[y] = 1/\theta$. The *Poisson regression model* arises from the specification:

$$E[y_i|\mathbf{x}_i] = \lambda_i = \exp(\mathbf{x}_i'\boldsymbol{\beta}).$$

The log-linear form is used to ensure that the mean is positive. Estimation of the Poisson model by ML is straightforward owing to the simplicity of the log-likelihood and its derivatives:

$$\begin{array}{ll} \ln L & = \sum_{i=1}^{n} -\lambda_i + y_i(\mathbf{x}_i'\boldsymbol{\beta}) - \ln\Gamma(y_i + 1) \\ \partial \ln L/\partial\boldsymbol{\beta} & = \sum_{i=1}^{n}(y_i - \lambda_i)\mathbf{x}_i \\ \partial^2 \ln L/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' & = \sum_{i=1}^{n} -\lambda_i x_i \mathbf{x}_i'. \end{array}$$

Inference about parameters is based on either the actual (and expected) Hessian:

$$V = \left[\sum_{i=1}^{n} \hat{\lambda}_i \mathbf{x}_i \mathbf{x}_i'\right]^{-1} = \left[\mathbf{X}'\hat{\Lambda}\mathbf{X}\right]^{-1},$$

or the BHHH estimator, which is:

$$\mathbf{V}_{\text{BHHH}} = \left[\sum_{i=1}^{n}(y_i - \hat{\lambda}_i)^2 x_i \mathbf{x}_i'\right]^{-1} = \left[\sum_{i=1}^{n} \varepsilon_i^2 \mathbf{x}_i \mathbf{x}_i'\right]^{-1} = \left[\mathbf{X}'\hat{\mathbf{E}}^2\mathbf{X}\right]^{-1}.$$

Hypothesis tests about the parameters may be based on the likelihood ratio or Wald statistics, or the LM statistic, which is particularly convenient here:

$$\lambda_{LM} = \left[\sum_{i=1}^{n} \hat{\varepsilon}_i^0 x\right]' V_{\text{BHHH}} \left[\sum_{i=1}^{n} \hat{\varepsilon}_i^0 x\right],$$

where the residuals are computed at the restricted estimates. For example, under the null hypothesis that all coefficients are zero save for the constant term, $\hat{\lambda}_i^0 = \overline{y}$, $\hat{\varepsilon}_i^0 = y_i - \overline{y}$ and:

$$\lambda_{LM} = \left[\sum_{i=1}^{n}(y_i - \overline{y})\mathbf{x}_i\right]' \left[\sum_{i=1}^{n}(y_i - \overline{y})^2 \mathbf{x}_i \mathbf{x}_i'\right]^{-1} \left[\sum_{i=1}^{n}(y_i - \overline{y})\mathbf{x}_i\right].$$

The Poisson model is one in which the MLE is robust to certain misspecifications of the model, such as the failure to incorporate latent heterogeneity into the mean (i.e., one fits the Poisson model when the negative binomial is appropriate.) In this case, the robust (sandwich) covariance matrix:

$$\text{Robust Est.Asy.Var}\left[\hat{\boldsymbol{\beta}}\right] = \left[\mathbf{X}'\hat{\boldsymbol{\Lambda}}\mathbf{X}\right]^{-1} \left[\mathbf{X}'\hat{\mathbf{E}}^2\mathbf{X}\right] \left[\mathbf{X}'\hat{\boldsymbol{\Lambda}}\mathbf{X}\right]^{-1},$$

is appropriate to accommodate this failure of the model. It has become common to employ this estimator with all specifications, including the negative binomial. One might question the virtue of this. Since the negative binomial model already accounts for the latent heterogeneity, it is unclear what *additional* failure of the assumptions of the model this estimator would be robust to.

11.6.1 Heterogeneity and the negative binomial model

The Poisson model is typically only the departure point for the analysis of count data. The simple model has (at least) two shortcomings that arise from heterogeneity that is not explicitly incorporated in the model.

One easily remedied minor issue concerns the units of measurement of the data. In the Poisson model (and negative binomial model below), the parameter λ_i is the expected number of events *per unit of time*. Thus there is a presumption in the model formulation, e.g., the Poisson, that the same amount of time is observed for each *i*. In a spatial context, such as measurements of the incidence of a disease per group of N_i persons, or the number of bomb craters per square mile in London in 1940, the assumption would be that the same physical area or the same size of population applies to each observation. Where this differs by individual, it will introduce a type of heteroskedasticity in the model. The simple remedy is to modify the model to account for the *exposure,* T_i, of the observation as follows:

$$\text{Prob}(y_i = j|\mathbf{x}_i, T_i) = \frac{\exp(-T_i\phi_i)(T_i\phi_i)^j}{j!},\ \phi_i = \exp(\mathbf{x}_i'\boldsymbol{\beta}),\ j = 0, 1, \ldots.$$

The original model is returned if we write $\lambda_i = \exp(\mathbf{x}_i'\boldsymbol{\beta} + \ln T_i)$. Thus, when the exposure differs by observation, the appropriate accommodation is to include the log of exposure in the regression part of the model with a coefficient of 1.0. (For less than obvious reasons, the term "*offset variable*" is commonly associated with the exposure variable T_i.) Note that if T_i is the same for all *i*, ln *T* will simply vanish into the constant term of the model (assuming one is included in $\mathbf{x}_i$).

The less straightforward restriction of the Poisson model is that $E[y_i|x_i] = \text{Var}[y_i|x_i]$. This equidispersion assumption is a major shortcoming. Observed data rarely, if ever, display this feature. The very large amount of research activity on functional forms for count models is often focused on testing for equidispersion and building functional forms that relax this assumption.

The overdispersion found in observed data can be attributed to omitted heterogeneity in the Poisson model. A more complete regression specification would be:

$$E[y_i|\mathbf{x}_i] = \lambda_i = h_i \exp(\mathbf{x}_i'\boldsymbol{\beta}_i) = \exp(\mathbf{x}_i'\boldsymbol{\beta} + \varepsilon_i),$$

where the heterogeneity, h_i, has mean one and non-zero variance. Two candidates for the distribution of ε_i have dominated the literature, the log-normal model discussed later and the log-gamma model. The most common specification is the log-gamma model, which derives from the gamma variable:

$$f[h_i] = [\theta^\theta / \Gamma(\theta)] \exp(-\theta h_i) h_i^{\theta-1}, \quad h_i \geq 0.^{25}$$

This gamma distributed random variable has mean 1.0 and variance $1/\theta$. (A separate variance parameter is not identified – the scaling in the model is, once again, absorbed by the coefficient vector.) If we write the Poisson–log-gamma model as:

$$f(y_i|\mathbf{x}_i, h_i) = \exp(-h_i\lambda_i)(h_i\lambda_i)^{y_i} / \Gamma(y_i + 1),$$

then the unconditional distribution is:

$$f(y_i|\mathbf{x}_i) = \int_0^\infty f(y_i, v_i|\mathbf{x}_i)dv_i = \int_0^\infty f(y_i|\mathbf{x}_i, v_i)f(v_i)dv_i.$$

The integral can be obtained in closed form; the result is the *negative binomial model*:

$$\begin{aligned}\text{Prob}(Y = y_i|\mathbf{x}_i) &= \frac{\Gamma(\theta + y_i)}{\Gamma(y_i + 1)\Gamma(\theta)} r_i^{y_i}(1 - r_i)^\theta,\\ \lambda_i &= \exp(\mathbf{x}_i'\beta),\\ r_i &= \lambda_i/(\theta + \lambda_i).\end{aligned}$$

The recent literature, mostly associating the result with Cameron and Trivedi (1986, 1998), defines this form of the negative binomial model as the *Negbin 2* (NB2) form of the probability. This is the default form of the model in the received econometrics packages that provide an estimator for this model. The *Negbin 1* (NB1) form of the model results if θ is replaced with $\theta_i = \theta\lambda_i$. Then, r_i reduces to $r = 1/(1 + \theta)$, and the density becomes:

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta\lambda_i + y_i)}{\Gamma(y_i + 1)\Gamma(\theta\lambda_i)} r^{y_i}(1 - r)^{\theta\lambda_i}.$$

This is not a simple reparameterization of the model. The results in the example below demonstrate that the log-likelihood functions of the two forms are not equal at the maxima, and their parameters are not simple transformations of each other. We are not aware of a theory that justifies using one form or the other for the negative binomial model. Neither is a restricted version of the other, so we cannot carry out a nested likelihood ratio test. The more general *Negbin P* (NBP) family (Greene, 2008b) does nest both of them, so this may provide a more general, encompassing approach to finding the right specification. The NBP model is obtained by replacing θ in the NB2 form with $\theta\lambda_i^{2-P}$. We have examined the cases of $P = 1$ and $P = 2$ above and, for general P:

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta\lambda_i^Q + y_i)}{\Gamma(y_i + 1)\Gamma(\theta\lambda_i^Q)} \left(\frac{\lambda}{\theta\lambda_i^Q + \lambda_i}\right)^{y_i} \left(\frac{\theta\lambda_i^Q}{\theta\lambda_i^Q + \lambda_i}\right)^{\theta\lambda_i^Q}, \quad Q = 2 - P.$$

The conditional mean function for the three cases considered is:

$$E[y_i|\mathbf{x}_i] = \exp(\mathbf{x}_i'\boldsymbol{\beta}) \times \theta^{2-P} = \alpha^{P-2}\lambda_i, \quad \text{where } \alpha = 1/\theta.$$

The parameter P is picking up the scaling. A general result is that, for all three variants of the model:

$$\text{Var}[y_i|\mathbf{x}_i] = \lambda_i(1 + \alpha\lambda_i^{P-1}).$$

Thus, the NB2 form has a variance function that is quadratic in the mean, while the NB1 form's variance is a simple multiple of the mean. There have been many

other functional forms proposed for count data models, including the generalized Poisson, gamma, and Polya–Aeppli forms described in Winkelmann (2003) and Greene (2007a, Ch. 24).

The heteroskedasticity in the count models is induced by the relationship between the variance and the mean. The single parameter θ picks up an implicit overall scaling, so it does not contribute to this aspect of the model. As in the linear model, microeconomic data are likely to induce heterogeneity in both the mean and variance of the response variable. A specification that allows independent variation of both will be of some virtue. The result:

$$\text{Var}[y_i|\mathbf{x}_i] = \lambda_i(1 + (1/\theta)\lambda_i^{P-1}),$$

suggests that a natural platform for separately modeling heteroskedasticity will be the dispersion parameter, θ, which we now parameterize as:

$$\theta_i = \theta \exp(\mathbf{z}_i'\boldsymbol{\delta}).$$

Operationally, this is a relatively minor extension of the model. But it is likely to introduce a quite substantial increase in the flexibility of the specification. Indeed, a heterogeneous NBP model is likely to be sufficiently parameterized to accommodate the behavior of most datasets. (Of course, the specialized models discussed below, e.g., the zero inflation models, may yet be more appropriate for a given situation.)

11.6.2 Extended models for counts: two-part, zero inflation, sample selection, bivariate

"Non-Poissonness" arises from a variety of sources in addition to the latent heterogeneity modeled in the previous section. A variety of *two-part models* have been proposed to accommodate elements of the decision process.

11.6.2.1 Hurdle model

The hurdle model (Mullahy, 1986; Gurmu, 1997) consists of a participation equation and a conditional Poisson or negative binomial model. The structural equations are:

$$\begin{aligned}
&\text{Prob}(y_i > 0|\mathbf{z}_i) && = \text{a binary choice mechanism, such as probit or logit}\\
&\text{Prob}(y_i = j|y_i > 0, \mathbf{x}_i) && = \text{truncated Poisson or negative binomial.}
\end{aligned}$$

(See Shaw, 1988.) For a logit participation equation and a Poisson count, the probabilities for the observed data that enter the log-likelihood function would be:

$$\text{Prob}(y_i = 0|\mathbf{z}_i) = \frac{1}{1 + \exp(\mathbf{z}_i'\alpha)}$$

$$\begin{aligned}
\text{Prob}(y_i = j|\mathbf{x}_i, \mathbf{z}_i) &= \text{Prob}(y_i > 0|\mathbf{z}_i) \times \text{Prob}(y_i = j|y_i > 0, \mathbf{x}_i)\\
&= \frac{\exp(\mathbf{z}_i'\boldsymbol{\alpha})}{1 + \exp(\mathbf{z}_i'\boldsymbol{\alpha})} \frac{\exp(-\lambda_i)\lambda_i^j}{j![1 - \exp(-\lambda_i)]}.
\end{aligned}$$

This model might apply for on-site counts of the use of certain facilities such as recreational sites. The expectation in the hurdle model is easily found using the rules of probability:

$$\begin{aligned} E[y_i|\mathbf{x}_i, \mathbf{z}_i] &= \frac{\exp(\mathbf{z}_i'\alpha)}{1+\exp(\mathbf{z}_i'\alpha)} E[y_i|y_i > 0, \mathbf{x}_i, \mathbf{z}_i] \\ &= \frac{\exp(\mathbf{z}_i'\alpha)}{1+\exp(\mathbf{z}_i'\alpha)} \frac{\lambda_i}{[1-\exp(-\lambda_i)]}. \end{aligned}$$

As usual, the intricacy of the function mandates some caution in interpreting the model coefficients. In particular:

$$\begin{aligned} \boldsymbol{\delta}_i(\mathbf{x}_i) &= \frac{\partial E[y_i|\mathbf{x}_i,\mathbf{z}_i]}{\partial \mathbf{x}_i} \\ &= \left\{ \frac{\exp(\mathbf{z}_i'\alpha)}{1+\exp(\mathbf{z}_i'\alpha)} \frac{\lambda_i}{[1-\exp(-\lambda_i)]} \left(1 - \frac{\lambda_i \exp(-\lambda_i)}{[1-\exp(-\lambda_i)]}\right) \right\} \boldsymbol{\beta}. \end{aligned}$$

The complication of the partial effects is compounded if $\mathbf{z}_i$ contains any of the variables that also appear in $\mathbf{x}_i$. The other part of the partial effect is:

$$\boldsymbol{\delta}_i(\mathbf{z}_i) = \left\{ \frac{\exp(\mathbf{z}_i'\alpha)}{[1+\exp(\mathbf{z}_i'\alpha)]^2} \frac{\lambda_i}{[1-\exp(-\lambda_i)]} \right\} \alpha.$$

11.6.2.2 Zero inflation models

A related formulation is the *zero inflation model*, which is a type of *latent class model*. The model accommodates a situation in which the zero outcome can arise in either of two mechanisms. In one regime, the outcome is always zero; in the other, the outcome is generated by the Poisson or negative binomial process that might also produce a zero. The example suggested in Lambert's (1992) pioneering application is a manufacturing process that produces a number of defective parts, y_i, equal to zero if the process is under control, or equal to a Poisson outcome if the process is not under control. The applicable distribution is:

$$\begin{aligned} \text{Prob}(y_i = 0|\mathbf{x}_i, \mathbf{z}_i) &= \text{Prob}(\text{regime } 0|\mathbf{z}_i) + \text{Prob}(\text{regime } 1|\mathbf{z}_i) \\ &\quad \text{Prob}(y_i = 0|\text{regime1}, \mathbf{x}_i) \\ &= F(r_i|\mathbf{z}_i) + [1 - F(r_i|\mathbf{z}_i)]\text{Prob}(y_i = 0|\mathbf{x}_i) \\ \text{Prob}(y_i = j|y_i > 0, \mathbf{x}_i, \mathbf{z}_i) &= [1 - F(r_i|\mathbf{z}_i)]\text{Prob}(y_i = j|\mathbf{x}_i). \end{aligned}$$

The density governing the count process may be the Poisson or negative binomial model. The regime process is typically specified as a logit model, though the probit model is often used as well. Finally, two forms are used for the regime model, the standard probit or logit model with covariate vector, $\mathbf{z}_i$, and the zero inflated poisson, ZIP(τ) form, which takes the form (for the logit–Poisson model):

$$\begin{aligned} \text{Prob}(y_i = 0|\mathbf{x}_i) &= \Lambda(\tau \mathbf{x}_i'\boldsymbol{\beta}) + [1 - \Lambda(\tau \mathbf{x}_i'\boldsymbol{\beta})] \exp(-\lambda_i) \\ \text{Prob}(y_i = j|y_i > 0, \mathbf{x}_i) &= [1 - \Lambda(\tau \mathbf{x}_i'\boldsymbol{\beta})] \exp(\lambda_i)\lambda_i^j/j!, \end{aligned}$$

where $\lambda_i = \exp(\mathbf{x}_i'\boldsymbol{\beta})$ and τ is a single new, free parameter to be estimated. (Researchers usually find that the τ form of the model is more restrictive than desired.) The conditional mean function is:

$$E[y_i|\mathbf{x}_i, \mathbf{z}_i] = [1 - F(r_i|\mathbf{z}_i)]\lambda_i.$$

11.6.2.3 Sample selection

We consider an extension of the classic model of sample selection (Heckman, 1979) to the models for count outcomes. In the context of the applications considered here, for example, we might consider a sample based on only those individuals who have health insurance. The generic model will take the form:

$s_i^* = \mathbf{z}_i'\boldsymbol{\alpha} + u_i, \quad u_i \sim N[0,1],$	
$s_i = \mathbf{1}(\mathbf{s}_i^* > 0)$	(probit selection equation)
$\lambda_i\|\varepsilon_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i), \varepsilon_i \sim N[0,1]$	(index function with heterogeneity)[26]
$y_i\|\mathbf{x}_i, \varepsilon_i \sim \text{Poisson}(y_i\|\mathbf{x}_i, \varepsilon_i)$	(Poisson model for outcome)
$[u_i, \varepsilon_i] \sim N[(0,1),(1,\rho,1)]$	
$y_i, \mathbf{x}_i$ are observed only when $s_i = 1$.	

The count model is the heterogeneity model suggested earlier with log-normal rather than log-gamma heterogeneity. The conventional approach of fitting the probit selection equation, computing an inverse Mills ratio, and adding it as an extra regressor in the Poisson model, is inappropriate here (see Greene, 1995, 1997, 2006). A formal approach for this model is developed in Terza (1994, 1998) and Greene (1995, 2006, 2007b). Formal results are collected in Greene (2006). The generic result for the count model (which can be adapted to the negative binomial or other models) is:

$$f(y_i, s_i|\mathbf{x}_i, \mathbf{z}_i) = \int_{-\infty}^{\infty} [(1 - s_i) + s_i f(y_i|\mathbf{x}_i, \varepsilon_i)] \Phi\left((2s_i - 1)[\mathbf{z}_i'\boldsymbol{\alpha}_i + \rho\varepsilon_i]/\sqrt{1-\rho^2}\right)\phi(\varepsilon_i)d\varepsilon_i,$$

with:

$$f(y_i|\mathbf{x}_i, \varepsilon_i) = \frac{\exp(-\lambda_i|\mathbf{x}_i, \varepsilon_i)(\lambda_i|\mathbf{x}_i, \varepsilon_i)^{y_i}}{\Gamma(y_i + 1)}, \ \lambda_i|\mathbf{x}_i, \varepsilon_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i).$$

The integral does not exist in closed form, but the model can be fitted by approximating the integrals with Hermite quadrature:

$$\ln L_Q = \sum_{i=1}^{N} \log\left[\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H} \omega_h\left[(1 - s_i) + s_i f(y_i|\mathbf{x}_i, \nu_h)\right]\Phi\left[(2s_i - 1)\left(\mathbf{z}_i'\boldsymbol{\gamma}_i + \tau\nu_h\right)\right]\right],$$

or simulation, for which the simulated log-likelihood is:

$$\ln L_S = \sum_{i=1}^{N} \log\frac{1}{R}\sum_{r=1}^{R}[(1 - s_i) + s_i f(y_i|\mathbf{x}_i, \sigma\varepsilon_{ir})]\Phi[(2s_i - 1)\left(\mathbf{z}_i'\boldsymbol{\gamma}_i + \tau\varepsilon_{ir}\right)],$$

where $\gamma = \boldsymbol{\alpha}/(1-\rho^2)^{1/2}$ and $\tau = \rho/(1-\rho^2)^{1/2}$. There is a minor extension of this model that might be interesting for the health care application examined in this study. The count variables and all the covariates in both equations would be observed for all observations. Thus, to use the full sample of data, the appropriate log-likelihood would be:

$$f(y_i, z_i|\mathbf{x}_i, \mathbf{z}_i) = \int_{-\infty}^{\infty} f(y_i|\mathbf{x}_i, \varepsilon_i)]\Phi\left((2s_i - 1)[\mathbf{z}_i'\boldsymbol{\gamma}_i + \tau\varepsilon_i]\right)\phi(\varepsilon_i)d\varepsilon_i.$$

11.6.2.4 Bivariate Poisson model

The application from which our examples are drawn was a study of the two count variables, DocVis (visits to the doctor) and HospVis (visits to the hospital). Riphahn, Wambach and Million (2003) were interested in a bivariate count model for the two outcomes. One approach to formulating a two-equation Poisson model is to treat the correlation as arising from the intervention of a latent common Poisson process. The model is:

$$y_1 = y_1^* + U$$
$$y_2 = y_2^* + U,$$

where y_1^*, y_2^* and U are three independent Poisson processes. This model is analogous to the seemingly unrelated regressions model (see King, 1989). The major shortcoming of this approach is that it forces the two variables to be positively correlated. For the application considered here, it is at least possible that the preventive motivation for physician visits could result in a negative correlation between physician and inpatient hospital visits. The approach proposed by Riphahn, Wambach and A. Million (2003) adapted for a random effects panel data model, is $y_{it,j} \sim$ Poisson $(\lambda_{it,j})$, where:

$$\lambda_{it,j} = \exp(\mathbf{x}_{it,j}'\boldsymbol{\beta} + u_{i,j} + \varepsilon_{it,j}), \qquad j = 1, 2.$$

and where the unique heterogeneity, $(\varepsilon_{it,1}, \varepsilon_{it,2})$, has a bivariate normal distribution with correlation ρ, and the random effects, which are constant through time, have independent normal distributions. Thus the correlation between the conditional means is that induced by the two log-normal variables, $\exp(\varepsilon_{it,1})$ and $\exp(\varepsilon_{it,2})$. The implied correlation between $y_{it,1}$ and $y_{it,2}$ was not derived. This would be weaker than ρ, since both variables have additional variation around the correlated conditional mean functions.

In order to formulate the log-likelihood function, the random components must be integrated out. There are no closed forms for the integrals based on the normal distribution – the problem is similar to that in the sample selection model. The authors used a quadrature procedure to approximate the integrals. The log-likelihood could also be maximized by using simulation. Separate models were fitted to men and women in the sample. The pooling hypothesis was rejected for all specifications considered.

11.6.3 Panel data models

Hausman, Hall and Griliches (1984) (HHG) report the following conditional density for the fixed effects negative binomial (FENB) model:

$$p\left(y_{i1}, y_{i2}, \ldots, y_{iT_i} | \sum_{t=1}^{T_i} y_{it}\right) = \frac{\Gamma(1+\Sigma_{t=1}^{T_i} y_{it})\Gamma(\Sigma_{t=1}^{T_i}\lambda_{it})}{\Gamma(\Sigma_{t=1}^{T_i} y_{it} + \Sigma_{t=1}^{T_i}\lambda_{it})} \prod_{t=1}^{T_i} \frac{\Gamma(y_{it}+\lambda_{it})}{\Gamma(1+y_{it})\Gamma(\lambda_{it})},$$

which is free of the fixed effects. This is the default FENB formulation used in popular software packages such as SAS, Stata and LIMDEP. Researchers accustomed to the admonishments that fixed effects models cannot contain overall constants or time invariant covariates are sometimes surprised to find (perhaps accidentally) that this fixed effects model allows both. (This issue is explored at length in Allison, 2000; Allison and Waterman, 2002.) The resolution of this apparent contradiction is that the HHG FENB model is not obtained by shifting the conditional mean function by the fixed effect, $\ln \lambda_{it} = \mathbf{x}_{it}'\boldsymbol{\beta} + \alpha_i$, as it is in the Poisson model. Rather, the HHG model is obtained by building the fixed effect into the model as an individual specific θ_i in the NB1 form. In the negative binomial models, the conditional mean functions are:

$$\text{NB1} : E[y_{it}|\mathbf{x}_{it}] = \theta_i \phi_{it} = \theta_i \exp(\mathbf{x}_{it}'\boldsymbol{\beta}) = exp(\mathbf{x}_{it}'\boldsymbol{\beta} + \ln\theta_i),$$

$$\text{NB2} : E[y_{it}|\mathbf{x}_{it}] = \exp(\alpha_i)\phi_{it} = \lambda_{it} = \exp(\mathbf{x}_{it}'\boldsymbol{\beta} + \alpha_i),$$

so, superficially, the formulations do produce the same interpretation. However, the parameter θ_i in the NB1 model enters the variance function in a different manner:

$$\text{NB1} : \quad \text{Var}[y_{it}|\mathbf{x}_{it}] = \theta_i\phi_{it}[1+\theta_i],$$

$$\text{NB2} : \quad \text{Var}[y_{it}|\mathbf{x}_{it}] = \lambda_{it}[1+\theta\lambda_{it}].$$

The relationship between the mean and the variance is different for the two models. For estimation purposes, one can explain the apparent contradiction noted earlier by observing that, in the NB1 formulation, the individual effect is identified separately from the mean in the skedastic (scaling) function. This is not true for the FENB2 form. In order to obtain a counterpart to the HHG model, we would replace θ with θ_i (and λ_i with λ_{it}). Greene (2007a) analyzes the more familiar FENB2 form with the same treatment of λ_{it}. Estimates for both models appear below. Comparison of the suggested NB2 model to the HHG model remains for future investigation.

Once again, theory does not provide a reason to prefer the NB1 formulation over the more familiar NB2 model. The NB1 form does extend beyond the interpretation of the fixed effect as carrying only the sum of all the time invariant effects in the conditional mean function. The appearance of $\ln\theta_i$ in the conditional mean is an artifact of the exponential mean form; θ_i is a scaling parameter in this model. In its favor, the HHG model, being conditionally independent of the fixed effects,

finesses the incidental parameters problem – the estimator of $\boldsymbol{\beta}$ in this model is consistent. This is not the case for the FENB2 form, where:

$$Q_i = \frac{\theta}{\theta + \Sigma_{t=1}^{T_i} \lambda_{it}}.$$

For estimation purposes, we have a negative binomial distribution for $Y_i = \Sigma_t y_{it}$ with mean $\Lambda_i = \Sigma_t \lambda_{it}$.

Like the fixed effects model, introducing random effects into the negative binomial model adds some additional complexity. We do note, since the negative binomial model derives from the Poisson model by adding latent heterogeneity to the conditional mean, that adding a random effect to the negative binomial model might well amount to introducing the heterogeneity a second time. However, one might prefer to interpret the negative binomial as the density for y_{it} in its own right, and treat the common effects in the familiar fashion. Hausman, Hall and Griliches' (1984) random effects negative binomial model is a hierarchical model that is constructed as follows. The heterogeneity is assumed to enter λ_{it} additively with a gamma distribution with mean 1, $\Gamma(\theta_i,\theta_i)$. Then, $\theta_i/(1+\theta_i)$ is assumed to have a beta distribution with parameters a and b. The resulting unconditional density after the heterogeneity is integrated out is:

$$p(y_{i1}, y_{i2}, \ldots, y_{iT_i}) = \frac{\Gamma(a+b)\Gamma\left(a + \Sigma_{t=1}^{T_i} \lambda_{it}\right) \Gamma\left(b + \Sigma_{t=1}^{T_i} y_{it}\right)}{\Gamma(a)\Gamma(b)\Gamma\left(a + \Sigma_{t=1}^{T_i} \lambda_{it} + b + \Sigma_{t=1}^{T_i} y_{it}\right)}.$$

As before, the relationship between the heterogeneity and the conditional mean function is unclear, since the random effect impacts upon the parameter of the skedastic function. An alternative approach that maintains the essential flavor of the Poisson model (and other random effects models) is to augment the NB2 form with the random effect:

$$\text{Prob}(Y = y_{it} | \mathbf{x}_{it}, \varepsilon_i) = \frac{\Gamma(\theta + y_{it})}{\Gamma(y_{it}+1)\Gamma(\theta)} r_{it}^{y_{it}} (1 - r_{it})^{\theta},$$

$$\lambda_{it} = \exp(\mathbf{x}_{it}'\boldsymbol{\beta} + \varepsilon_i),$$

$$r_{it} = \lambda_{it}/(\theta + \lambda_{it}).$$

We then estimate the parameters by forming the conditional (on ε_i) log-likelihood and integrating ε_i out either by quadrature or simulation. The parameters are simpler to interpret by this construction. Estimates of the two forms of the random effects model are presented below for comparison.

11.6.4 Application

The study by Ripahn, Wambach and Million (2003) that provided the data we have used in numerous earlier examples analyzed the two count variables DocVis and HospVis. The authors were interested in the joint determination of these two

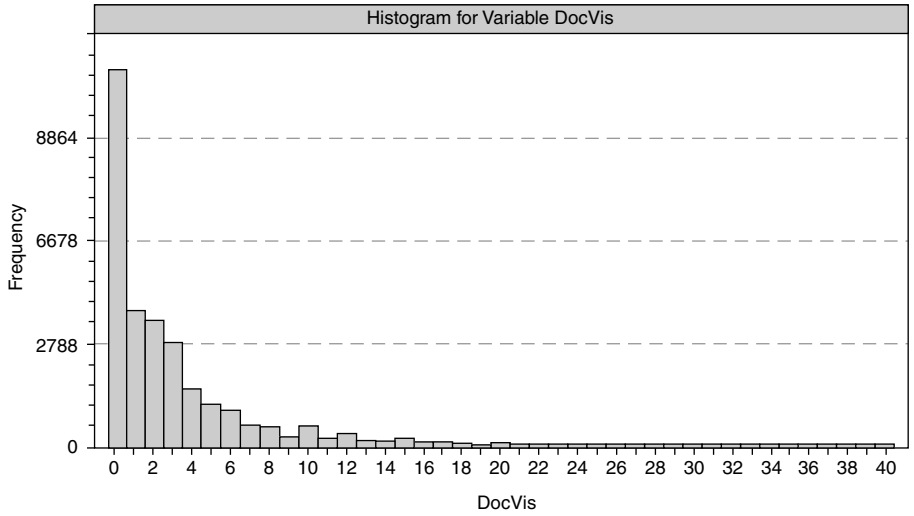

Figure 11.1 Histogram of count variable DocVis

count variables. One of the issues considered in the study was whether the data contained evidence of moral hazard, that is, whether health care utilization as measured by these two outcomes was influenced by the subscription to health insurance. The data contain indicators of two levels of insurance coverage: *Public*, which is the main source of insurance, and *Addon*, which is a secondary optional insurance. In the sample of 27,326 observations (family/years), 24,203 individuals held the public insurance. (There is quite a lot of within group variation in this, as individuals did not routinely obtain the insurance for all periods). Of these 24,203, 23,689 had only public insurance and 514 had both types. (One could not have only the addon insurance.) To explore the issue, we have analyzed the DocVis variable with the count data models described above. Figure 11.1 shows a histogram for this count variable. (There is a very long tail of extreme observations in these data, extending up to 121. The histogram omits the 91 observations with DocVis greater than 40. All observations are included in the sample used to estimate the models.) The exogenous variables in our model are:

$$\mathbf{x}_{it} = (1, \textit{Age, Education, Income, Kids, Public}).$$

(Variables are described in Table 11.2. Those listed are a small subset of those used in the original study, chosen here only for a convenient example.)

Table 11.7 presents the estimates of several count models. In all specifications, the coefficient on *Public* is positive, large, and highly statistically significant, which is consistent with the results in Riphahn, Wambach and Million (2003). The large spike at zero in the histogram casts some doubt on the Poisson specification. As a first step in extending the model, we estimated an alternative model that has a

distribution that appears more like that in the figure, a *geometric regression model*:

$$\text{Prob}(y_i = j|\mathbf{x}_i) = \pi_i(1-\pi_i)^j, \qquad \pi_i = 1/(1+\lambda_i), \lambda_i = \exp(\mathbf{x}_i'\boldsymbol{\beta}), \quad j = 0, 1, \ldots$$

This is the distribution for the number of failures before the first success in independent trials with success probability equal to π_i. It is suggested here simply as an alternative functional form for the model. The two models are similarly parameterized. The geometric model also has conditional mean equal to $(1-\pi_i)/\pi_i = \lambda_i$, like the Poisson. The variance is equal to $(1/\pi_i)\lambda_i > \lambda_i$, so the geometric distribution is overdispersed – it allocates more mass to the zero outcome. Based on the log-likelihoods, the Poisson model would be overwhelmingly rejected. However, since the models are not nested, this is not a valid test. Using, instead, the Vuong statistic based on $v_i = \ln L_i(\text{geometric}) - \ln L_i(\text{Poisson})$, we obtain a statistic of +37.89, which, as expected, strongly rejects the Poisson model.

The various formal test statistics strongly reject the hypothesis of equidispersion. Cameron and Trivedi's (1986) semiparametric tests from the Poisson model have *t*-statistics of 22.147 for $g_i = \mu_i$ and 22.504 for $g_i = \mu_i^2$. Both of these are far larger than the critical value of 1.96. The LM statistic (see Winkelmann, 2003) is 972,714.48, which is also larger than any critical value. On any of these bases, we would reject the hypothesis of equidispersion. The Wald and likelihood ratio tests based on the negative binomial models produce the same conclusion. For

comparing the different negative binomial models, note that NB2 is the worst of the three by the likelihood function, though NB1 and NB2 are not directly comparable. On the other hand, in the NBP model, the estimate of P is more than 10 standard errors from 1 or 2, so both NB1 and NB2 would be rejected in favor of the unrestricted NBP form of the model. The NBP and the heterogeneous NB2 model are not nested either, but on comparing the log-likelihoods, it does appear that the heterogeneous model is substantially superior. We computed the Vuong statistic based on the individual contributions to the log-likelihoods, with $v_i = \ln L_i(\text{NBP}) - \ln L_i(\text{NB2 – H})$. The value of the statistic is -3.27. On this basis, we would reject NBP in favor of NB2–H. Finally, with regard to the original question, the coefficient on PUBLIC is larger than 10 times its estimated standard error in every specification. We would conclude that the results are consistent with the proposition that there is evidence of moral hazard.

Estimates of the two two-part models, zero inflated and hurdle, are presented in Table 11.8. The regime equation for both is assumed to be a logit binary choice model with:

$$\mathbf{z}_{it} = (1, \textit{Age, Female, Married, Kids, Income, Self-employed}).$$

There is little theoretical basis for choosing between the two models. The interpretation of the data-generating process is quite similar in both cases. Each posits a regime in which the individual chooses whether or not to "participate" in the

health care system and a process that generates the count when they do. Nonetheless, there is little doubt that both are improvements on the Poisson regression. The average predicted probability of the zero outcome is 0.04826, so the Poisson model predicts $n\bar{\hat{P}}_0 = 1,319$ zero observations. The frequency in the sample is 10,135. The counterparts for the ZIP model are 0.36340 and 9,930. The Poisson model is not nested in the ZIP model – setting the ZIP coefficients to zero forces the regime probability to 0.5, not to 1.0. Thus the models cannot be compared by log-likelihoods. The Vuong statistic strongly supports the zero inflation model, being +47.05. Similar results are obtained for the hurdle model with the same specification.

The German health care panel data set contains 7,293 individuals with group sizes ranging from 1 to 7 and Table 11.9 presents the fixed and random effects estimates of the equation for DocVis. The pooled estimates are also shown for comparison. Overall, the panel data treatments bring large changes in the estimates compared to the pooled estimates. There is also a considerable amount of variation across the specifications. With respect to the parameter of interest, *Public*, we find that the size of the coefficient falls substantially with all panel data treatments. Whether using the pooled, fixed or random effects specifications, the test statistics (Wald, LR) all reject the Poisson model in favor of the negative binomial. Similarly, either common effects specification is preferred to the pooled estimator. There is no simple basis for choosing between the fixed and random effects models, and we have further blurred the distinction by suggesting two formulations for each of them. We do note that the two random effects estimators are producing similar results, which one might hope for, but the two fixed effects estimators are producing very different estimates. The NB1 estimates include two coefficients, on *Income* and *Education*, that are positive, but negative in every other case.

Moreover, the coefficient on *Public*, which is large and significant throughout the table, becomes small and less significant with the fixed effects estimators.

11.7 Multinomial unordered choices

We now extend the random utility, discrete choice model of sections 11.2–11.4 to a setting in which the individual chooses among multiple alternatives (see Hensher, Rose and Greene, 2005). The random utility model is:

$$U_{it,j} = \mathbf{x}_{it,j}'\boldsymbol{\beta} + \mathbf{z}_{it}'\boldsymbol{\gamma} + \varepsilon_{it,j}, \quad j = 1, \ldots, J_{it}, \quad t = 1, \ldots, T_i,$$

where, as before, we consider individual i in choice situation t, choosing among a possibly variable number of choices, J_{it}, and a possibly individual specific number of choice situations. For the present, for convenience, we assume $T_i = 1$ – a single-choice situation. This will be generalized later. The extension to variable choice set sizes, J_{it}, turns out to be essentially a minor modification of the mathematics, so it will also prove convenient to assume J_{it} is fixed at J. The random utility model is thus:

$$U_{i,j} = \mathbf{x}_{i,j}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma} + \varepsilon_{i,j}, \quad j = 1, \ldots, J, \quad i = 1, \ldots, n.$$

The earlier assumptions are extended as well. The axioms of choice will imply that preferences are transitive, reflexive and complete. Thus, in any choice situation, the individual will make a choice, and that choice, j_i, will be such that:

$$U_{i,ji} > U_{i,m} \text{ for all } m = 1, \ldots, J \text{ and } m \neq j_i.$$

Reverting back to the optimization problem, utility maximization over continuous choices subject to a budget constraint produces the complete set of demands, $\mathbf{d}_i$ (prices, income). Inserting the demands back into the utility function produces the indirect utility function:

$$U_i^* = U_i[\mathbf{x}(\text{prices, income})].$$

This formulation is convenient for discrete choice modeling, as the data typically observed on the right-hand sides of the model equations will be income, prices, other characteristics of the individual such as age and sex, and attributes of the choices, such as model or type. The random utility model for multinomial unordered choices is then taken to be defined over the indirect utilities.

11.7.1 Multinomial logit and multinomial probit models

Not all stochastic specifications for $\varepsilon_{i,j}$ are consistent with utility maximization. McFadden (1981) showed that the i.i.d. Type 1 extreme value distribution:

$$F(\varepsilon_{i,j}) = \exp(-\exp(-\varepsilon_{i,j})), \quad j = 1, \ldots, J, \quad i = 1, \ldots, n,$$

produces a probabilistic choice model that is consistent with utility maximization. The resulting choice probabilities are:

$$\text{Prob}(d_{i,j} = 1|\mathbf{X}_i, \mathbf{z}_i) = \frac{\exp(\mathbf{x}_{i,j}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})}{\Sigma_{m=1}^{J} \exp(\mathbf{x}_{i,m}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma})},$$

$$d_{i,j} = 1 \text{ if } U_{i,ji} > U_{i,m}, , m = 1, \ldots, J \text{ and } m \neq j.$$

This is the *multinomial logit model*. The components, $\mathbf{x}_{i,j}$, are the attributes of the choices (prices, features, etc.), while the $\mathbf{z}_i$ are the characteristics of the individual (income, age, sex). We noted at the outset of section 11.2 that identification of the model parameters requires that $\boldsymbol{\gamma}$ varies across the choices. Thus, the full model is:

$$\text{Prob}(d_{i,j} = 1|\mathbf{X}_i, \mathbf{z}_i) = \frac{\exp(\mathbf{x}_{i,j}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}_j)}{\Sigma_{m=1}^{J} \exp(\mathbf{x}_{i,m}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}_m)}, \boldsymbol{\gamma}_J = 0,$$

$$d_{i,j} = 1 \text{ if } U_{i,ji} > U_{i,m}, , m = 1, \ldots, J \text{ and } m \neq j.$$

The log-likelihood function is:

$$\ln L = \sum_{i=1}^{n} \sum_{j=1}^{J} d_{i,j} \ln \left[\frac{\exp(\mathbf{x}_{i,j}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}_j)}{\Sigma_{m=1}^{J} \exp(\mathbf{x}_{i,m}'\boldsymbol{\beta} + \mathbf{z}_i'\boldsymbol{\gamma}_m)} \right].$$

The multinomial logit specification implies the peculiar restriction that

$$\frac{\partial \ln \text{Prob}(choice = j)}{\partial \mathbf{x}_{i.m}} = [1(j = m) - \text{Prob}(choice = m)]\boldsymbol{\beta}.$$

Thus the impact of a change in an attribute of a particular choice on the set of choice probabilities is the same for all (other) choices. For example, in our application,

$$\frac{\partial \ln P_{TRAIN}}{\partial Cost_{AIR}} = \frac{\partial \ln P_{BUS}}{\partial Cost_{AIR}} = \frac{\partial \ln P_{CAR}}{\partial Cost_{AIR}} = (-P_{AIR})\boldsymbol{\beta}_{Cost}.$$

This striking result, termed *independence from irrelevant alternatives* (IIA), follows from the initial assumptions of independent and identical distributions for $\varepsilon_{i,j}$. This is a major shortcoming of the model, and has motivated much of the research on specification of discrete choice models. Many model extensions have been proposed, including a heteroskedastic extreme value model (Bhat, 1995), the Dogit (dodging the logit model, Gaudry and Dagenais, 1979), and a host of others. The major extensions of the canonical multinomial logit (MNL) model have been the multinomial probit (MNP) model, the nested logit model and the current frontier, the mixed logit model. We consider each of these in turn.

11.7.1.1 Multinomial probit model

The MNP model (Daganzo, 1979) replaces the i.i.d. assumptions of the MNL model with a multivariate normality assumption:

$$\boldsymbol{\varepsilon}_i \sim N_J[\mathbf{0}, \boldsymbol{\Sigma}].$$

This specification relaxes the independence assumption. In principle, it can also relax the assumption of identical (marginal) distributions as well. Recall that, since only the most preferred choice is revealed, information about utilities is obtained in the form of differences, $U_{i,j} - U_{i,m}$. It follows that identification restrictions are required, as only some, or certain combinations of, elements of $\boldsymbol{\Sigma}$ are estimable. The simplest approach to securing identification that is used in practice is to impose that the last row of $\boldsymbol{\Sigma}$ be equal to $(0, 0, \ldots, 1)$, and one other diagonal element also equals 1. The remaining elements of $\boldsymbol{\Sigma}$ may be unrestricted, subject to the requirement that the matrix be positive definite. This can be done by a Cholesky decomposition, $\boldsymbol{\Sigma} = \mathbf{C}\mathbf{C}'$, where $\mathbf{C}$ is a lower triangular matrix.

The MNP model relaxes the IIA assumptions. The shortcoming of the model is its computational demands. The relevant probabilities that enter the log-likelihood function and its derivatives must be approximated by simulation. The GHK simulator (Manski and Lerman, 1977; Geweke, Keane and Runkle, 1994) is commonly used. The Gibbs sampler with non-informative priors (Allenby and Rossi, 1999) has also proved useful for estimating the model parameters. Even with the GHK simulator, however, computation of the probabilities by simulation is time consuming.

11.7.2 Nested logit models

The nested logit model allows for the grouping of alternatives into "nests" with correlation across elements in a group. The natural analogy is to a "tree structure"; e.g., Figure 11.2 suggests an elaborate, three-level treatment of an eight-alternative-choice set.

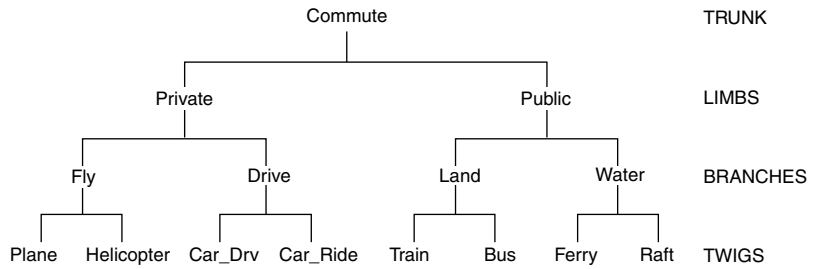

Figure 11.2 Nested choice set

The specific choice probabilities are redefined to be the conditional probability of alternative twig j in branch b, limb l, and trunk r, $j|b,l,r$, At the next level up the tree, we define the conditional probability of choosing a particular branch in limb l, trunk r, $b|l,r$, the conditional probability of choosing a limb in trunk r, $l|r$, and, finally, the probability of choosing a trunk r. By the laws of probability, the unconditional probability of the observed choices made by an individual is:

$$P(j,b,l,r) = P(j|b,l,r) \times P(b|l,r) \times P(l|r) \times P(r).$$

This is the contribution of an individual observation to the likelihood function for the sample. (Note that in our example, there is only one trunk, so $P(r) = 1$.)

The two-level nested logit model is the leading case, and occupies most of the received applications. In this instance, a common specification places the individual specific characteristics, such as demographic variables, in the branch probabilities. For this basic model, then:

$$P(j|b) = \frac{\exp(\mathbf{x}'_{j|b}\boldsymbol{\beta})}{\sum_{q|b}\exp(\mathbf{x}'_{q|b}\boldsymbol{\beta})} = \frac{\exp(\mathbf{x}'_{j|b}\boldsymbol{\beta})}{\exp(J_b)},$$

where J_b is the inclusive value for branch b,

$$J_b = \log \sum_{q|b} \exp(\mathbf{x}'_{q|b}\boldsymbol{\beta}).$$

At the next level up the tree, we define the conditional probability of choosing a particular branch:

$$P(b) = \frac{\exp\left[\lambda_b(\mathbf{z}'_i\boldsymbol{\gamma}_b + J_b)\right]}{\sum_s \exp\left[\lambda_s(\mathbf{z}'_i\boldsymbol{\gamma}_s + J_s)\right]} = \frac{\exp\left[\lambda_b(\mathbf{z}'_i\boldsymbol{\gamma}_b + J_b)\right]}{\exp(I)},$$

where I is the inclusive value for the model:

$$I = \log \sum_s \exp[\lambda_s(\mathbf{z}_i'\boldsymbol{\delta}_s + J_s)].$$

The original MNL results if the inclusive parameters, λ_s, are all equal to one.

Alternative normalizations and aspects of the nested logit model are discussed in Hensher and Greene (2002) and Hunt (2000). A second form moves the scaling down to the twig level, rather than at the branch level. Here it is made explicit that, within a branch, the scaling must be the same for all alternatives, but it can differ between the branches:

$$P(j|b) = \frac{\exp\left[\mu_b(\mathbf{x}_{j|b}'\boldsymbol{\beta})\right]}{\sum_{q|b}\exp\left[\mu_b(\mathbf{x}_{q|b}'\boldsymbol{\beta})\right]} = \frac{\exp\left[\mu_b(\mathbf{x}_{j|b}'\boldsymbol{\beta})\right]}{\exp(J_b)}.$$

Note that, in the summation in the inclusive value I, the scaling parameter is not varying with the summation index. It is the same for all twigs in the branch.

At the next level up the tree, we define the conditional probability of choosing the particular branch:

$$P(b|l) = \frac{\exp\left[\left(\mathbf{z}_i'\boldsymbol{\gamma}_s + (1/\mu_b)J_b\right)\right]}{\sum_s \exp\left[\left(\mathbf{z}_i'\boldsymbol{\gamma}_s + (1/\mu_s)J_s\right)\right]} = \frac{\exp\left[\left(\mathbf{z}_i'\boldsymbol{\gamma}_s + (1/\mu_b)J_b\right)\right]}{\exp(I)},$$

where I_l is the inclusive value for limb l:

$$I_l = \log \sum_{s|l} \exp\left[\gamma_l\left(\boldsymbol{\alpha}'\mathbf{y}_{s|l} + (1/\mu_{s|l})J_{s|l}\right)\right].$$

In the nested logit model with $P(j,b,l,r) = P(j|b,l,r)\times P(b|l,r)\times P(l|r)\times P(r)$, the marginal effect of a change in attribute "k" in the utility function for alternative "J" in branch "B" of limb "L" of trunk "R" on the probability of choice "j" in branch "b" of limb "l" of trunk "r" is computed using the following result: lower-case letters indicate the twig, branch, limb and trunk of the outcome upon which the effect is being exerted. Upper-case letters indicate the twig, branch, limb and trunk which contain the outcome whose attribute is being changed:

$$\frac{\partial \log P(alt = j, limb = l, branch = b, trunk = r)}{\partial x(k)|alt = J, limb = L, branch = B, trunk = r} = D(k|J,B,L,R) = \Delta(k)\times F,$$

where $\Delta(k)$ = coefficient on $x(k)$ in $U(J|B,L,R)$ and:

$$\begin{aligned}
F &= \mathbf{1}(r=R)\times\mathbf{1}(l=L)\times\mathbf{1}(b=B)\times[\mathbf{1}(j=J)\,P(J|BLR)] && \text{(trunk effect)},\\
&= 1(r=R)\times\mathbf{1}(l=L)\times[\mathbf{1}(b=B) - P(B|LR)]\times P(J|BLR)]\times\tau_{B|LR} && \text{(limb effect)},\\
&= 1(r=R)\times[\mathbf{1}(l=L) - P(L|R)]\times P(B|LR)\times P(J|BLR)\times\tau_{B|LR}\times\sigma_{L|R} && \text{(branch effect)},\\
&= [\mathbf{1}(r=R)P(R)]\times P(L|R)\times P(B|LR)\times P(J|BLR)\times\tau_{B|LR}\times\sigma_{L|R}\times\phi_R && \text{(twig effect)},
\end{aligned}$$

where $\tau_{B|LR,}$ $\sigma_{L|R}$ and ϕ_R are parameters in the MNL probabilities. The marginal effect is:

$$\partial P(j,b,l,r)/\partial x(k)|J,B,L,R = P(j,b,l,r)\Delta(k)F.$$

A marginal effect has four components: an effect on the probability of the particular trunk, one on the probability for the limb, one for the branch, and one for the probability for the twig. (Note that with one trunk, $P(l) = P(1) = 1$, and likewise for limbs and branches.) For continuous variables, such as cost, it is common to report, instead:

$$Elasticity = x(k)|J,B,L,R \times \Delta(k|J,B,L,R) \times F.$$

The formulation of the nested logit model imposes no restrictions on the inclusive value parameters. However, the assumption of utility maximization and the stochastic underpinnings of the model do imply certain restrictions. For the former, in principle, the inclusive value parameters must lie between zero and one. For the latter, the restrictions are implied by the way the random terms in the utility functions are constructed. In particular, the nesting aspect of the model is obtained by writing:

$$\varepsilon_{j|b,l,r} = u_{j|b,l,r} + v_{b|l,r}.$$

That is, within a branch, the random terms are viewed as the sum of a unique component and a common component. This has certain implications for the structure of the scale parameters in the model. In particular, it is the source of the oft cited (and oft violated) constraint that the IV parameters must lie between zero and one. These are explored in Hunt (2000) and Hensher and Greene (2002).

11.7.3 Mixed logit and error component models

This model is somewhat similar to the random coefficients model for linear regressions (see Bhat, 1996; Jain, Vilcassim and Chintagunta, 1994; Revelt and Train, 1998; Train, 2003; Berry, Levinsohn and Pakes, 1995). The model formulation is a one-level MNL for individuals $i = 1,\ldots,n$ in choice setting t. We begin with the basic form of the MNL model, with alternative specific constants α_{ji} and attributes $\mathbf{x}_{ji}$:

$$\text{Prob}(y_{it} = j|\mathbf{X}_{it}) = \frac{\exp\left(\alpha_{ji} +_i \mathbf{x}'_{it,j}\boldsymbol{\beta}_i\right)}{\sum_{q=1}^{J_{it}} \exp\left(\alpha_{qi} +_i \mathbf{x}'_{it,q}\boldsymbol{\beta}_i\right)}.$$

The random parameters model emerges as the form of the individual specific parameter vector, $\boldsymbol{\beta}_i$, is developed. The most familiar, simplest version of the model specifies:

$$\beta_{ki} = \beta_k + \sigma_k v_{ki},$$
$$\alpha_{ji} = \alpha_j + \sigma_j v_{ji},$$

where β_k is the population mean, v_{ki} is the individual specific heterogeneity, with mean zero and standard deviation one, and σ_k is the standard deviation of the distribution of the β_{ki}s around β_k. The term "mixed logit" is often used in the literature

(e.g., Revelt and Train, 1998, and, especially, McFadden and Train, 2000) for this model. The choice-specific constants, α_{ji}, and the elements of β_i are distributed randomly across individuals with fixed means. A refinement of the model is to allow the means of the parameter distributions to be heterogeneous with observed data $\mathbf{z}_i$ (which does not include a constant). This would be a set of choice invariant characteristics that produce individual heterogeneity in the means of the randomly distributed coefficients so that:

$$\beta_{ki} = \beta_k + \mathbf{z}_i'\boldsymbol{\delta}_k + \sigma_k v_{ki},$$

and likewise for the constants. The model is not limited to the normal distribution. One important variation is the log-normal model,

$$\beta_{ki} = \exp(\beta_k + \mathbf{z}_i'\boldsymbol{\delta}_k + \sigma_k v_{ki}).$$

The v_{ki}s are individual and choice specific, unobserved random disturbances – the source of the heterogeneity. Thus, as stated above, in the population, if the random terms are normally distributed:

$$\beta_{ki} \sim \text{Normal or Lognormal } [\beta_k + \mathbf{z}_i'\boldsymbol{\delta}_k, \sigma_k^2].$$

(Other distributions may be specified.) For the full vector of K random coefficients in the model, we may write the full set of random parameters as:

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta} z_i + \boldsymbol{\Gamma} v_i,$$

where $\boldsymbol{\Gamma}$ is a diagonal matrix which contains σ_k on its diagonal. For convenience at this point, we will simply gather the parameters or choice specific constants under the subscript "k."

Greene and Hensher (2006) have developed a counterpart to the random effects model that essentially generalizes the mixed logit model to a stochastic form of the nested logit model. The general notation is fairly cumbersome, but an example suffices to develop the model structure. Consider a four outcome-choice set: Air, Train, Bus, Car. The utility functions in an MNL or mixed logit model could be:

$$\begin{array}{llllll}
U_{it,Air} & = \alpha_{Air} & +\mathbf{x}_{it,Air}'\boldsymbol{\beta}_i & +\varepsilon_{it,Air} & +\theta_1 E_{i,Private} \\
U_{it,Train} & = \alpha_{Train} & +\mathbf{x}_{it,Train}'\boldsymbol{\beta}_{ii} & +\varepsilon_{it,Train} & +\theta_2 E_{i,Public} \\
U_{it,Bus} & = \alpha_{Bus} & +\mathbf{x}_{it,Bus}'\boldsymbol{\beta}_{ii} & +\varepsilon_{it,Bus} & +\theta_2 E_{i,Public} \\
U_{it,Car} & = \mathbf{x}_{it,Car}'\boldsymbol{\beta}_i & +\varepsilon_{it,Car} & +\theta_1 E_{i,Private}, &
\end{array}$$

where the components $E_{i,Private}$ and $E_{i,Public}$ are independent, normally distributed random elements of the utility functions. Thus this is a two-level nested logit model.

The probabilities defined above are conditioned on the random terms, $\mathbf{v}_i$, and the error components, $\mathbf{E}_i$. The unconditional probabilities are obtained by integrating v_{ik} and E_{im} out of the conditional probabilities: $P_j = E_{v,E}[P(j|\mathbf{v}_i,\mathbf{E}_i)]$. This is a multiple integral which does not exist in closed form. The integral is approximated by simulation (see Greene and Hensher, 2006, and Greene, 2007a, for discussion). Parameters are estimated by maximizing the simulated log-likelihood.

11.7.4 Application

The multinomial choice models are illustrated with a well-known data survey of commuters between Sydney and Melbourne (see Greene, 2007a, and references cited). A sample of 210 travelers between Sydney and Melbourne were asked which of four travel modes they chose air, train, bus or car. The variables used in the models are:

TTME = Terminal time, in minutes, zero for car,
INVT = In-vehicle time for the journey
GC = generalized cost = in-vehicle cost + a wage times INVT
HINC = household income
PSIZE = traveling party size:

Table 11.10 lists descriptive statistics for the variables in the model. The left-hand side for each panel lists the means and standard deviations for the variables

Table 11.10 Descriptive statistics for variables

Variable	*Mean*	*Std. dev.*	*Mean*	*Std. dev.*
AIR	All 210 obs.		58 observations that chose AIR

GC	95.414	46.827	89.085	49.833
PSIZE	1.743	1.012	2.203	1.270
HINC	34.548	19.711	42.220	17.685

for all observations, in each of the four choices. The right-hand side reports the same statistics for the observations that made the particular choices. Thus, for example, the average terminal time for all 210 observations for the air choice is 61.01 minutes. For the 58 individuals who chose air, the average terminal time for air is 46.534 minutes. We note before beginning that the sample proportions for the four travel modes in this sample are 0.27619, 0.30000, 0.14286 and 0.28095, respectively. Long study of this market revealed that the population values of these proportions should be closer to 0.14, 0.13, 0.09 and 0.64, respectively. The sample observations were deliberately drawn so that the car alternative received fewer observations than random sampling would predict. The sample is *choice based*. A general adjustment for that phenomenon is the Manski–Lerman (1977) weighted endogenous sampling maximum likelihood (WESML) correction, which consists of two parts. First, we would fit a weighted log-likelihood:

$$\ln L(\text{WESML}) = \sum_{i=1}^{n} \sum_{j=1}^{J} \frac{\pi_j}{p_j} d_{ij} \ln \Pi_{ij},$$

where $d_{ij} = 1$ if individual i chooses alternative j and 0 otherwise, π_j is the true population proportion, p_j is the sample proportion, and Π_{ij} is the probability for outcome j implied by the model. The second aspect of the correction is to use a sandwich style corrected estimator for the asymptotic covariance matrix of the MLE:

$$\text{V(WESML)} = \mathbf{H}^{-1}(\mathbf{G}'\mathbf{G})\mathbf{H}^{-1},$$

where $\mathbf{H}$ is the inverse of the (weighted) Hessian and $(\mathbf{G}'\mathbf{G})^{-1}$ would be the BHHH estimator based on first derivatives. The results to follow do not include this correction – the results in the example would change slightly if they were incorporated.

We fit a variety of models. The same utility functions were specified for all:

$$\text{U}_{i,\text{AIR}} = \alpha_{\text{AIR}} + \beta_{tt}\text{TTME}_{i,\text{AIR}} + \beta_{it}\text{INVT}_{i,\text{AIR}} + \beta_{\text{gc}}\text{GC}_{i,\text{AIR}} + \gamma_{\text{A}}\text{HINC}_i + \varepsilon_{i,\text{AIR}},$$

$$\text{U}_{i,\text{TRAIN}} = \alpha_{\text{TRAIN}} + \beta_{tt}\text{TTME}_{i,\text{TRAIN}} + \beta_{it}\text{INVT}_{i,\text{TRAIN}} + \beta_{\text{gc}}\text{GC}_{i,\text{TRAIN}} + \varepsilon_{i,\text{TRAIN}},$$

$$\text{U}_{i,\text{BUS}} = \alpha_{\text{BUS}} + \beta_{tt}\text{TTME}_{i,\text{BUS}} + \beta_{it}\text{INVT}_{i,\text{BUS}} + \beta_{\text{gc}}\text{GC}_{i,\text{BUS}} + \varepsilon_{i,\text{BUS}},$$

$$\text{U}_{i,\text{CAR}} = \beta_{tt}\text{TTME}_{i,\text{CAR}} + \beta_{it}\text{INVT}_{i,\text{CAR}} + \beta_{\text{gc}}GC_{i,\text{CAR}} + \varepsilon_{i,\text{CAR}}.$$

The estimated parameters for the several specifications are given in Table 11.11. Model MNL is the base case multinomial logit model. Model MNP is the multinomial probit model. The three nested logit (NL) models are nested logit models with different tree structures:

NL(1) = Private (air, car), Public (train, bus).
NL(2) = Fly (air), Ground (train, bus, car)
NL(3) = Fly (air), Rail (train), Drive (car), Autobus (bus).

For the third of these, one of the inclusive value parameters, μ_j, must be constrained to equal one. Model HEV (heteroskedastic extreme value) is the extreme value

[d] Scale parameters are standard deviations of random parameters.

model with the variances allowed to differ across utility functions. In addition, we introduced heteroskedasticity in the model, so that:

$$\text{Var}[\varepsilon_{i,j}] = \sigma_j^2 \times \exp(\theta \text{ party size}).$$

Finally, the last model, RPL (random parameters logit), is a random parameters specification in which the parameters on TTME, INVT and GC are allowed to vary randomly across individuals.

It is difficult to obtain a precise interpretation of the coefficients in the utility functions. The elasticities of the probabilities of specific outcomes with respect to changes in the attributes of those and other outcomes are more informative. We write these:

$$\delta(m)_{j,l} = \frac{\partial \log P_j}{\partial \log x_{m,l}},$$

where m indicates the mth attribute, j is the choice probability affected and l is the choice utility function in which $x_{m,l}$ changes. These are given in Table 11.12. (specific forms of these appear in Greene, 2008a; Hensher *et al.*, 2005). The values given are averaged over the observations. Note that for the MNL form, $\delta(m)_{j,l}$ is the same for all l. This is the force of the IIA assumptions made at the outset. This is a motivation for the more elaborate functions considered.

11.8 Summary and conclusions

This chapter has outlined the basic modeling frameworks that are used in analyzing microeconomic data when the response variable corresponds to a discrete choice. The essential binary choice model is the foundation for a vast array of applications and theoretical developments. The full set of results for the fully parametric models based on the normal distribution, as well as many non- and semiparametric models,

are well established. Ongoing contemporary theoretical research is largely focused on less parametric approaches and on panel data. The parametric models developed here still overwhelmingly dominate the received applications.

Notes

1. For a lengthy and detailed development of these ideas, see Daniel McFadden's Nobel Prize Lecture (McFadden, 2001).
2. See, as well, Samuelson (1947) and Goldberger (1987).
3. Some formulations of the models, such as models of heteroskedasticity and the random parameters, will also involve additional parameters. These will be introduced later. They are omitted at this point to avoid cluttering the notation.
4. The formulation assumes that the T_i choices made by individual i are unconditionally independent. This assumption may be inappropriate. In one of our applications, the assumption is testable.
5. See, e.g., the documentation for LIMDEP (Econometric Software, Inc., 2007) or Stata (Stata, Inc., 2007).
6. We are assuming that the data are "well behaved" so that the conditions underlying the standard optimality properties of MLEs are met here. The conditions and the properties are discussed in Greene (2008a). We will take them as given in what follows.
7. The sign of the result for the logistic distribution is obvious. See, e.g., Maddala (1983, p. 366) for a proof of the result for the normal distribution.
8. There are data configurations, in addition to simple multicollinarity, that can produce singularities. Another possibility is that of a variable in $\mathbf{x}_i$ or $\mathbf{z}_i$ that can predict d_i perfectly based on a specific cut point in the range of that variable.
9. Recall that the average predicted probability, $\overline{\hat{P}}$, equals the average outcome in the binary choice model, P_1. To a fair approximation, the standard deviation of the predicted probabilities will equal $[P_1(1 - P_1)]^{0.5}$. If the sample is highly unbalanced, say $P_1 < 0.05$ or $P_1 > 0.95$, then a predicted probability as large as (or as small as) 0.5 may become unlikely. It is common in unbalanced panels for the simple prediction rule always to predict the same value.
10. A symposium on the subject is Hardle and Manski (1993).
11. See Manski (1975, 1985, 1986) and Manski and Thompson (1986). For extensions of this model, see Horowitz (1992), Charlier, Melenberg and van Soest (1995) and Kyriazidou (1997).
12. Bootstrapping has been used to estimate the asymptotic covariance matrix for the maximum score estimator. However, Abrevaya and Huang (2005) have recently cast doubt on the validity of that approach. No other strategy is available for statistical inference in this model.
13. One would proceed in precisely this fashion if the central specification were a linear probability model (LPM) to begin with. See, e.g., Eisenberg and Rowe (2006) or Angrist (2001) for an application and some analysis of this case.
14. This is precisely the platform that underlies the generalized linear models/generalized estimating equations (GLIM/GEE) treatment of binary choice models in, e.g., the widely used programs SAS and Stata.
15. Much of the recent research in semiparametric and nonparametric analysis of discrete choice and limited dependent variable models has focused on how to accommodate individual heterogeneity in panel data models while avoiding the incidental parameters problem.
16. The requirement does not state how large R must be, only that it "increase" faster than $n^{1/2}$. In practice, analysts typically use several hundred, perhaps up to 1,000, random draws for their simulations.

17. See, as well, Hsiao (2003) for a survey of dynamic panel data models and other applications by van Doorslaer and Nonneman (1987), Wagstaff (1993) and Vella and Verbeek (1999).
18. This is the formulation used by Contoyannis *et al.* (2004). Wooldridge (2006) suggested, instead, that the projection be upon all of the data, $(\mathbf{x}_{i1},\mathbf{x}_{i2},\ldots)$. Two major practical problems with this approach are that, in a model with a large number of regressors, which is common when using large, elaborate panel data sets, the number of variables in the resulting model will become excessive. Second, this approach breaks down if the panel is unbalanced, as it was in the Contoyannis *et al.* study.
19. Beck *et al.* (2001) is a bit different from the others mentioned in that, in their study of "state failure," they observe a large sample of countries (147) observed over a fairly large number of years, 40. As such, they are able to formulate their models in such a way that makes the asymptotics with respect to T appropriate. They can analyze the data essentially in a time series framework. Sepanski (2000) is another application which combines state dependence and the random coefficient specification of Akin, Guilkey and Sickles (1979).
20. Wynand and van Praag (1981) used a two-step procedure similar to Heckman's (1979) procedure for the linear model. Applications since then have used the MLE.
21. Since the coefficient vectors are assumed to be the same in every period, it is only necessary to normalize one of the diagonal elements in $\mathbf{R}$ to 1.0. See Greene (2004a) for discussion.
22. For example, the parameters can be written in terms of a set of latent parameters so that $\mu_1 = \tau_1^2$, $\mu_2 = \tau_1^2 + \tau_2^2$, etc. Typically, the explicit reparameterization is unnecessary.
23. One could argue that this reformulation achieves identification purely "through functional form," rather than through the theoretical underpinnings of the model. Of course, this assertion elevates the linear specification to a default position of prominence, which seems unwarranted. Moreover, arguably the underlying theory (as, in fact, suggested in passing by Pudney and Shields, 2000) *is* that there are different effects of the regressors on the thresholds and on the underlying utility.
24. Cross-section versions of the ordered probit model with individual specific thresholds appear in Terza (1985), Pudney and Shields (2000) and in Greene (2007a).
25. No theory justifies the choice of the log-gamma density. It is essentially the same as a conjugate prior in Bayesian analysis, chosen for its mathematical convenience.
26. The use of the linear index form is a convenience. The random component, ε, could enter the model in some other form, with no change in the general approach.

Panel Data Methods and Applications to Health Economics

Andrew M. Jones

Abstract

Much of the empirical analysis done by health economists seeks to estimate the impact of specific health policies, and the greatest challenge for successful applied work is to find appropriate sources of variation to identify the treatment effects of interest. Estimation can be prone to selection bias when the assignment to treatments is associated with the potential outcomes of the treatment. Overcoming this bias requires variation in the assignment of treatments that is independent of the outcomes. One source of independent variation comes from randomized controlled experiments. But, in practice, most economic studies have to draw on non-experimental data. Many studies seek to use variation across time and events that takes the form of a quasi-experimental design, or "natural experiment," that mimics the features of a genuine experiment. This chapter reviews the data and methods that are used in applied health economics with a particular emphasis on the use of panel data. The focus is on nonlinear models and methods that can accommodate unobserved heterogeneity. These include conditional estimators, maximum simulated likelihood, Bayesian MCMC, finite mixtures and copulas.

12.1 Introduction

A common thread that runs through this chapter is the "evaluation problem": is it possible to identify the impact of policies from empirical data? The focus of the chapter is on individual-level longitudinal data, so consider an "outcome" y_{it}, for individual i at time t. The treatment effect of interest is:

$$TE_{it} = \Delta_{it} = y_{it}^1 - y_{it}^0, \tag{12.1}$$

where 1 denotes treatment and 0 denotes control.[1] The pure treatment effect cannot be identified because the counterfactual can never be observed: each individual is either treated or untreated at a particular point in time so only one of the potential outcomes can be observed. The outcome that is actually observed can be written in terms of the potential outcomes:

$$y_{it} = y_{it}^0 + d_{it}(y_{it}^1 - y_{it}^0), \tag{12.2}$$

where d_{it} is an indicator of treatment.

One response to the problem of defining a counterfactual is to concentrate on the average treatment effect (ATE), comparing the average outcomes between the treated and controls:

$$ATE = E\left(y_{it}^1 - y_{it}^0\right). \tag{12.3}$$

When there is heterogeneity in individual responses to the treatment that may influence the assignment of treatment, for example, when doctors select patients on the basis of their capacity to benefit, attention is likely to focus on the average treatment effect on the treated (ATET) rather than the ATE:

$$ATET = E\left(y_{it}^1 - y_{it}^0 \mid d_{it} = 1\right). \tag{12.4}$$

This is the average effect of treatment for those individuals who would actually select into treatment.

Moving towards a regression framework, assume that the observed outcome under the two treatment regimes is given by the general regression model:

$$y_{it} = f_j(x_{it}, u_{jit}), j = 0, 1. \tag{12.5}$$

The vector x includes observable factors that influence the outcome and may influence the assignment of treatment (reflecting "selection on observables"). The u are unobservable factors that influence the outcomes and may influence the assignment of treatment ("selection on unobservables"). Formulating the problem in this way requires the SUTVA (stable unit-treatment value assumption) to hold – an individual's potential outcomes and treatments are independent of others in the population, ruling out spillover and general equilibrium effects. These spillovers may be important in some health economics applications and the evaluation of treatment effects would then have to be designed to accommodate them (see Chandra and Staiger, 2007; Miguel and Kremer, 2004). Using linear functions for $f(.)$ gives a switching regression model:

$$y_{it} = x_{it}'\beta_j + u_{jit}, j = 0, 1. \tag{12.6}$$

A simplification of this model, which assumes a homogeneous treatment effect so that only the intercept varies with treatment, gives the regression function:

$$y_{it} = x_{it}'\beta + d_{it}\,\delta + u_{it}\,. \tag{12.7}$$

In this case ATE = ATET = δ.

If unobserved factors (u) influence whether an individual is selected into the treatment group or how they respond to the treatment, this will lead to biased estimates of the treatment effect. A randomized experimental design may achieve the desired orthogonality of measured covariates (x, d) and unobservables (u). However, econometric studies typically rely on observational data gathered in a non-experimental setting. One strategy is to rely on selection on observables: finding a sufficiently rich set of observable characteristics so that unobservables can be assumed to have no systematic influence on treatments. This approach includes matching estimators and inverse probability weighted estimators. In contrast, the selection on unobservables strategy looks for factors that predict treatment, but have no direct effect on outcomes and which can therefore be used to mimic random assignment of treatment. This approach includes using within-individual variation to allow for time invariant individual heterogeneity in panel data models (fixed effects) as well as conventional instrumental variables (IVs) estimators. It also includes multiple equation models in which equations for the treatment and outcome are estimated jointly by full information maximum likelihood (FIML). "Natural experiments" often lead to the use of difference-in-differences estimators, which combine selection on observables (by including x in the regression models) with selection on unobservables (by using differencing to control for time invariant heterogeneity).

Natural experiments are often also linked to IV estimation, which relies on instruments (z) that predict the assignment of treatment, but do not have a direct effect on the outcome. When there is heterogeneity in the response to treatment the IV estimator identifies a local average treatment effect, or LATE (Imbens and Angrist, 1994; McClellan *et al.,* 1994). This is the average treatment effect over the sub-group of the population that are induced to participate in the treatment by variation in the instrument. The fact that IV estimates only identify the LATE and that the results are therefore contingent on the set of instruments explains why different empirical studies can produce quite different estimates, even though they examine the same outcomes and treatments. Heterogeneity in treatment effects is likely to be widespread: for example, Auld (2006a) finds considerable heterogeneity in the treatment effect of local HIV infection prevalence on risky sexual behavior among gay men in the San Francisco Men's Health Study (SFMHS), with HIV prevalence having less impact among those at high risk.

Recent work by Heckman and Vytlacil has extended the analysis of local treatment effects by specifying a model for the assignment of treatment and using it to identify those individuals who are indifferent between treatments, given x and z (see, e.g., Heckman and Vitlacyl, 1999, 2007; see Basu *et al.,* 2007, for an application to health data). This approach defines the marginal treatment effect (MTE): the treatment effect among those individuals at the margin. The MTE provides a building block for the LATE, ATET and ATE. It can be identified using local instrumental variables (LIVs) methods or by specifying multiple equation models with a common factor structure (see, e.g., Aakvik *et al.,* 2005; Basu *et al.,* 2007).

For example, in Aakvik *et al.* (2005) the treatment is a Norwegian vocational rehabilitation (VR) program and the outcome is a binary measure of employment. Analysis is based on a 10% sample of all those who applied for VR in 1989. To define the treatment effects of interest, Aakvik *et al.*, specify a discrete choice model with a common factor structure. There is a switching regression for the binary indicator of employment under the two treatment regimes:

$$\begin{aligned} y_i^1 &= f_1(x_i, u_{1i}) = 1(x_i' \beta_1 \geq u_{1i}) \\ y_i^0 &= f_0(x_i, u_{0i}) = 1(x_i' \beta_0 \geq u_{0i}), \end{aligned} \tag{12.8}$$

along with a latent variable model for the assignment of treatment:

$$\begin{aligned} &d_i = 1 \\ &\text{if} \\ &d_i^* = z_i' \beta_d - u_{di} > 0. \end{aligned} \tag{12.9}$$

The error terms are assumed to have a common factor structure:

$$\begin{aligned} u_{di} &= -\eta_i + \varepsilon_{di} \\ u_{1i} &= -\alpha_1 \eta_i + \varepsilon_{1i} \\ u_{0i} &= -\alpha_0 \eta_i + \varepsilon_{0i}\,. \end{aligned} \tag{12.10}$$

Estimation is by FIML, assuming that the error components are jointly normal.

Given this set-up, the treatment effects of interest can be defined as follows:

$$MTE(x,u) = E\left(\Delta | x, d^* = 0\right) = E\left(\Delta | x, u_d = z_i' \beta_d\right) \tag{12.11}$$

$$ATE(x) = \int_u MTE(x,u) dF(u) = E\left(\Delta | x\right) \tag{12.12}$$

$$ATE = E(ATE(x)) = \int_x E\left(\Delta | x\right) dF(x) \tag{12.13}$$

$$ATT(x,u) = E\left(\Delta | x, d = 1\right) = E\left(\Delta | x, u_d < z_i' \beta_d\right), \tag{12.14}$$

where $F(u)$ is the distribution of u and $F(x)$ is the distribution of the xs. Aakvik *et al.* (2005) do not use the concept of the LATE in their study but, based on the notation of their model, it could be expressed as:

$$LATE(x, z, \tilde{z}) = E\left(\Delta | x, z_i' \beta_d < u_d < \tilde{z}_i' \beta_d\right), \tag{12.15}$$

where, for illustration, it is assumed that assignment to treatment is monotonically related to a single instrument that takes two values z and $\tilde{z}$, where $z_i' \beta_d < \tilde{z}_i' \beta_d$. The LATE defines the treatment effect for all those individuals who are induced into the treatment by the change in the instrument (see, e.g., Basu *et al.*, 2007).

The nonlinear model is identified by functional form, but an exclusion restriction is also imposed by including an instrument – the degree of rationing of VR places in the individual's locality – in z, but not in x. The apparent positive impact of

the VR program is reversed when selection bias is taken into account and there is evidence of perverse cream-skimming, with those most likely to benefit being the least likely to be selected by the program administrators.

A note on the scope of the chapter

This chapter takes the identification of treatment effects as its starting point and concentrates on microeconometric methods that can be used with longitudinal and other complex and multilevel datasets. Although the methods described in the chapter are widely used throughout applied econometrics, the applications reviewed here all relate to one specific area: health economics. The chapter follows an earlier review of the literature on "health econometrics" (Jones, 2000) and concentrates on studies that have appeared as peer-reviewed publications from 2000 onwards. The emphasis is on applications that use health and health care as outcomes. Less attention is devoted to the large number of studies of health-related behaviors, such as diet, smoking, drinking and illicit drugs (see, e.g., Cowell, 2006; Dee *et al.,* 2005; Forster and Jones, 2001; Harris *et al.,* 2006; Terza, 2002; Van Ours, 2006) and to those that investigate the impact of health, health care and health insurance on labor market outcomes (see, e.g., Askildsen *et al.,* 2005; Au *et al.,* 2005; Auld, 2002; Bradley *et al.,* 2005; Contoyannis and Rice, 2001; Disney *et al.,* 2006; French, 2005; Hogelund and Holm, 2006; Morris, 2006, 2007; Royalty and Abraham, 2006; Stewart, 2001; Van Ours, 2004) or labor outcomes for health care professionals (see, e.g., Arulampalam *et al.,* 2004; Frijters *et al.,* 2006; Holmas, 2002). The scope does not include studies that use econometric techniques in the context of contingent valuation and discrete choice experiments, where random effects models are often applied (see, e.g., Ryan *et al.,* 2006); multinomial models of the choice of insurance plans or health care providers (see, e.g., Deb and Trivedi, 2006; Ho, 2006; Sahn *et al.,* 2003); productivity analysis based on models of cost and production functions and estimation of stochastic frontier models (see, e.g., Bradford *et al.,* 2001; Burgess, 2006; Dranove and Lindrooth, 2003; Smith and Street, 2005; Wilson and Carey, 2004); and in the context of cost-benefit and cost-effectiveness analysis, where econometric methods are starting to be used alongside methods from biostatistics and epidemiology (see, e.g., Briggs, 2006; Hoch *et al.,* 2002; Willan *et al.,* 2004).

The focus is primarily on studies that use micro-level data derived from longitudinal, multilevel and other complex data structures. Relatively few cross-section studies are discussed and the chapter does not attempt to review studies that use aggregate time series or panels and that apply pure time series methods (see, e.g., Aakvik and Holmas, 2006; Abadie and Gay, 2006; Chou, 2007; García-Ferrer *et al.,* 2007; Leigh and Jencks, 2007; Or *et al.,* 2005; Paton, 2002; Ruhm, 2003; Wang and Rettenmaier, 2007). Analysis of longitudinal data often makes use of the methods of survival analysis (see, e.g., Arulampalam *et al.,* 2004; Chou, 2002; Disney *et al.,* 2006; Farsi and Ridder, 2006; Forster and Jones, 2001; Frijters *et al.,* 2006; Harrison, 2007; Holmas, 2002; Kyle, 2007; Picone *et al.,* 2003a; Stewart, 2001; Van Ours, 2004, 2006), but these methods are not discussed in detail here.

The empirical findings of many of the studies are discussed, but no attempt is made to provide a systematic synthesis of the empirical results. It is notable that meta-analyses of regression results are beginning to appear in the health economics literature. For example, Gallet and List (2003) present a meta-analysis of the tobacco price elasticity and Gemmill *et al.* (2007) carry out a meta-regression of estimates of the price elasticity of prescription drugs.

On the whole, the original sources for the econometric methods are not cited. These are reviewed in Volume 1 of this Handbook (particularly the chapters by Badi Baltagi, William Greene and Lung-fei Lee) and in other chapters in this second volume, in particular those by Colin Cameron, William Greene, and David Jacho-Chávez and Pravin Trivedi.

12.2 Identification strategies: finding relevant variation

The success of applied work depends on finding appropriate sources of variation to identify the effects of interest. Estimation of treatment effects can be prone to selection bias, where the assignment to treatments is associated with the potential outcomes of the treatment. Overcoming this selection bias requires variation in the assignment of treatments that is independent of the outcomes. One source of independent variation comes from randomized controlled experiments. While these are the norm in the evaluation of new clinical therapies, their use for the evaluation of social programs remains rare (Gertler, 2004; Kremer, 2003; Miguel and Kremer, 2004). Most economic studies have to draw on non-experimental, or observational, data. This section presents a series of case studies from the recent literature and describes how these have sought out relevant identifying information.

12.2.1 Randomized experiments

The "gold standard" methodology that is used to identify the efficacy and effectiveness of new medical technologies is the randomized clinical trial (RCT). Much of the work done by health economists to measure the cost-effectiveness of these technologies draws on data collected within RCTs to perform statistical analyses (Briggs, 2006) or to calibrate decision analytic models (Claxton *et al.,* 2006). Econometric methods are sometimes used in secondary analysis of such data to model costs and outcomes as functions of observable covariates (Willan *et al.,* 2004).

Broader randomized social experiments are far less prevalent. One exception, which has played a highly influential role in the development of health economics and has driven many of the early developments in the use of econometrics in the field, is the RAND Health Insurance Experiment (Manning *et al.,* 1987). The RAND experiment was designed to address the problem of self-selection in the choice of insurance plans. Participants were randomized between a health maintenance organization (HMO) and reimbursement plans and across plans with different levels of co-payments and a plan with deductibles. The RAND study has had a strong influence, especially in the US. It has focused attention on the use of two-part or multi-part models to model health care utilization and expenditures and on the choice of functional form to deal with heavily skewed data and the consequent

problems of retransformation back to the "natural scale" in the presence of individual heterogeneity (Manning, 2006). The RAND data is available over the internet and has been used to test more recent developments of econometric methods (Bago d'Uva, 2006; Deb and Trivedi, 2002; Gilleskie and Mroz, 2004; Vera-Hernandez, 2003).

More recently, randomized experiments have begun to play an influential role in research and policy in developing countries. This is exemplified by the studies of Gertler (2004) and Miguel and Kremer (2004). The Mexican government's PROGRESA program, which was initiated in 1997, has received considerable attention and has influenced policy throughout Latin America. The program relies on conditional cash transfers that are designed to influence the use of health and welfare services for children in poor families. It covers 2.6 million families in 50,000 rural villages. The program focuses on health, hygiene and nutrition. It links substantial cash transfers, on average amounting to 20–30% of household income, to the use of prenatal care, well-baby care and immunization, nutrition monitoring and supplementation, preventive check-ups and participation in educational programs. PROGRESA works by first selecting whole communities to participate in the scheme and then selecting households within those communities that satisfy the eligibility criteria to receive the benefits of the scheme. Financial constraints on the implementation of PROGRESA meant that its introduction was phased. To make the implementation equitable, communities were selected randomly to receive the benefits either immediately or with a delay. The random phasing provides researchers with an ideal opportunity to use a randomized design in the evaluation of the impact of the program. Of the communities selected for the program, 320 were randomly selected to receive the intervention in August–September 1998 with the remaining 185 delayed for two years. The communities in the control group were not informed that they would eventually receive the program, reducing the scope for anticipation of treatment to influence the outcome.

Gertler (2004) focuses on health outcomes among children. These include self-reported morbidity, measured by illnesses in the past month, as reported by the child's mother, and objective measures including anthropometric measures of height and stunting and a biomarker for anaemia (haemoglobin levels). The analysis is restricted to those households, in both the treatment and control groups, that satisfy the eligibility criteria for PROGRESA. Although the data is randomized, multivariate regression models are used to control for observed covariates and to reduce idiosyncratic variation. Individual and village random effects are included, the latter to allow for the clustered sampling. The results show significant improvements in both self-reported and objective measures of health and the impact increases with length of exposure to the program. Gertler (2004) is careful to note that the comparison of treated and controls does not explain the mechanism behind this effect: for example, it is not possible to say whether an unconditional transfer would have had the same effect as the conditional one.

In their "worms" paper, Miguel and Kremer (2004) analyze a randomized experiment to evaluate the impact of the Kenyan Primary School Deworming Project

(PSDP) on hookworm infection rates and on school attendance. The program included drug therapy and public health education on avoiding hookworm infection, with the assignment of treatment randomly phased. Randomization was done at the level of schools rather than individuals: one group of schools received treatment in 1998 and 1999, another group only in 1999 and a third group only in 2003. Data was collected in 1998 and 1999 so, in the Miguel and Kremer study, the first group are the treated and the second and third groups make up the controls. Miguel and Kremer argue that randomization at the levels of schools is crucial in this context as it avoids biases created by spillover effects of the deworming program in reducing infection rates. They argue that an ideal prospective study would randomize treatments across pupils within schools, across schools within clusters and across these clusters. This multilevel variation in the assignment of treatments could then be used to estimate different levels of the treatment effect in the case where spillovers are important.

12.2.2 Natural experiments

12.2.2.1 Health shocks

Almond (2006) makes inventive use of the 1918 influenza pandemic as a natural experiment to provide evidence in favour of the "fetal origins hypothesis." Cohorts that were in utero during the pandemic, between the fall of 1918 and January 1919, are shown to have poorer outcomes: lower educational attainment, more disability, lower income, lower socioeconomic status and higher transfer payments. The pandemic has the potential to be used as a natural experiment: it was unanticipated, the period of exposure was short and the impact varied systematically across states. The study uses discontinuity across birth cohorts to identify the long-term effects, drawing on data from the 1960, 1970 and 1980 US Census microdata (which identify quarter of birth). Geographic variation is also exploited, based on the "laggard" states where the epidemic had less pronounced long-term effects, although this does reduce the sample size available. This is a paper where simple graphical analysis tells the main story, although it is backed up by thorough statistical modeling.

Doyle (2005) makes innovative use of data on severe traffic accidents to measure variation in unanticipated health shocks and finds that, in the United States, the uninsured receive 20% less treatment and have a substantially higher mortality rate. The Crash Outcome Data Evaluation System (CODES) links police accident reports to hospital discharge data. This study uses data for Wisconsin covering 1992–97, with a sample of 28,236 individuals, 10% of whom were uninsured. Severe traffic accidents are assumed to be unanticipated at the time that insurance is taken out and the consequent use of health care is non-discretionary. Descriptive evidence suggests that the uninsured are riskier drivers and have worse health problems, creating a problem of selection bias. To deal with selection a control group is selected from those with medical insurance, but without car insurance. Within-hospital variation and time effects are controlled for. The robustness of the findings is checked by using the sub-sample where both insured and uninsured individuals

are injured in the same crash, allowing for different severities of accident (accident fixed effects). Also the sample of passengers is used to abstract from differences in the quality of driving between the treated and control groups. Robustness is assessed by doing separate analyses by diagnoses and by medical procedures. In the light of these results, the lower levels of treatment for the uninsured are attributed to decisions made by providers in response to insurance status rather than differences in background characteristics of the patients. Similar issues are faced by Levitt and Porter (2001), who address the problem of selection bias in the US Fatality Analysis Reporting System (FARS), which they use for an analysis of the effectiveness of seat belts and air bags. The problem arises because data is only included for fatal crashes. The use of safety devices influences the probability of survival and hence of inclusion in the sample. The identification strategy adopted to get around this problem is to use a sample based on crashes where someone in a different car dies. The aim is to make the sample selection independent of the observation's own treatment status and outcomes. In doing so they find that seat belts are more effective and air bags are less effective than previous evidence had suggested.

12.2.2.2 Economic shocks

Evans and Lien (2005) make use of the 1992 Port Authority Transit (PAT) strike in Allegheny County, Pennsylvania, as a source of independent variation in access to prenatal care. Prenatal visits were affected most for black women and city residents (in Pittsburgh) and the results show that, for these groups, missing visits early in pregnancy had a detrimental effect, but missing those later in the pregnancy did not. The main source of information is observational data from the 1990–94 US Natality Detail Files, which contain a census of births in each given year, taken from birth records. This is augmented by survey data that is used to assess the impact of the strike on access to prenatal care. A control group of counties that were not affected by the strike are selected on the basis of regression analyses. The use of prenatal care by women who were pregnant at the time of the strike is included in regression equations for birth weight, gestation, maternal weight gain and maternal smoking. Models are estimated by ordinary least squares (OLS) and two-stage least squares (2SLS), the latter using the strike as an instrument. These produce similar results, suggesting that selection bias is not a problem. The clearest effect of prenatal care is on maternal smoking. The robustness of the findings is tested by checking for a general decline in earnings or employment coincident with the strike and for evidence of increases in abortions or "unwanted" births.

In Frijters *et al.* (2005) the reunification of Germany in 1990 provides a natural experiment to assess the causal effect of income on self-reported health satisfaction. A positive and statistically significant effect is found, but the effect is small. The increase in incomes for those in East Germany is used as a source of independent variation in income that is not contaminated by reverse causality from health. The suitability of this setting as a natural experiment is justified by the fact that the changes in income associated with the fall of the Berlin Wall are assumed

to have been unanticipated, that the income transfers were large in magnitude (affecting the real value of savings, collectively bargained wages and pay in general) and that there was individual variation in the impact, with civil servants experiencing an immediate effect. This variation is exploited in an econometric framework that also allows for entry and attrition from the panel dataset and for inherent individual heterogeneity. The analysis uses longitudinal data from the German Socio-economic Panel (GSOEP) from 1984 to 2002 for West Germans and from 1990 to 2002 for East Germans. Data for East Germans is not available prior to reunification, so separate models are estimated for East and West Germans and the natural experiment has to be used indirectly.

In 1996 a crisis in the public pension system in Russia meant that 14 million of the 39 million state pensioners faced substantial arrears in their payments. Jensen and Richter (2004) exploit this pensions crisis as a natural experiment. Their findings show a doubling of poverty rates, significant declines in calorie and protein intake, and reductions in the use of health services and medications. They also show evidence of attempts to mitigate the loss of pension income through work, sales of assets, borrowing and private transfers. Data from the Russian Longitudinal Monitoring Survey (RLMS) for 1995 and 1996 is used to assess the impact of the crisis. Identification stems from geographic variation in arrears, which arises because decisions were regionally decentralized across administrative areas (oblasts) and discretion was exercised within oblasts. The control group is made up of households who continued to receive their pensions. Estimation uses a difference-in-differences design, with the policy effect measured by an interaction between the post-1996 period and whether an individual's pension was in arrears. The identification strategy relies on the assignment of arrears not being associated with outcomes prior to the crisis. The paper attempts to assess the validity of this assumption and presents evidence of a common trend for treated and controls prior to the crisis.

In contrast to Jensen and Richter (2004), Duflo (2000) uses a positive economic shock associated with public pensions as a source of exogenous variation in income in her study of child health in South Africa. The end of the Apartheid era in the early 1990s led to large increases in benefits for black Africans within the South African Old Age Pension System. Duflo's study uses cross-section data collected during 1993 and faces a selection problem, as children living in households with pension recipients are more likely to be disadvantaged and to live in rural areas. Her identification strategy compares eligible and non-eligible households and those children exposed to the increased household pension income for all of their lives or for only a fraction of their lives. Outcomes are measured using height-for-age z-scores and there is evidence of an effect on child health and nutrition. This effect is entirely attributable to pensions received by women and the effect is strongest for girls.

Chay and Greenstone (2003) bring together a comprehensive set of data sources within a quasi-experimental research design to investigate the impact of atmospheric pollution on infant health in the US. They find significant effects of total suspended particles (TSPs) on infant mortality, mostly driven by deaths within one

month of birth. There is heterogeneity in this effect, with the impact on infant mortality rates being twice as large among blacks. Identification is based on geographic variation in the impact of the 1981–82 recession on levels of TSP, which is treated as a source of random variation. County-level data from various sources are merged for the period 1978–84. First differenced (fixed effects) models and, unusually, differenced models with fixed effects for the trend (double differencing) are used. The latter allows for heterogenity in trends. The analysis goes a step further by selecting neighboring counties as controls. This uses non-manufacturing counties that either are or are not neighbors to manufacturing counties to try and isolate the effects of pollution from the socioeconomic effects of the recession.

Lindahl (2005) shows how lottery winnings can provide one source of exogenous variation in income, in an attempt to overcome the selection biases inherent in disentangling the socioeconomic gradient in health. There is a statistically significant effect of income on morbidity and mortality and the magnitude of this effect is largely unchanged when lottery winnings are used as an instrument, although the estimates are less precise. This income effect is not apparent for the sub-sample aged over 60. Data from the Swedish Level of Living Surveys (SLLS) for 1968, 1974 and 1981 are matched with register data on income and deaths up to 1997. Morbidity is measured by combining 48 symptoms into a standardized measure and mortality is measured as death within five or ten years of the surveys. Lottery winnings are treated as a source of exogenous variation in income: assuming that the variation is independent of health. Models are estimated with lottery winnings included directly. Then OLS and instrumental variable estimates (using winnings as the instrument) are compared for the sample of individuals who are identified as "players." The magnitudes of the income effects are similar although standard errors are inflated when IV is used. A similar strategy is adopted by Gardner and Oswald (2007). They use data on the General Health Questionnaire (GHQ-12) measure of psychological well-being from the British Household Panel Survey (BHPS) for 1996–2003 and compare those who received lottery winnings of between £1,000 and £120,000 to two control groups, those with smaller wins and those with no wins. The study finds a statistically significant effect of 1.4 GHQ-12 points after two years (compared to the average drop of 5 points associated with widowhood). An important caveat is the small number of treated cases: there are only 137 observations with large lottery wins.

In Van Den Berg *et al.* (2006) the state of the economy during infancy is shown to have long-term consequences for mortality rates in this inventive study of those born in the nineteenth century in the Netherlands. The analysis finds a significant effect of the stage of the business cycle (boom or bust) at the time of birth on individuals' subsequent age of death. Data from the Historical Sample of the Netherlands (HSN), drawn from registers of births, marriages and deaths, covers 14,000 individuals born between 1812 and 1912 with follow-up to 2000. This data is merged with macroeconomic time series that are used to identify the phases of the business cycle. Macroeconomic conditions early in life are used as

an instrument for socioeconomic conditions in infancy in order to avoid the problems of unobservable heterogeneity bias that plague cross-section comparisons. The impact of early life conditions is analyzed nonparametrically, comparing those born in booms and recessions, and through duration analysis of the individual mortality data.

12.2.2.3 Educational reforms

Lleras-Muney (2005) shows how historical changes in the US educational system can be used as a natural experiment, based on a discontinuity design, to identify the effect of education on adult health. The estimated effect is larger than previous studies have suggested, with the magnitude of the instrumental variables estimate of the local average treatment effect three times larger than the OLS estimate. The natural experiment is based on changes across states in compulsory schooling and child labor laws between 1915 and 1939. Identification stems from variation over states and across time in the age at which children had to enter school, the age at which they could leave school and get a work permit, and whether those with work permits had to continue in school part time. Estimation uses a regression discontinuity design, which attributes any jumps associated with school leaving age to the policy effect. This is applied using a linear probability specification for deaths as a function of years of schooling. Synthetic cohorts are constructed from successive US Censuses (1960, 1970 and 1980) to select those who were aged 14 between 1915 and 1939 and to follow-up subsequent mortality rates. These are synthetic in the sense that they do not follow the same individuals and are based on gender, birth cohort and state of birth.

Educational reforms are also used as a natural experiment in Arendt (2005). In this case the analysis focuses on Denmark and reforms in 1958 that removed formal tests before middle school, and 1975, that increased the compulsory minimum school leaving age. Data are taken from the Danish National Work Environment Cohort Study (WECS), with two waves in 1990 and 1995, and covers workers aged 18–59 in 1990. The impact of years of schooling on outcomes later in life is estimated using two-stage conditional maximum likelihood (2SCML) estimates, allowing for a random individual effect, for self-reported health. Models are also estimated for body mass index and for an indicator of never having smoked. The latter is included for comparison as, for most people, it is determined while they are still in education. The impact of education on health is amplified when instruments are used, but, at the same time, the standard errors are inflated so that exogeneity is not rejected. However, tests suggest that there may be a problem of weak instruments, as the reforms have low explanatory power in the reduced form equations.

12.2.2.4 Health policies and reforms

Bleakley (2007) is a good example of combining a natural experiment with a long-term follow-up to explore the economic consequences of a public health

intervention aimed at children. A program aimed at the eradication of hookworm is shown to lead to a long-term gain in the income of beneficiaries. Areas with greater scope for benefiting, due to higher levels of hookworm infection, show greater contemporaneous increases in school enrollment and attendance and in literacy among children. The natural experiment is the Rockefeller Sanitary Commission's (RSC's) funding of treatment and education programs to eradicate hookworm in the Southern US, which took place around 1910–15. This policy intervention was implemented over a well-defined and relatively short period. Geographic differences in infection rates prior to the intervention can be used to formulate and identify a treatment/control design, estimated using difference-in-differences. Data on long-term consequences for the cohorts exposed to the eradication program are obtained from the US Census available through the Integrated Public Use Micro Sample (IPUMS).

In 1966 the Ceauşescu regime in Romania banned abortion and family planning. Birth rates doubled the following year. In Pop-Eleches (2006) this provides an interesting contrast to studies that have examined moves in the opposite direction in the United States. The raw data show an improvement in educational attainment and labor market outcomes associated with the ban, but these results are reversed by allowing for compositional changes in the type of families having children. The findings are explained by the fact that affluent urban women were more likely to have abortions and use contraception before the ban. Data are drawn from a 15% sample of the 1992 Romanian census and focus on children born between January and October 1967. There is a spike in births between July and October due to the ban, but all of these children entered school in the same year and experienced the same overcrowding effect. Although it is not labeled as such, the paper uses a discontinuity design estimating a simple difference equation that includes a dummy variable for the period after the policy. Additional covariates are included, but there is no control group and identification relies on any sudden changes in outcomes for those born just before or just after the ban.

Lakdawalla *et al.* (2006) present a careful application of the method of instrumental variables, based on state-level variation in Medicaid eligibility in the US, which shows that an unintended consequence of highly active antiretroviral therapy (HAART) is to increase risky sexual behavior among patients who are HIV+. Simple correlations show lower sexual activity among those who are HIV+, but this is because of the debilitating effects of the disease and does not show the causal effect of treatment. Panel data on HIV+ patients in care are taken from the HIV Costs and Sevices Utilization Study (HCSUS) for the period 1996–98. The outcome of interest is the number of sex partners of the previous six months and the treatment is HAART, which is inferred from records of medications. Simple, unconditional estimates do not show a difference in sexual activity. But when treatment is instrumented by variation in the eligibility rules for Medicaid across states a positive effect emerges. The validity of these instruments is checked by examining the reduced form association between Medicaid eligibility and sexual activity prior to

the introduction of HAART in 1996. There is no association pre-1996, but there is post-1996.

12.2.3 Natural controls

12.2.3.1 Families

Auld and Sidhu (2005) present evidence that around a quarter of the association between schooling and health is attributable to variation in cognitive ability and that the causal effect of schooling on health is concentrated among those with low levels of education. Estimates that allow for both schooling and health to be influenced by a common "third factor" diminish the effect of schooling on health except for those individuals with no greater than high school education. The models are estimated using the 1979 and 2000 US National Longitudinal Survey of Youth (NLSY). The validity of the estimated causal effects relies on the use of parental education as a source of independent variation, using variation in the individual's own education that is associated with their parents' educational achievements.

Siblings who are brought up together share common background characteristics which may be unobserved and also influence the treatments and outcomes of interest to researchers. Using within-sibling variation can control for these factors. Holmlund (2005) shows how variation within biological sisters can be used to assess the long-term consequences of teenage pregnancy for educational outcomes. The siblings approach and standard cross-section methods produce similar results providing heterogeneity within the family is controlled for. The potential for selection bias is that teenage mothers may have family backgrounds that would lead to poorer outcomes irrespective of an early pregnancy. Variation within biological sisters can be used to control for these "family effects." However, within-sibling variation will not deal with heterogeneity within the family and the study controls for observable pre-motherhood school performance, measured by the grade point average (GPA) from primary school, to try and control for this. Data are taken from a 20% sample of each cohort born in Sweden between 1974 and 1977, with the population register used to identify siblings.

Sibling fixed effects play a role in Currie and Stabile's (2006) study of the impact of Attention Deficit Hyperactivity Disorder (ADHD) on educational outcomes. Within-sibling variation is used to control for omitted variables at the level of the family. Data from the Canadian National Longitudinal Survey of Children and Youth (NLSCY) and the US NLSY are used. ADHD symptoms are based on parental reports and are recorded in 1994 in the Canadian data and between 1990 and 1994 in the US data. Educational outcomes include the repetition of grades, enrollment in special education, reading and math tests and delinquency. These are measured in 1998 for Canada and 1998–2000 for the US. The study finds large effects, relative to chronic physical conditions, and for low levels of ADHD symptoms in cases that would not usually receive treatment. The results for Canada and the US are similar to each other.

12.2.3.2 Twin studies

Within-sibling variation can control for common factors relating to family background, upbringing and environment. But siblings are born at different times and they have different genes. Twin studies take the notion of natural controls a step further by removing the genetic variation (at least for monozygotic twins). In the context of research on birth outcomes, using twins means that the siblings share the same pregnancy and are born at the same time. This controls for unobservable characteristics of their mother and her behavior and environment during the pregnancy. Almond *et al.* (2005) show that using variation in birth weight between twins leads to lower estimates of the impact of low birth weight (LBW), defined as less than 2,500 g, on short-run outcomes than is typically found in cross-section studies. They find heterogeneity in the effects of LBW, suggesting a highly nonlinear relationship. Two identification strategies are adopted. The first exploits variation "within mothers" by comparing outcomes for heavier and lighter infants for all twins born in the US between 1983 and 2000. Using this within-variation should control for all observed and unobserved characteristics of the mother. The second exploits variation "between mothers" in a complementary analysis of maternal smoking and singleton births. The strategy here is to attribute the whole effect of smoking to LBW and compare it with the twins estimates. Data are drawn from two sources: linked birth and infant deaths data from the US National Center for Health Statistics (NCHS), covering the population of US twins, and data from hospital discharge abstracts from the Healthcare Cost and Utilization Project (HCUP) state inpatient database. There are some caveats to bear in mind with this study. Some useful descriptive analysis presented in the paper highlights the inherent differences between twins and singletons (the latter are more healthy). This raises questions about external validity of analysis based on samples of twins rather than the general population. The study only uses short-run outcomes and may miss long-term consequences (see the studies by Behrman and Rosenzweig, 2004, and Black *et al.,* 2007, below). For fraternal twins, genetic differences may mean that changes in birth weight may be associated with changes in unobservables (there is evidence of a negative correlation of birth weight with congenital defects) and the fixed effects approach may overestimate the impact of birth weight. Also the data do not distinguish between monozygotic (identical) and dizygotic (fraternal) twins.

In Behrman and Rosenzweig (2004), variation between monozygotic twins provides a way of identifying the impact of birth weight on long-term outcomes, such as measures of adult health, anthropometric measures and adult schooling and earnings. Increased birth weight, as measured on the birth certificate, increases schooling among adults and this effect is underestimated by 50% when cross-section variation is used to identify the effect. Data were collected through a survey mailed to monozygotic twins on the Minnesota Twins Registry, the largest birth certificate based registry in the US. The identification strategy assumes that difference in birth weight reflects random differences in nutrition in the womb that are uncorrelated with individual endowments and therefore avoids selection

bias. The estimates allow for heterogeneous treatment effects and show an impact on labor market outcomes for low birth weight, but not for high. The implications of the US results for worldwide health inequalities are explored at the end of the paper.

Black *et al.* (2007) use Norwegian registry data and, like Behrman and Rosenzweig (2004), they use twins to investigate the impact of low birth weight on long-term socioeconomic outcomes rather than just short-run outcomes. Within-twins fixed effects estimates are shown to be significant and similar to standard least squares estimates for long-run outcomes, such as height, IQ , earnings and education, while the estimates for short-run outcomes are smaller for the twins data, as suggested by Almond *et al.* (2005). The analysis is made possible by the richness of the data, which use personal identifiers to link all Norwegian births between 1967 and 1997, as recorded in the birth registry, with other registry data for those aged 16–74 in the period 1986–2002. The register data is augmented with military records and a survey of twins that identifies zygocity. Within-twin variation is used to capture unobservable socioeconomic and genetic factors that may confound the causal effect of birth weight. This means that identification stems from differences in nutrition in utero (resulting from different placentas for fraternal twins and different positioning on the placenta for monozygotic). Birth order is included as a control. The robustness of the findings is assessed by separate analyses for mothers who have more than one singleton birth, allowing for mother fixed effects rather than pregnancy fixed effects. To assess the role of zygocity the sample is restricted to same-sex twins. The sub-sample where there is survey data on zygocity is also used. The findings are robust, but reveal interesting evidence that those who participate in twins studies are a self-selected sample. Also it should be borne in mind that selection into the sample of registry data for long-run outcomes may be affected by infant mortality. Finally, there are substantial differences between twins and singletons in terms of factors, such as gestation and the age of their mothers, and twins usually appear in the lower part of the distribution of birth weights.

12.2.3.3 Communities

Many studies use variation within groups, communities or geographic areas to control for unobservable factors that are common to all those within the community or locality. For example, Wagstaff (2007) controls for village effects in a study of the impact of health shocks, such as the death of a working-age member of the household, on incomes of urban and rural households in Vietnam based on the Vietnam Living Standards Survey (VLSS). Arcidiacono and Nicholson (2005) find that adding fixed effects for individual medical schools eliminates the positive peer effects that appear to exist when selection bias is not taken into account. The inclusion of school effects means that the impact of peer effects on a student's achievements and on their choice of specialty are identified by variations over time within schools in the ability and preferences of students. The aim is to separate correlated effects from exogenous peer effects. The study relies on data for graduates from US Medical Schools over a relatively short period, 1996–98, so identification may be limited by a lack of variation over time. Currie and Neidell (2005) use

variation within Californian zip code areas to identify the impact of air pollution on infant mortality. They find a statistically significant effect even at low levels of air pollution. The impact of this effect is quantified: it is estimated that reduction in pollution in California over the 1990s saved around 1,000 infant lives. The study takes data from the California birth cohort files and matches it to EPA data on air quality - specifically measures of carbon monoxide, ozone and particulate matter (PM10) – and information on weather patterns from the National Climatic Data Center. A linear model is used to approximate the discrete hazard function for infant deaths and month, year and zip code fixed effects are included in the model, this relies on variation within cells of observations defined by month, year and locality. The study complements the natural experiment presented by Chay and Greenstone (2003) that is described above.

12.2.4 Anti-tests

One way to assess the robustness of an identification strategy is to find an anti-test (or placebo test). Anti-tests provide counter-evidence by applying a model or identification strategy in a context where no effect should be detected. If an apparent "effect" is found then the validity of the identification strategy must be called into question.

For many years the standard empirical strategy to test for the phenomenon of supplier-induced demand (SID) in medical care has been to include a measure of the supply of doctors – usually the physician density, measuring the number of doctors in a locality per head of population – in empirical models of health care utilization or expenditure. This strategy is plagued by omitted variable bias and identification problems. To assess the robustness of the approach, Dranove and Wehner (1994) apply the physician density strategy using the obstetrician/population ratio and the volume of births as the measure of utilization. The physician density test shows evidence that the number of births (and hence pregnancies) is "supplier induced": casting obvious doubt on the reliability of the approach. However, failure of the methodology does not imply rejection of SID. For example, Gruber and Owings (1996) find evidence of increased C-section rates in response to a fall in fertility in the US between 1970 and 1982: a shift by obstetricians to more lucrative procedures in response to economic pressures.

In their "addiction to milk" paper, Auld and Grootendorst (2004) use non-addictive substances, such as milk, eggs and oranges, to construct an anti-test and demonstrate that evidence for the rational addiction hypothesis based on aggregate data may be spurious. Numerous studies have applied the canonical rational addiction equation of Becker *et al.* (1994) to substances such as alcohol, cigarettes and cocaine, and claim to have found support for rational addiction; but Auld and Grootendorst (2004) show that these findings are mimicked when the model is applied to Canadian aggregate data for non-addictive substances. Monte Carlo simulations show that spurious evidence is likely when the time series data exhibit high serial correlation, when prices are poor instruments, when overidentified instrumental variable estimators are used, or when theoretical restrictions are imposed by fixing the implied discount rate in the model.

The idea of an anti-test may provide a useful strategy as part of a robustness/sensitivity analysis. A good example of this is Galiani *et al.*'s (2005) evaluation of the impact of the privatization of local water services on child mortality in Argentina. They adopt two strategies for assessing the reliability of their difference-in-differences approach that can both be interpreted as anti- or placebo tests. The first, which is a good practice to adopt in any difference-in-differences analysis, is to estimate a placebo regression: the model of interest is estimated using only data from the pre-treatment period, but including an indicator of those cases that will go on to be treated. If this indicator of hypothetical treatment is significant it is a sign that the treated and controls are not comparable and that the "parallel trends" assumption required for difference-in-differences analysis is not valid. The second strategy adopted by Galiani *et al.* (2005) is that, as well as measuring deaths from infectious and parasitic diseases, they include measures of deaths from causes unrelated to water quality. The fact that they detect a reduction for the former but not for the latter creates confidence in their difference-in-differences identification strategy.

12.3 Data and measurement issues

12.3.1 Administrative data or sample surveys

Much of the applied work done by health economists uses social surveys. These are often designed to provide representative random samples of the underlying population. Most often the sampling follows a multi-stage design with clustered and/or stratified sampling (see, e.g., Jones *et al.,* 2007b). Data may be collected by face-to-face interviews or postal, telephone or web-based questionnaires, and in health surveys this is often supplemented by clinical tests and measurements. Many surveys are one-off cross-sections, but increasingly researchers have turned to longitudinal, or panel, surveys which give repeated observations on the units of interest, whether they be individuals, households or organizations. Sample surveys are the mainstay of microeconometric research and some of the more popular datasets are summarized in Table 12.1.

In health economics, administrative datasets often prove more useful and reliable than social surveys. Administrative datasets include sources, such as tax records, reimbursement and claims databases, and population registers of births, deaths, cancer cases, HIV/AIDS cases, unemployment, etc. (see, e.g., Aakvik *et al.,* 2003; Aakvik *et al.,* 2005; Atella *et al.,* 2006; Black *et al.,* 2007; Chalkley and Tilley, 2006; Dano, 2005; Dranove *et al.,* 2003; Dusheiko *et al.,* 2004, 2006, 2007; Farsi and Ridder, 2006; Gravelle *et al.,* 2003; Ho, 2002; Lee and Jones, 2004, 2006; Marini *et al.,* 2008; Martin *et al.,* 2007; Propper *et al.,* 2002, 2004, 2005; Rice *et al.,* 2000; Seshamani and Gray, 2004). These datasets are collected primarily for administrative purposes and are made available to researchers for secondary analysis. Some countries allow comprehensive linkage of different sources of administrative data based on personal identification numbers (see, e.g., Black *et al.,* 2007). Administrative datasets are typically large, often with millions rather than thousands of

observations, and are comprehensive, often providing observations on a complete population rather than a random sample. They tend to be less prone to unit and item non-response than survey data and may give better coverage of hard-to-reach groups of the population and the socially disadvantaged. Also they tend to be less affected by reporting bias, but are still vulnerable to data input and coding errors. Given their primary purpose, administrative datasets are not designed by and for researchers. This means they may not contain all of the variables that are of interest to researchers, such as socioeconomic characteristics, and many different sources may have to be combined to produce a usable dataset. In some cases, sources of administrative data may be combined and made available with researchers in mind. For example, the Oxford Record Linkage Study (ORLS), used by Seshamani and Gray (2004), is a longitudinal dataset that links statistical abstracts for hospital inpatient and day cases to birth and death certificates for people living in the Oxford region of England. It provides 10 million records for over 5 million people between 1963 and 1999.

Dusheiko *et al.*'s (2004) study of the impact of practice budgets for GPs on hospital waiting times in the English National Health Service (NHS) provides an example of the complex and painstaking process that is often required to link administrative data. Information on waiting times was obtained from the Hospital Episode Statistics (HES) for 1997/98 to 2000/01. HES is an annual database of hospital inpatient activity, including day cases, with more than 10 million records per year. Dusheiko *et al.* extracted information on the waiting times for over 5 million finished consultant episodes and linked average waiting times to GP practices. Information on practice populations was obtained from the Primary Care Trust (PCT) database at the National Primary Care Research and Development Centre (NPCRDC: http://www.primary-care-db.org.uk). Practice characteristics, such as the GP's age and sex, qualifications, size of practice, etc., were obtained from the Prescription Pricing Authority, the Department of Health's Organisational Codes Service and their General Medical Statistics, along with the NPCRDC database. Patient characteristics for each practice were obtained from the 1991 Census and components of the Index of Multiple Deprivation, with these small area data mapped to GP practices. Finally, supply side factors, such as distances to hospitals, were obtained from the Department of Health's Allocation of Resources to English Areas (AREA) project.

Some of the key administrative datasets that have been used in health economics are summarized in Table 12.1.

12.3.1.1 Non-response and attrition

Non-response and attrition are a common feature of longitudinal survey data. Nicoletti and Peracchi (2005) list possible reasons for non-response: these include demographic events, such as death; movement out of the scope of the survey, such as institutionalization or emigration; refusal to respond at subsequent waves; absence of the person at the address, along with other types of non-contact. Jones *et al.* (2006) investigate health-related non-response in the first 11 waves of the BHPS and the full eight waves of the European Community Household Panel

(ECHP). They explore its consequences for dynamic models of the association between socioeconomic status and self-assessed health (SAH). Descriptive evidence shows that there is health-related non-response in the data, with those in very poor initial health more likely to drop out, and variable addition tests provide evidence of non-response bias in the panel data models of SAH. Nevertheless a comparison of estimates – based on the balanced sample, the unbalanced sample and corrected for non-response using inverse probability weights – shows that, on the whole, there are not substantive differences in the average partial effects of the variables of interest.

Inverse probablity weights are used to attempt to control for attrition: this works by estimating separate probit equations for whether an individual responds or does not respond at each of the waves of the panel. Then the inverse of the predicted probabilities of response from these models are used to weight the contributions to the log likelihood function in the pooled probit models for SAH. The rationale for this approach is that a type of individual who has a low probability of responding represents more individuals in the underlying population and therefore should be given a higher weight. The appropriateness of this approach relies on the assumption that non-response is ignorable conditional on the variables that are included in the models for non-response ("selection on observables"). If this assumption holds then inverse probability estimates give consistent estimates. The findings in Jones *et al.* (2006) and the earlier work by Contoyannis *et al.* (2004b) suggest that, while health-related non-response clearly exists, on the whole it does not appear to distort the magnitudes of the estimated dynamics of SAH and the relationship between socioeconomic status and SAH. Similar findings have been reported concerning the limited influence of non-response bias in models of income dynamics and various labor market outcomes and on measures of social exclusion, such as poverty rates and income inequality indices.

12.3.2 Health outcomes

12.3.2.1 Self-reported data

Self-assessed health is often included in general social surveys. For example, in the BHPS, SAH is an ordered categorical variable based on the question: "Please think back over the last 12 months about how your health has been. Compared to people of your own age, would you say that your health has on the whole been excellent/good/fair/poor/very poor?" The validity of self-reported measures of health has caused considerable debate. As a self-reported subjective measure of health, SAH may be prone to measurement error. General evidence of non-random measurement error in self-reported health is reviewed in Currie and Madrian (1999) and Lindeboom (2006).

Self-assessed health is not the only source of concern with self-reported data. Baker *et al.* (2004) use careful record linkage to check for flaws in self-reported data on specific chronic conditions. Survey data from the Canadian National Population Health Survey for 1996–97 are linked to ICD-9 (International Classification of Diseases – ninth revision) codes for Ontario residents from administrative data on

utilization of services for the Ontario Health Insurance Plan (OHIP) for the survey year and the five previous years. Linear probability models are used to analyze the probabilities of false negatives and false positives in the self-reported data. This shows that reporting errors are associated with individual characteristics. The data reveal a large number of false negatives, although the probability declines for those with more recorded medical treatments, suggesting that this reflects undiagnosed conditions and lack of information among respondents. The number of false positives is much smaller, but there is some evidence of "justification bias": those not in work are more likely to report false positives for conditions, such as hypertension, ulcers and bronchitis.

A more favorable view of self-reported measures emerges in the work of Benitez-Silva *et al.* (2004). They take the relatively small sub-sample of respondents to the first three waves of the US Health and Retirement Survey (HRS) who had applied for disability benefit from the Social Security Administration (SSA) and compare their self-reported disability to the outcome of the SSA decision. In this case the SSA decision to award benefits is used as an objective indicator to assess the reliability of the self-reported data on limitations that prevent work. Conditional moment tests for whether self-reported disability is an unbiased indicator of the SSA decision suggest that a large fraction of this population report their health accurately. Unlike Baker *et al.* (2004), this study relies on information collected within the HRS rather than matching the survey data with administrative records. McGarry (2004) adopts another strategy to get around the problem of "justification bias." Rather than using data on actual retirement, she uses information from the HRS on the subjective expected probability of retirement by age 62, which is collected while people are still in work. Using this measure she finds strong effects of health on expected retirement age.

It is sometimes argued that the mapping of health into SAH categories may vary with respondent characteristics. This source of measurement error has been termed "state-dependent reporting bias" (Kerkhofs and Lindeboom, 1995), "scale of reference bias" (Groot, 2000) and "response category cut-point shift" (Murray *et al.* 2001; Sadana *et al.* 2000). Regression analysis of SAH is often done by specifying an ordered probability model, such as the ordered probit or logit. Then the symptoms of measurement error can be captured by making the cut-points dependent on some or all of the exogenous variables used in the model and estimating a generalized ordered model. This requires strong *a priori* restrictions on which variables affect health and which affect reporting in order to separately identify the influence of variables on latent health and on measurement error. Attempts to surmount this fundamental identification problem include modeling the reporting bias based on more "objective" indicators of true health (Kerkhofs and Lindeboom, 1995; Lindeboom and Van Doorslaer, 2004) and the use of "vignettes" to fix the scale (Das and Hammer, 2005; Murray *et al.,* 2001). Lindeboom and Van Doorslaer (2004) analyze SAH in the Canadian National Population Health Survey and use the McMaster Health Utility Index (HUI-3) as their objective measure of health. They find evidence of reporting bias with respect to age and gender, but not for income, education or linguistic group.

A similar identification strategy to Lindeboom and Van Doorslaer (2004), that relies on objective measures capturing all of the genuine variation in health, is adopted by Etilé and Milcent (2006), who estimate generalized ordered probit models with a four-category measure of SAH. They construct synthetic measures of objective health from a latent class analysis of a set of self-reported indicators, such as activities of daily living (ADLs) and body mass index (BMI). The latent class analysis is used to condense the sample into six classes and indicators for these classes are included in the ordered probit model. This works by constructing classes such that the underlying health indicators are independent of each other, conditional on class membership. Latent class models are presented as an alternative to the grade of membership approach that has been used in some earlier work (see, e.g., Lindeboom *et al.,* 2002). Estimates on a sample of 2,956 individuals aged under 65 from the French Enquête Permanente sur les Conditions de Vie des Menages (EPCV) survey show evidence of reporting bias and, unlike Lindeboom and Van Doorslaer (2004), there is evidence that this is related to income. Etilé and Milcent's (2006) findings suggest a concave relationship between health and income in terms of health production and convexity with respect to reporting, with overoptimism among the rich and overpessimism among the poor. They conclude that the problems of reporting bias can be minimized by collapsing the four-point scale into a binary measure of poor health.

Jurges (2007) focuses on cross-country differences in reporting of SAH as measured for those aged over 50 in the ten countries covered by the first wave of the Survey of Health, Ageing and Retirement in Europe (SHARE). Generalized ordered probit models are used to regress SAH on a set of objective measures, such as grip strength, walking speed and BMI, to get a set of disability weights. The average thresholds across the SHARE countries are then used to reclassify the reported data, assuming that the disability weights are constant across countries. The variation in SAH is decomposed into the component that is explained by the objective measures and the component attributed to reporting bias. The findings suggest that those in the Danish and Swedish samples overrate their health, while those in Germany underrate their health. For Austria and Greece there is little bias.

12.3.2.2 Anthropometric measures

Anthropometric measures have long played a role in studies of developing countries, especially those focused on child health issues. With the growing problem of adult and childhood obesity in more affluent nations, they are increasingly being used in that context as well. Typical anthropometric measures are height and weight, which may be self-reported or measured by a professional; infant length for children aged under two; demi-span, which is based on the length of an outstretched arm and is used among older populations who may have difficulties standing straight; the waist-to-hip ratio; and BMI, which is the most commonly used indicator of obesity. BMI is calculated as weight in kilograms divided by height in meters squared, with a BMI of 30 or greater indicating obesity and 25–30 indicating overweight. The confounding effect of levels of muscle development means

that measures of body fat are sometimes used instead of BMI. The height-for-age z-score standardizes a child's measured height using the median (or mean) and standard deviation for children of the same age and sex from a reference population, such as the US National Center for Health Statistics reference population of well-nourished American children (e.g., Duflo, 2000). Height is also compared to a standard distribution to construct measures of stunting (e.g., Gertler, 2004). For example, Chen and Zhou (2007) use height to measure the long-term health consequences of childhood exposure to the 1959–61 famine in China, which is estimated to have caused 15–30 million excess deaths. They adopt a difference-in-differences approach that exploits regional differences in exposure to the famine.

Anthropometric measures may also play a role as biomarkers (discussed in more detail below). For example, height and weight can be used as predictors of mortality, stroke and cardiovascular disease and the waist-to-hip ratio is a predictor for hypertension, late-onset diabetes, cardiovascular disease, stroke and some forms of cancer.

12.3.2.3 Biomarkers

Biological markers, or biomarkers, are likely to play an increasing role in future research in health economics as they become incorporated into an increasing range of datasets, including longitudinal datasets, such as the US Health and Retirement Survey (HRS), the English Longitudinal Survey of Ageing (ELSA) and the planned UK Longitudinal Household Study. This trend is likely to be enhanced by the availability of DNA information and genetic screening, which provide greater potential to control for individual heterogeneity. Biomarkers are biological or physiological measures that indicate the presence of a disease or the propensity to develop a disease. They can be used to identify risk factors and as objective measures of health that avoid contamination by reporting bias (see, e.g., Adda and Cornaglia, 2006; Banks *et al.*, 2006; Currie *et al.*, 2007).

Biomarkers for cardiovascular disease include elevated blood pressure and variability in the heart rate. Metabolic biomarkers include serum HDL (high-density lipoprotein) and total cholesterol and triglycerides, which are predictors of heart disease; fibrinogen, which is linked to blood clotting and the risk of heart disease; and glycated haemoglobin, which is a proxy indicator for diabetes. Biomarkers linked to the immune system include interleukin-6 (IL-6), which is a predictor of Alzheimer's disease, arthritis, diabetes and osteoporosis; C-reactive protein (CRP), which indicates lupus, pneumonia, rheumatoid arthritis, rheumatic fever and tuberculosis; ferritin and hemoglobin, which indicate iron deficiency; serum retinol, which indicates vitamin A deficiency. Biomarkers linked to hormonal indicators of stress (HPA axis) include cortisol, adrenocorticotropic hormone (ACTH) and dehydroepiandrosterone-sulphate (DHEA-S). Biomarkers linked to the sympathetic nervous system include norepiphrenine, which is associated with longevity, and epiphrenine (adrenaline), which is linked to cognitive decline and longevity. Biomarkers may also be used as objective indicators of physical functioning and

health limitations; these include lung function tests, such as forced expiratory volume (FEV) and forced vital capacity (FVC), as measured by a spirometer, and grip strength, measured by a gripometer.

Datasets which contain biomarkers and that have been used in economic research include ELSA, the UK Health and Lifestyle Survey (HALS), the US Health and Retirement Survey (HRS), the Health Survey of England (HSE), the UK National Child Development Study (NCDS) and the more recent cohort studies, the US National Health and Nutrition Examination Surveys (NHANES), SHARE, and the Whitehall Study of English civil servants. To take ELSA as an example: participants in the study are visited by a registered nurse who takes measurements of blood pressure; lung function; height, weight and the waist-to-hip ratio; grip strength, as a measure of upper body strength; a measure of lower body strength, based on standing up from a chair without using the arms; a saliva sample, that is used to measure cortisol, which is a marker for stress; and a blood sample, which is used to test total cholesterol, HDL cholesterol, fibrinogen, CRP, ferritin, glycated haemoglobin and haemoglobin. The blood samples from ELSA and from wave 7 of the NCDS will allow DNA to be extracted. DNA can also be collected using mouth or cheek swabs (as in the US AddHealth Survey).

Banks *et al.* (2006) study the socioeconomic gradient in health in the UK and the US and they compare both self-reported outcomes and objective outcomes based on biomarkers. To do this they use the ELSA data for the UK and the HRS and NHANES data for the US. The self-reported measures include the general question on SAH as well as self-reported indicators of chronic conditions, such as diabetes, hypertension and cancer. The biomarkers are glycosated hemoglobin levels above 6.5%, as a marker for diabetes; systolic blood pressure over 140 mm Hg, and diastolic blood pressure over 90 mm Hg, as a measure of hypertension; CRP greater than 3 mg/L, as a marker of high risk of arteriosclerosis; fibrinogen over 400 mg/dl, as a marker for cardiovascular disease, and HDL cholesterol over 40 mg/dl, as an indicator of reduced risk of coronary heart disease. Banks *et al.* (2006) find that, on average, respondents in the US reported better SAH, but the opposite holds true for the biomarkers. Their results show a strong socioeconomic gradient in self-assessed health, self-reported diseases and in the biomarkers. The gradient appears strongest for the biomarkers. Comparing the self-reported data with the biomarkers allows a measure of the socioeconomic gradient in undiagnosed cases. A gradient is apparent for diabetes, but not for hypertension.

A novel feature of Adda and Cornaglia (2006) is the use of biomarkers, in this case cotinine, within an economic study of smoking. Cotinine is a metabolite of nicotine and can be used as a biomarker for levels of tobacco consumption that is not contaminated by problems of measurement error, such as recall bias and deliberate deception, that may affect self-reported consumption. The study shows that smokers engage in compensatory behavior, increasing their intensity of smoking and offsetting the impact of tobacco tax increases. Data on cotinine is collected from saliva samples as part of the repeated cross-section data in the NHANES for 1999–2000. Evidence based on the biomarker is contrasted with

self-reported consumption. Cotinine has another advantage in studies of smoking and health as it provides a way of measuring passive smoking, especially among children.

12.3.3 Modeling costs and expenditure

Individual-level data on medical expenditures and costs of treatment is typically distinguished by a spike at zero, if there are non-users in the data, and a strongly skewed distribution with heavy tails. This kind of data is most often used in two areas of application: risk adjustment and cost-effectiveness analysis. In risk adjustment the emphasis is on predicting the treatment costs for particular types of patient, often with very large datasets. Cost-effectiveness analyses tend to work with smaller datasets and the scope for parametric modeling may be more limited (Briggs *et al.,* 2005). In the context of clinical trials, attention has focused on methods to deal with censoring of cost data due to limited follow-up (e.g., Baser *et al.,* 2006; Raikou and McGuire, 2004, 2006).

The presence of a substantial proportion of zeros in the data has typically been handled by using a two-part model, which distinguishes between a binary indicator, used to model the probability of any costs, and a conditional regression model for the positive costs. OLS applied to the level of costs (y) can perform poorly, due to the high degree of skewness and excess kurtosis, and the positive observations are often transformed prior to estimation. The most common transformation is the logarithm of y, although the square root is sometimes used as well. As the policy interest typically focuses on modeling costs on the original scale, the regression results have to be retransformed back to that scale. This weakens the case for working with transformed data and, in particular, problems arise with the retransformation if there is heteroskedasticity in the data on the transformed scale (Manning, 1998; Manning and Mullahy, 2001; Mullahy, 1998). Ai and Norton (2000) provide standard errors for the retransformed estimates when there is heteroskedasicity.

More recently, attention has shifted to other estimators. Basu *et al.* (2004) compare log-transformed models to the Cox proportional hazard model. Gilleskie and Mroz (2004) propose a flexible approach that divides the data into discrete intervals then applies discrete hazard models, implemented as sequential logits. Conway and Deb (2005) use a finite mixture model. Cooper *et al.* (2007) use hierarchical regressions implemented using Bayesian Markov chain Monte Carlo (MCMC) estimation. But the dominant approach in the recent literature has been the use of generalized linear models (GLMs) (e.g., Buntin and Zaslavsky, 2004; Manning, 2006; Manning *et al.,* 2005; Manning and Mullahy, 2001). The GLM specifies a link function for the relationship between the conditional mean, $\mu = E(y|x)$, and a linear function of the covariates and specifies the form of the conditional variance, $V(y|x)$, usually assuming that it can be specified as a simple function of the mean. The models are estimated using a quasi-likelihood approach derived from the quasi-score or "estimating equations." The most popular specification of the GLM for costs has been the log-link with a gamma error (Blough *et al.* 1999; Manning *et al.,* 2005; Manning and Mullahy, 2001, 2005). Cantoni and Ronchetti (2006) propose a

robust variant of GLM that is less sensitive to outliers. In response to the problem of selecting the appropriate link and variance functions, Basu and Rathouz (2005) suggest a flexible semiparametric extension of the GLM model. Their model incorporates a Box–Cox transformation into the link function which includes the log-link as a special case along with other power functions of y. The model, which is labeled the extended estimating equations (EEE) approach, also allows for flexible specifications of the variance using the power variance and quadratic variance families to nest common distributions, such as the Poisson, gamma, inverse Gaussian and negative binomial. Basu *et al.* (2006) apply the EEE method to claims data on the incremental costs associated with heart failure.

12.4 Methods for dealing with unobserved heterogeneity and dependence

12.4.1 Deviations and conditional estimates

Consider a linear panel data regression model with repeated measurements ($t = 1, \ldots, T_i$) for a sample of n individuals ($i = 1, \ldots, n$):

$$y_{it} = x_{it}' \beta + u_i + \varepsilon_{it} . \tag{12.16}$$

Correlation between the unobservable individual effects (u) and the regressors (x) will lead to an omitted variable bias and inconsistent estimates of the βs. The individual effects can be swept from the equation by transforming variables into deviations from their within-group means, or by using orthogonal deviations, based on the mean of the future values of the variables. Applying least squares to the mean deviations gives the covariance or within-groups estimator of β. Similarly, the model could be estimated in first differences to eliminate the individual effects. Identification of β rests on there being sufficient variation over time so the estimators may perform poorly when there is insufficient variation.

Many of the outcomes used in health economics are binary or ordered categorical measures, such as SAH. Fixed effects panel data methods, that allow for a correlation between the individual effect and the regressors of the model, are not, however, readily available for categorical data due to the incidental parameter problem, which means that the individual effect cannot in general be swept out of the model by taking deviations. For binary data the problem can be surmounted by using the conditional fixed effects logit, which uses a sufficient statistic to eliminate the individual effect from the log-likelihood function (Chamberlain, 1980). In the case of the logistic regression, the within-individual sum of y_{it} is a sufficient statistic and conditional maximum likelihood (ML) estimates are consistent. Although the conditional logit provides consistent parameter estimates, the approach has practical drawbacks for the researcher. First, by only using observations that have within-individual variation in the outcome and in the regressors, the method often leads to a substantial reduction in sample size. Second, it is hard to calculate partial effects of a variable of interest due to the inherent lack of information on

the distribution of the individual heterogeneity, which is conditioned out of the model.

The conditional logit can be applied to ordered data by choosing a particular threshold value and collapsing the data into a binary measure. A recent extension of Chamberlain's model, the conditional ordered fixed effects logit, proposed by Ferrer-i-Carbonel and Frijters (2004), and applied to data on SAH by Frijters *et al.* (2005), suggests a method to reduce the drastic loss in the number of observations by identifying individual-specific threshold values to collapse the ordered dependent variable into a binary format. Das and van Soest (1999) combine adjacent categories so that the dependent variable is summarized as a binary variable, and then use conditional logits. They repeat this for all the possible combinations of adjacent categories to get a set of estimates of the parameters of interest. They then define a linear combination of these estimates, with the optimal weighting matrix used to compute the final estimate obtained from a minimum distance approach. Ferrer-i-Carbonel and Frijters (2004) also propose an estimator that collapses the ordered variable into a binary format, but they use an individual specific threshold value. To find this individual threshold, the authors maximize a weighted sum of log-likelihood functions, similar to Das and van Soest (1999), subject to the constraint that the sum of squared weights across all possible threshold values across all individuals must be equal to the number of individuals in the sample. The threshold is selected for which the analytical expected Hessian is minimized. However, this formulation of the estimator is highly computation intensive, a fact which makes its wider application less attractive. In a simplification of this estimator, one can simply use the within-individual means as a cut-off criterion.

12.4.1.1 Dynamic models

Even for linear models the within-groups estimator breaks down in dynamic models, such as:

$$y_{it} = \alpha y_{it-1} + u_i + \varepsilon_{it}\,. \tag{12.17}$$

This is because the group mean is a function of $\varepsilon_{it}$and ε_{it-1}. An alternative is to use the differenced equation:

$$\Delta y_{it} = \alpha \Delta y_{it-1} + \Delta \varepsilon_{it}, \tag{12.18}$$

in which case both y_{it-2} and Δy_{it-2} are valid instruments for Δy_{it-1} as long as the error term (ε_{it}) does not exhibit autocorrelation. Arellano and Bond (1991) proposed generalized method of moments (GMM) estimators for dynamic panel data models: linear models that can include leads and lags of the dependent variable as well as a fixed effect. Instruments are created within the model by first taking differences of the equation to sweep out the individual effect and then using lagged levels or differences of the regressors as instruments.

Bover and Arellano (1997) extend the use of GMM to dynamic specifications for categorical and limited dependent variable models, where it is not possible to take first differences or orthogonal deviations as the latent variable y^* is unobserved.

One of the advantages of using panel data is the possibility of accounting for the correlation amongst the effects and the explanatory variables. To allow for this correlation, Chamberlain (1984) suggested using a random effects approach and specifying a distribution for the individual effects conditional on the values of the explanatory variables at each wave of the panel. This specification may contain polynomial terms and interactions in the *x*s as well. Combining this with assumptions about the conditional expectation of the initial and final values of the latent variable allows the dynamic model to be solved out to give linear reduced forms for the latent variables at each wave of the panel. Estimates of the reduced forms will be sensitive to assumptions about the distribution of the error terms, the linearity of the expected value, and the conditional mean independence assumption. However, these hypotheses can be checked by specification tests at the level of the reduced form, which is easier to do than testing the dynamic specification. At the second stage, on the basis of the reduced form coefficients, the parameters of the underlying dynamic structural model can be derived using various estimators. The simplest is to apply the within-groups transformation to the dynamic model after replacing the latent variables by their predicted counterparts (Bover and Arellano, 1997). This two-step within-groups procedure is simple to apply, but provides inefficient parameter estimates. Chamberlain (1984) proposed a fully efficient minimum distance (MD) estimator. Instead of using Chamberlain's approach, Bover and Arellano (1997) propose a three-step within-groups GMM, which also facilitates tests of the over identifying restrictions.

12.4.2 Numerical integration and classical simulation-based inference

In panel data specifications, unobserved heterogeneity is often modeled as a random effect and "integrated out" of the log-likelihood function. Monte Carlo simulation techniques can be used to deal with the computational intractability of nonlinear models, such as panel and multinomial probit models. Popular methods of simulation-based inference include classical maximum simulated likelihood (MSL) estimation, and Bayesian MCMC estimation. This section introduces the classical approach (for a review of the methods and applications to health economics, see Contoyannis *et al.,* 2004a).

Numerical integration by quadrature works well with low dimensions, but computational problems arise with higher dimensions. Instead, Monte Carlo simulation can be used to approximate integrals that are numerically intractable. This includes numerous models derived from the multivariate normal distribution. Simulation approaches use pseudo-random draws of the evaluation points and computational cost rises less rapidly than with quadrature.

The principle behind simulation-based estimation is to replace a population value by a sample analogue. This means that laws of large numbers and central limit theorems can be used to derive the statistical properties of the estimators. The basic problem is to evaluate an integral of the form:

$$\int_u [h(u)]dF(u) = E_u [h(u)], \tag{12.19}$$

where $h(u)$ is a nonlinear function of the random vector u, which has a multivariate density $f(u)$and distribution function $F(u)$. This kind of expression arises in panel data models with random effects specifications and with autocorrelated errors and in multiple equation models with correlated unobservables. The integral can be approximated using draws from $f(u), u_r, r = 1, \ldots, R$, such that:

$$\int [h(u)]dF(u) \approx \frac{1}{R}\sum_{r=1}^{R}\left[h(u_r)\right]. \tag{12.20}$$

MSL is a simple extension of classical ML estimation and is useful in many cases where the log-likelihood function involves high dimensional integrals. The idea is to replace individual contributions to the sample likelihood function (L_i) with an average over R random draws:

$$l_i = \frac{1}{R}\sum_{r=1}^{R}\left[l(u_{ir})\right], \tag{12.21}$$

where $l(u_{ir})$ is an unbiased simulator of L_i.The MSL estimates are the parameter values that maximize:

$$Lnl_{=}\sum_{i=1}^{n}\left[Lnl_i\right]. \tag{12.22}$$

For likelihoods derived from the multivariate normal the Geweke–Hajivassilou–Keane (GHK) simulator is often used. In practice, Halton sequences or antithetics can be used to reduce the variance of the simulator (see Contoyannis *et al.,* 2004a, for details).

12.4.3 Bayesian MCMC

In Bayesian analysis a prior density of the parameters of interest, say $\pi(\theta)$, is updated using information from sample data. Given a specified sample likelihood for the observed data, $l(y|\theta)$, the posterior density of θ is given by Bayes' theorem:

$$\pi(\theta|y) = \frac{\pi(\theta)l(y|\theta)}{\pi(y)}, \tag{12.23}$$

where:

$$\pi(y) = \int \pi(\theta)l(y|\theta)d\theta. \tag{12.24}$$

The scaling factor $\pi(y)$ is known as the predictive likelihood and is used to compare models. It determines the probability that the specified model is correct. The posterior density $\pi(\theta|y)$ reflects updated beliefs about the parameters. Given the posterior distribution, a 95% credible interval can be constructed that contains the

true parameter with probability equal to 95%. Point estimates for the parameters can be computed using the posterior mean:

$$E(\theta|y) = \int \theta\pi(\theta|y)d\theta. \tag{12.25}$$

Bayesian estimates can be difficult to compute directly. For instance, the posterior mean is an integral with dimension equal to the number of parameters in the model. In order to overcome the difficulties in obtaining the characteristics of the posterior density, MCMC simulation methods are often used. The methods provide a sample from the posterior distribution and posterior moments and credible intervals are obtained from this sample (see Contoyannis *et al.,* 2004a, for details).

Bayesian MCMC simulation is built on the Gibbs sampling algorithm. To implement Gibbs sampling the vector of parameters is sub-divided into groups. For example, with two groups let $\theta = (\theta_1, \theta_2)$. Then, a draw from the joint distribution $\pi(\theta_1, \theta_2)$ can be obtained in two steps: first, draw θ_1 from the marginal distribution $\pi(\theta_1)$; then draw θ_2 from the conditional distribution $\pi(\theta_2|\theta_1)$. However, in many situations it is possible to sample from the conditional distribution, but it is not obvious how to sample from the marginal. The Gibbs sampling algorithm solves this problem by sampling iteratively from the full set of conditional distributions. Even though the Gibbs sampling algorithm never actually draws from the marginal, after a sufficiently large number of iterations the draws can be regarded as a sample from the joint distribution. There are situations in which it is not possible to sample from a conditional density, and hence Gibbs sampling cannot be applied directly. In these situations, Gibbs sampling can be combined with a so-called Metropolis step as part of a Metropolis–Hastings algorithm. In the Metropolis step, values for the parameters are drawn from an arbitrary density, and accepted or rejected with some probability. An attraction of MCMC is that latent or missing data can be treated as parameters to be estimated. Although this data augmentation method introduces many more parameters into the model, the conditional densities often belong to well-known families and there are simple methods to sample from them. This makes the use of MCMC especially convenient in nonlinear models, where the latent variables (y^*) can be treated as parameters to be estimated. Once the y^*s have been simulated, the estimation step involves the estimation of normal-linear models for y^*.

12.4.4 Finite mixture models

12.4.4.1 Latent class models

Recently the latent class framework has been used in models for health care utilization with individual data. Deb and Trivedi (2002) note that this framework "provides a natural representation of the individuals in a finite number of latent classes, that can be regarded as types or groups."[2] The segmentation can represent individual unobserved characteristics, such as unmeasured health status. The latent class (or finite mixture) framework offers a representation of heterogeneity, where individuals are drawn from a finite number of latent classes. For example, Conway and Deb (2005) show that allowing for heterogeneity between

"normal" and "complicated" pregnancies leads to evidence that early prenatal care is effective: on average, bringing the onset of prenatal care forward by one week increases birth weights by 30–60 g in normal pregnancies. Using a finite mixture model to capture the bimodality of the distribution of birth weights counteracts evidence from the standard 2SLS approach that the effects of prenatal care are weak or nonexistent. Estimates of the mixture model use observational data from the 1988 US National Maternal and Infant Health Survey, and the empirical findings are augmented by simulation results that show that the conventional findings could be attributable to the existence of a relatively small proportion (10–15%) of "complicated" pregnancies in the population.

To specify a finite mixture model, consider a vector of outcomes y_i that are observed for individual i: these may be repeated observations in a panel data model or related outcomes in a multiple equation model and they are linked by common unobservable heterogeneity. Then assume that each individual belongs to one of a set of latent classes $j = 1, \ldots, C$, and that individuals are heterogeneous across classes. Conditional on the observed covariates, there is homogeneity within a given class j. Given the class that individual i belongs to, the outcomes have a joint density $f_j(y_i|x_i;\theta_j)$ where the θ_j are vectors of parameters that are specific to each class. The probability of belonging to class j is π_{ij}, where $0 < \pi_{ij} < 1$ and $\sum_{j=1}^{C} \pi_{ij} = 1$. Unconditionally on the latent class the individual belongs to, the joint density of y_i is given by:

$$f\left(y_i|x_i;\pi_{i1},\ldots,\pi_{iC};\theta_1,\ldots,\theta_C\right) = \sum_{j=1}^{C} \pi_{ij} f_j\left(y_i|x_i;\theta_j\right). \tag{12.26}$$

The discrete distribution of the heterogeneity has C mass points and the πs need to be estimated along with the θ_js.

In many empirical applications of finite mixture models the class membership probabilities are treated as fixed parameters $\pi_{ij} = \pi_j, j = 1, \ldots, C$, (e.g., Atella *et al.*, 2004; Bago d'Uva, 2006; Deb, 2001; Deb and Holmes, 2000; Deb and Trivedi, 1997, 2002; Jiménez-Martin *et al.*, 2002). A more general approach is to parameterize the heterogeneity as a function of individual characteristics. To implement this approach in the case of the latent class model, class membership can be modeled as a multinomial logit (as in, e.g., Clark *et al.*, 2005; Etilé, 2006):

$$\pi_{ij} = \frac{\exp\left(z_i'\gamma_j\right)}{\sum_{k=1}^{C} \exp\left(z_i'\gamma_k\right)}, \; j = 1, \ldots, C, \tag{12.27}$$

with the normalization $\gamma_C = 0$. This approach specifies the determinants of class membership. In a panel data context, this parameterization provides a way to account for the possibility that the observed regressors may be correlated with the individual heterogeneity. Letting $z_i = \bar{x}_i$ be the average over the observed panel of the observations on the covariates is in line with what has been done in recent studies to allow for the correlation between covariates and random effects,

following the suggestion of Mundlak (1978) and Chamberlain (1984). The vectors of parameters $\theta_1, \ldots, \theta_C, \gamma_1, \ldots, \gamma_{C-1}$ are estimated jointly by ML.

After estimating the model, it is possible to calculate the posterior probability that each individual belongs to a given class. The posterior probability of membership of class j depends on the relative contribution of that class to the individual's likelihood function. This is given by:

$$P[i \in j] = \frac{\pi_{ij} f_j\left(y_i | x_i; \theta_j\right)}{\sum_{k=1}^{C} \pi_{ik} f_k\left(y_i | x_i; \theta_k\right)}. \tag{12.28}$$

Each individual can then be assigned to the class that has the highest posterior probability for them.

12.4.4.2 Finite density estimators and discrete factor models

In LCMs class membership has a discrete distribution with a fixed number of mass points. The models are very flexible in that all of the parameters can be allowed to vary across classes. A special case of this general model assumes that the slope coefficients are fixed across classes and that only the intercepts vary. This case is widely used to model unobserved heterogeneity, without imposing parametric assumptions on the distribution of the heterogeneity. The specification has a dual interpretation: the population may truly fall into a discrete set of classes or types or, alternatively, the mass points can be viewed as an approximation of some underlying continuous distribution – the finite density estimator. The finite density estimator was introduced into the econometrics literature by Heckman and Singer (1984) in the context of hazard models (see, e.g., Van Ours, 2004, 2006). More recently, the finite density estimator has been widely used in multiple equation models where a common factor structure is assumed, as in equation (12.9) above. This is often called the discrete factor model (DFM).

Since the DFM includes an intercept for each equation, the location of the distribution of the common factor η is arbitrary; also the scale of η is arbitrary and undetermined (Mroz, 1999). Therefore, identification of the DFM requires some normalizations. The existing literature on the DFM offers a range of equivalent strategies to identify the additional parameters of the discrete distribution by fixing the scale and the location of the distribution. If both are fixed, one of the factor loadings is set to 1 and either one of the η_j is set to 0 (see Mroz, 1999) or the mean of the discrete distribution is restricted to be 0, so that one of the η_j can be expressed as a function of the others (Kan *et al.,* 2003). If only the location is fixed, the first and last mass points are set to 0 and 1 (this strategy is used by Mroz, 1999, when $C > 2$). Other applications also impose that the remaining mass points follow a logistic distribution such that $\eta_k \in (0,1)$ (see Mello *et al.*, 2002, Picone *et al.*, 2003b). The π_k can be parameterized using various distributions, such as the logistic, normal or the sine function, such that each π_k is between 0 and 1 and they sum to 1.

12.4.5 Copulas

The presence of common unobservables leads to multiple equation models and the need to specify multivariate distributions. But the menu of parametric forms available for bivariate and, more generally, multivariate distributions is limited. In many applications multivariate normality may be unappealing: for example, with heavily skewed and long-tailed data on costs of care or on quality adjusted life-years (QALYs) (Quinn, 2005) or for rare events. Copulas provide an alternative and are a method of constructing multivariate distributions from univariate marginal distributions (see Trivedi and Zimmer, 2005). A copula is a function that can be interpreted as a joint probability whose arguments are the univariate cumulative distribution functions (CDFs) of the marginal distributions. The fact that the CDF is used means that the marginal distributions are fixed and invariant to transformations of the random variable. The functional form selected for the copula uniquely determines the form of the dependence, independently of the functional forms of the marginal distributions. The attractions of copulas are that they are flexible – they can mix together marginal distributions of different types, whether they be continuous, integer valued counts or categorical; they allow for richer concepts of dependence than the standard linear measure, including measures of tail dependence; and they are computationally tractable and avoid the need for numerical integration or simulation.

A key result in the theory of copulas is Sklar's theorem, which shows that all multivariate distributions can be represented by a copula. So in the bivariate case, if two random variables have a joint distribution $F(x_1, x_2)$ and marginal distributions $F_1(x_1)$ and $F_2(x_2)$ then Sklar's theorem establishes that there exists a copula function $C(\cdot)$ such that:

$$F(x_1, x_2) = C(F_1(x_1), F_2(x_2)). \tag{12.29}$$

In practice the unique copula that characterizes the true joint distribution is unknown. So particular functional forms have to be selected and compared in terms of their goodness of fit. There is a long list of copulas to choose from. Common choices include the Frank copula and the Farlie–Gumbel–Morgenstern (FGM) copula, which is a first-order approximation of the Frank copula and is tractable to use in applied work (Prieger, 2002; Smith, 2003; Zimmer and Trivedi, 2006). The bivariate form of the Frank copula is:

$$C_\theta(u, v) = -\theta^{-1} \log\left(1 + \frac{(e^{-\theta u} - 1)(e^{-\theta v} - 1)}{e^{-\theta} - 1}\right), \tag{12.30}$$

where the parameter θ captures dependence. The bivariate form of the FGM copula is:

$$C_\theta(u, v) = uv(1 + \theta(1 - u)(1 - v)). \tag{12.31}$$

Other common choices include elliptical copulas, such as the Gaussian and Student's t, and the Clayton copulas. The Gaussian copula is an example of a copula derived by the method of inversion and takes the form:

$$C_\theta(u, v) = \Phi_2(\Phi_1^{-1}(u), \Phi_1^{-1}(v)), \tag{12.32}$$

where Φ_2 and Φ_1 denote bivariate and univariate standard normal distribution functions.

12.5 Models for longitudinal data

12.5.1 Applications of linear models

12.5.1.1 Models for longitudinal and spatial panels

In Lindeboom *et al.* (2002) models for cognitive status and emotional well-being are estimated using linear fixed effects specifications, estimated in first differences. The data are taken from three waves of the Dutch Longitudinal Ageing Study Amsterdam (LASA) and exhibit considerable attrition. Lindeboom *et al.* note that the fixed effects specification is robust to selection associated with time invariant unobservables, but they also include indicators of patterns of response in their model. They find a large impact of life events, such as bereavement, on mental health among the elderly. Carey (2000) estimates the impact of length of stay (LOS) on total hospital costs using a panel of 2,792 US hospitals for the period 1987–92. The individual effect in these models captures factors, such as the quality of care provided in each hospital, which is likely to be correlated with both costs and LOS. To allow for these correlated effects, she uses the Chamberlain minimum distance estimator and finds that the elasticity of total costs with respect to LOS is low.

The rapid growth in dental care expenditure in Taiwan, after the inauguration of national health insurance (NHI) in 1995, led the government to reform the payment system and introduce global budgeting for outpatient dental care in July 1998. In response to the introduction of global budgets, dentists might alter their supply behavior, changing the number of visits, the amount of expenditure, and the type of services provided. Lee and Jones (2004) develop two-way fixed effects models to estimate these effects using panel data constructed from outpatient dental care expenditures claims from the Taiwanese National Health Insurance system. The availability of a long panel, with up to 48 monthly observations, allows them to estimate a policy effect for each dentist in the panel, using within-dentist variation and effectively treating each dentist as their own control group. The individual effects are an important component in the panel data model to investigate dentists' responses to the introduction of global budgeting. The magnitude of the dentist effects measures individual heterogeneity in activities that could not be captured by observable factors in the regression. This allows them to estimate individual-specific responses to the payment reform as well as calculating the average policy effect. They model the individual response to the policy changes by estimating the differences of individual fixed effects between two separate models: pre- and post-global budget. This policy effect can be interpreted as, holding other observable variables constant, the extent to which each individual dentist's activity changed after the introduction of global budgeting. They use OLS to analyze the factors influencing variation in the policy effects across different dentists. These factors include information on the dentist's demographic characteristics, such as age and gender; the type and ownership of affiliated medical institutions (public or

private and hospital or clinic); environmental characteristics, such as the dentist-population ratio and annual household income; and whether the dentist practices in a deprived area. The overall effect of global budgets is to constrain costs, but there is evidence of a change in the mix of services. Male and younger dentists have higher policy effects than female and older dentists. Global budgets favor dentists in deprived areas and there is some evidence of increases in the expenditure per visit and the volume of composite resin fillings.

Applications of linear models are not confined to longitudinal datasets. Moscone *et al.* (2007) take a spatial panel approach to data on mental health expenditure by local authorities in England. They compare specifications that allow for a spatial autoregressive process in the error term; a random effects model with spatially lagged dependent variables; and a random effects model with spatial autocorrelation. The random effects model with lagged dependent variables proves to be the preferred specification.

12.5.1.2 Dynamic panel data models: GMM estimators

Brown *et al.* (2005) apply dynamic panel data models to assess the impact of HMOs on the supply of doctors at the local level. They construct a panel of Californian counties for the years 1988–98 using data from the American Medical Association and specify reduced-form models for the supply of doctors per 100,000 inhabitants for both specialists and primary care. First differencing is used to deal with omitted variables and dynamics are included to allow for inertia in supply responses. The models are estimated by the systems version of the Arellano–Bond estimator (Arellano and Bond, 1991; Arellano and Bover, 1995; Blundell and Bond, 1998), with both one-step and two-step estimates of the standard errors. The internal instruments, drawn from lagged variables, are augmented by some external instruments. The tests for autocorrelation are consistent with the assumptions of the Arellano–Bond model: there is evidence of first order autocorrelation in the residuals, but not of higher order autocorrelation. The results show that the supply of specialists is responsive to changes in the relative market penetration of HMOs, but the supply of primary care doctors is not.

The Arellano–Bond approach is also adopted by Tamm *et al.* (2007) to estimate price effects on insurers' market shares. They use an unbalanced panel of insurers, who were active in the German social health insurance system between January 2001 and April 2004. This issue is important as price sensitivity among consumers is a precursor for the success of reforms based on the notion of managed competition. They adopt a dynamic panel data model for the logarithm of each insurer's market share. This aggregate model is motivated by an individual-level multinomial logit model for the choice of insurer and dynamics are introduced to capture the fact that only a fraction of consumers will switch companies during a given year. The model is estimated using the Arellano–Bond estimator and the systems-GMM estimator. The standard Arellano–Bond GMM estimator, which relies on lagged levels to instrument lagged differences, may perform poorly. This suggests using the systems approach, but this approach requires stronger restrictions on the initial conditions: the first-period error term and the first differences of the regressors

have to be uncorrelated with the individual effect. In this case the orthogonality conditions for the systems approach are rejected. The hypothesis of a unit root is not rejected and models are also estimated for differences in log-market share as a function of levels of the regressors. The estimated short-run price elasticities are small but, due to the dynamics, the long-run impact of prices is substantial.

Other applications of the GMM and systems-GMM approaches include Baltagi *et al.* (2005), who estimate dynamic equations for the log of hours worked by Norwegian doctors, using panel data from the personnel register of the Norwegian Association of Local and Regional Authorities. Clark and Etilé (2002) use seven waves of BHPS to estimate dynamic models for cigarette consumption. This creates some problems when the data are first differenced as there is considerable heaping of the self-reported data around focal values, such as 20 cigarettes per day. Health shocks are shown to influence levels of smoking. Hauck and Rice (2004) use 11 waves of the BHPS to estimate models for mental health, measured by the GHQ-12 score. They compare static variance components models and dynamic GMM estimators and find greater persistence of mental health problems among those with lower socioeconomic status. Windmeijer *et al.* (2005) use the systems-GMM estimator in panel data models of the demand for outpatient visits by GP practices in England.

12.5.2 Applications with categorical outcomes

12.5.2.1 Pooled and random effects specifications

Contoyannis *et al.* (2003) consider the determinants of a binary indicator for functional limitations using seven waves (1991–97) of the BHPS. Their models allow for persistence in the observed outcomes due to state dependence (a direct effect of previous health status), unobservable individual effects (heterogeneity which is due to unobserved factors that are fixed over time) and persistence in the transitory error component. Allowing for persistence is important: a comparison of the observed outcomes with those predicted by a simple binomial model shows that persistence is substantial in the data. They estimate models for the repeatedly observed binary health indicator, with and without state dependence, using panel probit models. These are estimated by MSL using the GHK simulator with antithetic acceleration. They also implement a test for the existence of asymptotic bias due to simulation which is used to select the number of replications required for use in MSL.

In related work Contoyannis *et al.* (2004b) explore the dynamics of SAH in the BHPS. The variable of interest is an ordered measure and the BHPS reveals evidence of considerable persistence in individual's health status. As SAH is measured at each wave of the panel there are repeated measurements for a sample of individuals. SAH is modeled using a latent variable specification, which is estimated using pooled ordered probits (with robust inference) and random effects ordered probit models. The presence of lagged health is designed to capture state dependence, the influence of previous health history on current health. The error term is split into two components; the first captures time invariant individual heterogeneity; the second is a time varying idiosyncratic component.

In this kind of application it is quite likely that the unobserved individual effect will be correlated with the observed regressors, such as household income. To allow for this possibility Contoyannis *et al.* (2004b) parameterize the individual effect (Chamberlain, 1984; Mundlak, 1978; Wooldridge, 2005). This allows for correlation between the individual effects and the means of the regressors. In addition, because they are estimating dynamic models, they need to take account of the problem of initial conditions. It is well known that in dynamic specifications the individual effect will be correlated with the lagged dependent variable, which gives rise to what is known as the *initial conditions problem*, that an individual's health at the start of the panel is not randomly distributed and will reflect the individual's previous experience and be influenced by the unobservable individual heterogeneity. To deal with the initial conditions an attractively simple approach suggested by Wooldridge (2005) is used. This involves parameterizing the distribution of the individual effects as a linear function of initial health at the first wave of the panel and of the within-individual means of the regressors, and assuming that it has a conditional normal distribution. As long as the correlation between the individual effect and initial health and the regressors is captured by this equation it will control for the problem of correlated effects. Its ease of implementation stems from the fact that the equation for u_i can be substituted back into the main equation and the model can then be estimated as a pooled ordered probit or a random effects ordered probit using standard software to retrieve the parameters of interest. Contoyannis *et al.* (2004b) find that SAH is characterized by substantial positive state dependence and unobserved permanent heterogeneity. Including state dependence dramatically reduces the impact of individual heterogeneity. Conditioning on the initial period health outcomes and within-individual averages of the exogenous variables reduces the impact of heterogeneity and state dependence. Unobservable heterogeneity accounts for around 30% of the unexplained variation in health.

Similar dynamic panel probit models are used by Gannon (2005). In her case the outcome of interest is a binary measure of labor force participation, which is assumed to be a function of past labor force participation and health limitations. This gives dynamic panel probit models that are estimated in pooled and random effects versions using the Wooldridge (2005) approach to deal with the initial conditions problem. The models are estimated with the Living in Ireland Survey (LIS), which is the Irish component of the ECHP. Nolan (2007) also uses the LIS, but uses a dynamic random effects Poisson specification to model GP visits. She adopts the Wooldridge approach to model the initial conditions. In contrast, Arulampalam and Bhalotra (2006) use Heckman's approach to specify the initial conditions in a Markov model of infant deaths among Indian families.

12.5.2.2 GMM estimators

In Jones and Labeaga (2003) a panel of Spanish households is used to test the empirical formulation of the rational addiction model (Becker *et al.,* 1994). This dataset raises problems of measurement errors, censoring, and unobservable heterogeneity. Jones and Labeaga (2003) use sample separation information to exclude those

households who never purchase tobacco. To deal with the remaining zeros, they compare specifications based on infrequency of purchase and on censoring. GMM and systems-GMM are used to deal with errors-in-variables and unobservable heterogeneity (Arellano and Bond, 1991; Bover and Arellano, 1997). Within-groups two-step, within-groups three-step GMM and MD methods are used to allow for censoring. To reduce the influence of distributional assumptions they adopt a semiparametric approach to estimate each of the T cross-section equations using Powell (1986) symmetrically censored least squares (SCLS). There is evidence that the rational addiction specification is sensitive to unobservable heterogeneity and censoring and the results suggest that failure to account for heterogeneity may lead to overestimates of the impact of addiction. The panel data estimators imply that behavior is more forward-looking than suggested by the results that fail to correct for heterogeneity.

12.5.2.3 Finite mixture models

Deb (2001) applies a random effects probit model in which the distribution of the individual effect is approximated by a discrete density. This is an example of a finite mixture model and it relaxes the normality assumption for the distribution of the random effects. Deb uses Monte Carlo experiments to assess the small sample properties of the estimator. These show that only 3–4 points of support are required for the discrete density to mimic normal and chi-square densities and to provide approximately unbiased estimates of the structural parameters and the variance of the individual effects. Deb applies the model to a cross-section of individuals clustered in families, where the random effect represents unobserved family effects. It is assumed therefore that all individuals in each family belong to the same latent class. This approach aims to approximate the distribution of the random (family) intercepts, whereas the responses to the explanatory variables are not allowed to vary across latent classes. Clark *et al.* (2005) develop a latent class ordered probit model for reported well-being, in which individual time invariant heterogeneity is allowed both in the intercept and in the income effect.

12.5.3 Applications with count data

12.5.3.1 Poisson/log-normal mixtures

Winkelmann (2004a) proposes an alternative two-part, or hurdle, model based on a Poisson/log-normal mixture rather than the usual negative binomial (Negbin) variants. Hurdle, or two-part, models make a distinction between the decision to seek care, modeled as a binary choice, and the conditional number of visits, modeled as a truncated count data regression. They are the most widely used specification in the recent applied literature (see, e.g., Alvarez and Delgado, 2002; Chang and Trivedi, 2003; Sarma and Simpson, 2006; Yen *et al.,* 2001), although Santos Silva and Windmeijer (2001) have pointed out that they may be problematic in applications where it cannot be assumed that there is a single spell of illness for each period of observation in the data. Winkelmann's (2004a) model leads to a probit equation for the first hurdle and a truncated Poisson/log-normal model for the second. Unlike the Negbin model, the latter does not have a closed form and is

estimated using Gauss–Hermite quadrature. An application to the 1997 reform of co-payments for prescription drugs in Germany uses data on quarterly doctor visits in the GSOEP. This confirms Deb and Trivedi's (2002) result that finite mixture models outperform Negbin hurdle models, but the results show that the normal hurdle model fits better than both of these specifications.

The innovation in Van Ourti (2004) is to include a Gaussian random effect in the two-part model. The time invariant individual effect appears as a common factor in both parts of the model, with the factor loading in the first equation normalized to one for identification. The individual effect is then integrated out with the resulting integral evaluated by Gauss–Hermite quadrature. In an empirical application to GP and specialist visits and to nights in hospital in the Panel Study of Belgian Households (PSBH), the panel version of the two-part model (2PM-PA) is compared to a one part-model with a Gaussian individual effect (1PM-PA) and to pooled versions of the one-part and two-part models (1PM-PO, 2PM-PO). On the basis of the log-likehoods and the Akaike information criterion (AIC) and Bayesian information criterion (BIC), the 2PM-PA specification is preferred to the simpler specifications.

While Van Ourti (2004) extends the Gaussian random effects model to the two-part specification for count data, Munkin and Trivedi (1999) and Riphahn *et al.* (2003) do the same for a bivariate count data model, dealing with the case where there are two dependent variables both measured as integer counts. Munkin and Trivedi (1999) propose a model that is designed for cross-section data and that is applied to the number of emergency room visits and of hospitalizations in data from the US National Medical Expenditure Survey, 1987–88 (as used by Deb and Trivedi, 1997). They construct the bivariate model by specifying the marginal distributions of the counts and then adding a correlated heterogeneity term to give a Poisson-log-normal mixture. This has conditional mean functions:

$$\begin{aligned} \lambda_{i1} &= \exp(x_{i1}^{'}\beta_1 + \varepsilon_{i1}) \\ \lambda_{i2} &= \exp(x_{i2}^{'}\beta_2 + \varepsilon_{i2}) \\ (\varepsilon_{i1}, \varepsilon_{i2}) &\sim N[(0,0), (\sigma_1^2, \rho\,\sigma_1\,\sigma_2, \sigma_2^2)]. \end{aligned} \tag{12.33}$$

The log-likelihood function for the model involves a two-dimensional integral and is estimated by MSL with antithetics and a correction for first order simulation bias. Using a bivariate model does not lead to substantial changes in the estimated effects of the regressors, but the overall fit of the model does improve.

The model proposed by Riphahn *et al.* (2003) is designed for panel data and they apply it to separate measures of doctor visits and hospital inpatient visits from 12 waves of the GSOEP for 1984–95, focusing on West Germans aged between 25 and 65. Their specification extends the single equation model of Geil *et al.* (1997) by adding two Gaussian error components to each equation; one, a time invariant individual effect (u_{ij}); the other, a time-varying idiosyncratic error term (ε_{itj}):

$$\begin{aligned} \lambda_{it1} &= \exp(x_{it1}^{'}\beta_1 + u_{i1} + \varepsilon_{it1}) \\ \lambda_{it2} &= \exp(x_{it2}^{'}\beta_2 + u_{i2} + \varepsilon_{it2}). \end{aligned} \tag{12.34}$$

Correlation between the two equations is introduced by assuming that the error terms are drawn from a bivariate normal distribution. Although it is not clear from the paper, it appears that the individual effects (u_{ij}) are assumed to be independent of each other, which seems rather restrictive. Computation is based on a combination of Gauss–Hermite quadrature, to integrate over the time invariant individual effect, and Gauss–Legendre quadrature, to integrate over the bivariate distribution within each period.

12.5.3.2 Finite mixtures

Deb and Trivedi (1997, 2002), Deb and Holmes (2000), Jiménez–Martin *et al.* (2002) and Sarma and Simpson (2006) estimate finite mixture models for count measures of health care use, in which a Negbin distribution is assumed within each latent class. Lourenço and Ferreira (2005) extend the application of the Negbin finite mixture model to a truncated sample from the 2003–04 Europep survey for Portugal, where data are only collected for those who visit health centers. This means that the data are drawn from an endogenous sampling scheme and are truncated at zero, and raises the question of whether the distribution of unobserved heterogeneity should be defined over the whole population or only the truncated sample.

Jochmann and Leon-Gonzalez (2004) propose a specification that uses a semiparametric Bayesian approach, which can be seen as an extension of Deb and Trivedi (1997). They start with a parametric "random coefficients" specification of the Poisson model as a benchmark. In this model the random slopes (b_i) are assumed to be drawn from a multivariate normal distribution, so the conditional mean function takes the form:

$$\lambda_{it} = \exp(x_{it}' \beta + w_{it}' b_i + \varepsilon_{it}). \tag{12.35}$$

The semiparametric element of the model is introduced by using a Dirichlet process mixture for the prior on the random effects. This gives a mixture model with a random number of components and extends the usual treatment of LCMs that fix the number of components. The Dirichlet process specifies a base distribution, in this case assumed to be normal, and a fixed number of mass points, in this case set equal to 10. Then, new draws of the random effects are a mixture of draws from the base distribution and draws from existing clusters of values. The end product is a discrete distribution where the number of mass points is random. Estimation of the model is done by MCMC, based on Gibbs sampling, with data augmentation (the random effects and latent variables are treated as parameters to be estimated) and incorporating a Metropolis–Hastings step where the Gibbs sampling cannot be used. The MCMC algorithm was run for 30,000 iterations, discarding the first 5,000 for the burn-in period. The application uses data on the number of visits to the doctor in the previous quarter from the 1997–2001 waves of the GSOEP. The aim is to test for horizontal equity in the delivery of care by seeing whether non-need factors play a significant role in explaining variation in utilization. This is tested using Bayes factors and horizontal equity is not rejected with these data.

The two dominant strands in the recent literature, hurdle models and finite mixture models, are brought together in the latent class hurdle model developed

by Bago d'Uva (2006). Her model uses a panel of individuals across time: individuals i are observed T_i times. Let y_{it} represent the number of doctor visits in year t. The joint density of $y_i = \left(y_{i1}, \ldots, y_{iT_i}\right)$ is given by:

$$g\left(y_i|x_i;\pi_{i1},\ldots,\pi_{iC};\theta_1,\ldots,\theta_C\right) = \sum_{j=1}^{C}\pi_{ij}\prod_{t=1}^{T_i} f_j\left(y_{it}|x_{it};\theta_j\right), \tag{12.36}$$

where x_i is a vector of covariates, including a constant, the θ_j are vectors of parameters, and $0 < \pi_{ij} < 1$ and $\sum_{j=1}^{C}\pi_{ij} = 1$. Conditional on the class that the individual belongs to, the number of visits in period t, y_{it}, is assumed to be determined by a hurdle model. The underlying distribution for the two stages of the hurdle model is the Negbin. Formally, for each component $j = 1, \ldots C$, it is assumed that the probability of zero visits and the probability of observing y_{it} visits, given that y_{it} is positive, are given by the following expressions:

$$\begin{aligned} f_j\left(0|x_{it};\beta_{j1}\right) &= P\left[y_{it}=0|x_{it},\beta_{j1}\right] = \left(\lambda_{j1,it}^{1-k}+1\right)^{-\lambda_{j1,it}^{k}} \\ f_j\left(y_{it}|y_{it}>0,x_{it};\beta_{j2}\right) &= \frac{\Gamma\left(y_{it}+\frac{\lambda_{j2,it}^{k}}{\alpha_j}\right)\left(\alpha_j\lambda_{j2,it}^{1-k}+1\right)^{-\frac{\lambda_{j2,it}^{k}}{\alpha_j}}\left(1+\frac{\lambda_{j2,it}^{k-1}}{\alpha_j}\right)^{-y_{it}}}{\Gamma\left(\frac{\lambda_{j2,it}^{k}}{\alpha_j}\right)\Gamma(y_{it}+1)\left[1-\left(\alpha_j\lambda_{j2,it}^{1-k}+1\right)^{-\frac{\lambda_{j2,it}^{k}}{\alpha_j}}\right]} \end{aligned}, \tag{12.37}$$

where $\lambda_{j1,it} = \exp\left(x_{it}'\beta_{j1}\right)$, $\lambda_{j2,it} = \exp\left(x_{it}'\beta_{j2}\right)$, α_j are overdispersion parameters and k is an arbitrary constant.

As in the standard hurdle model, β_{j1} can be different from β_{j2}, reflecting the fact that the determinants of care are allowed to have different effects on the probability of seeking care and on the conditional number of visits. On the other hand, having $\left[\beta_{j1},\beta_{j2}\right] \neq \left[\beta_{l1},\beta_{l2}\right]$ for $j \neq l$ reflects the differences between the latent classes. Various special cases are nested within the general model. It can be assumed that all the slopes are the same, varying only the constant terms, $\beta_{j1,0}$ and $\beta_{j2,0}$, and the overdispersion parameters α_j. This represents a case where there is unobserved individual heterogeneity, but not in the responses to the covariates. The most flexible version allows α_j and all elements of β_{j1} and β_{j2} to vary across classes. The finite mixture hurdle model also accommodates a mixture of sub-populations for which health care use is determined by a Negbin model (the two decision processes are indistinguishable) and sub-populations for which utilization is determined by a hurdle model. This is obtained by setting $\beta_{j1} = \beta_{j2}$ for some classes. Setting them equal for all of the classes gives a panel data version of Deb and Trivedi's (1997) latent class Negbin model. Bago d'Uva (2006) applies the latent class hurdle model to panel data from the RAND Health Insurance Experiment and finds a higher price effect on health care utilization for the latent class of "low users." This is mostly attributable to the impact of price on the probability of seeing a doctor rather than the conditional number of visits.

12.5.4 Applications of quantile regression and other semiparametric methods

Quantile regression is of particular value when there is interest in the full conditional distribution of an outcome rather than just the conditional expectation of the variable. The method provides one way to allow for heterogeneity in treatment effects over the range of the conditional distribution. It is a semiparametric approach that avoids distributional assumptions about the error term. It also has the attractive property of invariance to monotone transformations of y and therefore avoids the retransformation problem.

Kan and Tsai (2004) apply quantile regression to the conditional distribution of BMI using data from the Cardiovascular Disease Risk Factors Two-Township Study (CVDFACTS) for Taiwan. Quantile regression is well suited to an analysis of obesity as interest focuses on the upper tail of the distribution of BMI rather than the area around the mean. Other studies have tended to create an indicator variable for obesity using the published clinical thresholds, but the quantile approach makes better use of the available variation in BMI in the upper tail of the distribution.

Lee and Jones (2006) use the same dataset for Taiwan dentistry as Lee and Jones (2004) to provide evidence on heterogeneity in dentists' activity. The heterogeneity is of particular importance because dentists' responses are likely to differ widely from high- to low-activity dentists. Quantile regressions provide a useful method to investigate the differential responses of dentists to various observable variables. It is shown that time trends for dentists at higher quantiles have greater fluctuations than those at lower quantiles. The clinic–hospital gap in activity at higher quantiles is greater than at low quantiles. Clinic dentists at higher quantiles have much higher numbers of visits and numbers of treatments than those at lower quantiles, but they provide less intensity of care. Dentists in deprived areas have higher activity than those in non-deprived areas, but only when they are located at higher quantiles.

Winkelmann (2006) applies quantile regression to count data on doctor visits in the GSOEP. This allows an evaluation of the impact of the 1997 reform of copayments for medicines on the full conditional distribution and not just the mean. The quantiles of a count are integer valued and cannot be represented by a continuous function of the covariates, such as $\exp(x'\beta)$, so Winkelmann (2006) adopts the method proposed by Machado and Santos Silva (2005). This transforms the data by "jittering": adding a uniform random variable to the counts and then applying quantile regression to the resulting continuous variable. The results show a greater impact of the reform on the lower quantiles, which is consistent with the earlier evidence from a hurdle model in Winkelmann (2004) that showed a larger effect in the first part of the model.

Applications of other semiparametric regression methods are relatively sparse in the health economics literature. Askildsen *et al.* (2003) use Kyriazidou's (1997) semiparametric estimator for a panel data sample selection model in order to estimate nurses' labor supply in Norway. This allows for individual effects in the selection equation and the hours equation that may be correlated with each other

and with the observed covariates. A conditional logit is used to estimate the selection equation. Then the hours equation is estimated in first differences by weighted least squares, with kernel weights applied to the difference in the linear index from the selection equation between different periods. The aim is to difference observations across periods for which the probability of selection is (approximately) the same. Rettenmaier and Wang (2006) use a semiparametric estimator for the Tobit model to model persistence in Medicare reimbursements. The model allows for fixed effects and a lagged dependent variable, but assumes that initial conditions are fixed.

It is widely believed that income has a direct effect on health, but it is often argued that indirect income effects due to relative deprivation may be equally important. Wildman and Jones (2007) investigate these relationships using parametric and semiparametric panel data models. By allowing for a flexible functional form for income, they seek to ensure that coefficients on relative deprivation variables are not an artifact of a highly non-linear relationship between health and income. Parametric estimation may lead to biased coefficients if the parameterization of the explanatory variables is incorrect. Semiparametric partially linear estimation overcomes this problem by allowing an unspecified relationship between health and income (Robinson, 1998). The results provide strong evidence for the impact of income on self-reported measures of health for men and women. These results are robust across a range of techniques and are resilient to the inclusion of measures of relative deprivation. The parametric results for relative deprivation largely reject its influence on health, although there is some evidence of an effect in the semiparametric models.

12.6 Multiple equation models

12.6.1 Applications using MSL

Balia and Jones (2008) use the first wave of the British HALS from 1984 to 1985 along with the longitudinal follow-up from May 2003 to model the determinants of premature mortality and to assess the relative contribution of lifestyle factors to the gradient in mortality in Britain. A behavioral model, that relates mortality to observable and unobservable factors, is used to motivate the empirical specification. Death, SAH and a range of health-related behaviors are measured as binary outcomes and, to capture the effect of lifestyles on mortality and morbidity in the presence of common unobservable factors, the model is estimated as a recursive multivariate probit. The full system is estimated by MSL and health inequality is explored using a decomposition analysis of the Gini coefficient. The results contradict the view that lifestyles only play a minor part in health inequalities.

Deb and Trivedi (2006) and Deb *et al.* (2006a) use a latent factor specification to model selection into treatment in nonlinear models and adopt a MSL estimator. The aim is to estimate causal effects using a structural model, motivated by a selection on unobservables approach, in which the parametric distribution of

the unobservables is specified and the full model is estimated by ML. In this case the outcomes of interest are binary and count measures of health care utilization. The treatment variables reflect the individual's choice of insurance plan, which is modeled using a random utility framework. The options are categorized as HMOs, other-managed care and non-managed care plans, with the choice of options specified using a multinomial logit specification. In Deb and Trivedi (2006) the data are taken from the 1996 US Medical Expenditure Panel Survey (MEPS), while in Deb *et al.* (2006a) the MEPS data are augmented by the 1996 Community Tracking Survey (CTS) as a test for the external validity of the findings. Utilization and insurance plan are modeled simultaneously to take account of the possibility of selection by patients, insurers and providers. Identification of the latent factor model rests on the assumption that each of the multinomial choices depends on a unique latent factor, based on independent and identically distributed (i.i.d.) normal draws, and these are allowed to be freely correlated with the error in the outcome equation. The parametric specification is identified by functional form, but exclusion restrictions are also imposed, using employment status and occupational sector as predictors of insurance plans, while excluding them from the outcome equations. Simple linear models are used to provide informal checks for the validity of these instruments. Estimation uses MSL, accelerated by using quasi-random draws from Halton sequences. The results do not show evidence of favorable selection into HMO plans, but the average treatment effects on the use of care are much larger when selection is taken into account and there is considerable heterogeneity in the effects. Monte Carlo simulation is also used to compute the standard errors of these treatment effects.

Other applications of MSL include Lindeboom *et al.* (2002), who use the LASA panel to estimate a five-equation model for the use of long-term care services among elderly residents of Amsterdam. They take draws from a multivariate normal distribution and use antithetics to accelerate the estimation. The results show strong effects of health status, sex, socioeconomic status and prices on the use of institutional care. Two papers by Pudney and Shields (2000a, 2000b) use MSL to estimate a system of equations comprised of a generalized ordered probit model for British nurses' pay grades along with auxiliary equations for training, career breaks, work outside the NHS, and part-time work. A common factor structure leads to a log-likelihood based on the multivariate normal and hence the need for simulation estimation. The MSL estimation only uses 50 replications, without acceleration, which is relatively few for this kind of application. Pudney and Shields (2000b) make a case for identification based on functional form rather than exclusion restrictions. Vera-Hernandez (2003) makes use of MSL to estimate a structural model of insurance coverage and health care use applied to data from the RAND Health Insurance Experiment.

12.6.2 Applications using Bayesian MCMC

Patient selection makes it hard to identify the impact of the size and characteristics of hospitals on the quality of their outcomes. The problem arises when there is

selective admission that is influenced by unobservables, such as unmeasured severity, that are also associated with the quality of outcomes. Geweke *et al.* (2003) find evidence of patient selection among 78,848 Medicare patients treated in 114 hospitals in Los Angeles county between 1989 and 1992. They focus on patients aged over 65 with a diagnosis of pneumonia taken from administrative data on hospital discharges collected by the State of California Office of Statewide Health Planning and Development. The quality of the clinical outcomes is measured by deaths in hospital within ten days of admission. A structural probit model for deaths is coupled with a reduced form multinomial probit model for the patient's choice of hospital, allowing correlation in the error terms to capture patient selection. The system of equations is estimated by a Bayesian approach using the MCMC simulator of the posterior distribution. Gibbs sampling with data augmentation breaks the estimation into steps, first simulating the latent dependent variables and then estimating the linear simultaneous equations system. The model is identified by using distances from the patients' homes to the hospitals as an instrument. The raw data and simple probits do not show a relationship between hospital size and mortality rates, but the MCMC results reveal a U-shaped relationship, with better quality in the smallest and largest hospitals.

Deb *et al.* (2006b) start with a conventional two-part model for medical expenditure. This is applied to data on ambulatory care, which has 17% zero observations, and hospital care, which has 94% zero observations and which exhibits positive skewness and excess kurtosis. The data are drawn from the US MEPS for 1996–2001, giving six repeated cross-sections and 20,460 observations. The standard two-part set-up is used with a binary choice equation and a conditional regression for the logarithm of expenditure. However, this is augmented by a multinomial probit model to allow for the endogenous selection of insurance plans, which fall into three categories: HMO, PPO (preferred provider organization) and FFS (fee-for-service). To capture the possibility of selection bias the error terms from the insurance equations (u) are assumed to be linearly associated with the error terms in the two parts of the model for expenditure:

$$\begin{aligned} \varepsilon_1 &= u'\delta + \upsilon \\ \varepsilon_2 &= u'\pi + \tau. \end{aligned} \tag{12.38}$$

This assumes that the εs are only conditionally independent given u and relaxes the usual assumption that the two parts of the model are independent. Like Geweke *et al.* (2003), the full system of equations is estimated by Bayesian MCMC and Bayes factors are used to construct a test for the exogeneity of the choice of insurance plan. This test shows evidence of substantial selection bias. Having estimated the model, the authors show how to define and compute estimated treatment effects for the impact of insurance plan on expenditure, using data augmentation to impute the latent variables. It should be noted that the approach used to compute the treatment effects involves a standard retransformation for log-scale data and therefore relies on a strong assumption about the absence of heteroskedasticity in the expenditure data (Manning and Mullahy, 2001).

12.6.3 Applications using finite mixtures

The common factor model was introduced earlier in this chapter in the context of Aakvik *et al.*'s (2005) evaluation of a Norwegian VR program (see equations (12.8)–(12.10) above). Aakvik *et al.*'s application takes a parametric approach and assumes that the common factor is normally distributed. An alternative, semiparametric approach is to use a finite density and estimate a DFM. The DFM has two main advantages over MSL. First, it is semiparametric and therefore more robust than the parametric approach, which relies on strong distributional assumptions. Also, in general, it is easier to compute, involving standard numerical methods for maximum likelihood estimation or the use of the expectation maximization (EM) algorithm, rather than computationally intensive Monte Carlo simulation (see, e.g., Arcidiancono *et al.,* 2007). However, in practice there can be problems with identification, manifested in failure of convergence and problems with multiple optima.

Like Aakvik *et al.* (2005), Aakvik *et al.* (2003) use a latent variable framework to specify the impact of multidisciplinary treatment for back pain on the probability of leaving sickness benefits. Using a structural model, based on latent variables, allows them to define the ATE, the ATET and to allow for heterogeneous MTEs. In this application the unobservables are modeled using a discrete factor structure with distance to the nearest hospital used to identify the model. The estimates show a positive effect of around 6 percentage points on the probability of leaving sickness benefits.

Rous and Hotchkiss (2003) use data from 254 Texas counties on all reported births in 1993 to explore the impact of prenatal care on birth weight. They estimate a discrete factor model with three equations: a logit model for whether the pregnancy is carried to full-term and linear regressions for a measure of prenatal care visits and for birth weight. Travel distance to the nearest provider of abortions is used to identify the first equation, the availability of obstetricians is used for the second and the gender of the child for the third. The factor model shows evidence of adverse selection effects. Picone *et al.* (2003b) merge panel data from the US National Long-Term Care Survey (NLTCS) for 1984–95 with the National Death Index to investigate the impact of treatment intensity on survival rates and other health outcomes. Their model involves a system of three equations for treatment intensity, length of stay and health outcomes. These are assumed to have a common factor structure which is estimated using a one-factor model. The selection of models is based on the likelihood ratio (LR) statistic (Mroz, 1999) and 1,000 bootstrap replications are used to avoid the problem of local optima. The model is identified by excluding area data on the cost of capital, the Herfindahl index for hospital concentration and a wage index from the mortality equation. The results suggest that treatment intensity has a beneficial effect. Hamilton *et al.* (2000) compare US and Canadian data to see whether waiting time for surgery for hip fractures influences the outcomes of the treatment, measured by length of stay and inpatient mortality. They use discharge data for 20,995 patients admitted to acute hospitals in Quebec and Massachusetts between 1990 and 1992 and estimate a competing

risks model for delay before surgery and post-surgery length of stay. They use the Heckman–Singer specification for the common heterogeneity with two mass points (Heckman and Singer, 1984). Day of week of admission is used as an instrument for delay until surgery. The raw data show a strong relationship between delays and outcomes, but this disappears once unobserved frailty is taken into account. The higher observed inpatient mortality in Quebec is attributed to the longer length of stay rather than poorer outcomes: the longer the patients remain in hospital, the more likely they are to die there rather than at home.

Other applications of the discrete factor model include Bhattacharya *et al.* (2003), who model the impact of public and private insurance on HIV-related mortality. Mello *et al.* (2002) use a discrete factor specification for a two-equation model of health plan choice, whether to join a Medicare HMO, and various measures of subsequent health care utilization applied to data from the Medicare Current Beneficiary Survey for 1993–96. A similar model of HMO enrollment and subsequent hospital use by Kan *et al.* (2003) finds evidence of strong selection effects when a discrete factor specification is used to deal with unobservables. Rous and Hotchkiss (2003) use the Nepal Living Standards Survey for 1996 in a model of choice of health care provider, levels of expenditure and health outcomes with a two-factor specification to allow for community and household effects. Holmes (2005) combines a multinomial logit model with a discrete factor specification to evaluate the US National Health Service Corps (NHSC) program that was designed to encourage doctors to locate in underserviced areas.

The discrete factor model allows for a common factor in the intercept of each equation. In contrast, the LCM allows all of the parameters to vary across the latent classes. Clark and Etilé (2006) use the latent class framework to approximate the continuous distribution of the individual effects in a dynamic random effects bivariate probit model. They apply the model to data on smoking among couples in the BHPS and use the simulated annealing version of the EM algorithm to estimate the model. Atella *et al.* (2004) develop a latent class model for the joint decisions of consulting three types of physician. The authors assume that, within a latent class, each decision can be modeled by an independent probit, so the joint distribution of the three binary outcomes is a product of probits.

12.6.4 Applications using copulas

The copula approach leads to closed forms and avoids the need for numerical integration. It also circumvents the problem of the limited menu of parametric specifications of multivariate distributions that are available, especially when normality is an unsuitable assumption, for example, when dealing with highly skewed data.

Although copulas are not mentioned explicitly, Prieger (2002) proposes an extension of the sample selection model that is built around the FGM copula. This is applied to data from the 1996 wave of the MEPS. The outcome equation is a duration model for hospital length of stay and the selection equation measures whether the individual had an inpatient stay or not during the survey period.

Prieger's approach builds on Lee's (1983) selection model that uses a bivariate normal copula. In both cases the use of copulas to model the joint distribution allows for the marginal distributions to be non-normal. As the outcome is a measure of duration, exponential, gamma, log-logistic, log-normal and Weibull specifications are considered and the gamma is selected as the preferred model. This reflects an attractive feature of the copula approach, that model selection can focus on finding an acceptable specification of the marginal distributions before turning to the joint distribution. The specifications of the full selection model are compared using the AIC, BIC, and the consistent Akaike information criterion (CAIC) as well as the Voung test for non-nested models. These tests favor the FGM over the bivariate normal copula in terms of goodness-of-fit. Smith (2003) uses the same data as Prieger (2002), but a different copula, the Frank copula from the Archimedean class, that improves the fit of the model and changes the estimates of average length of stay.

Copulas are used by Zimmer and Trivedi (2006) to model dependence in a system of nonlinear reduced form equations. Their application focuses on couples' decisions about insurance coverage and health care use and consists of three equations: one for the husband's utilization, one for the wife's and one for whether or not the couple take out separate health insurance policies. The marginal distributions for utilization are assumed to be Negbin (NB2) and a probit is used for the insurance equation. The equations are assumed to be linked by common unobservable factors and the joint distribution is modeled using a trivariate Frank copula, which is derived using the mixture-of-powers approach. The use of copulas avoids having to select a parametric specification for the unobservable heterogeneity and is computationally tractable. To emphasize these points, Zimmer and Trivedi compare their results to those derived from an MSL approach, based on multivariate normality. The model is applied to data from four waves of the US MEPS. An apparent limitation of the copula approach is that it works by specifying marginal distributions and then modeling dependence, so that the emphasis is on a system of reduced form equations rather than on conditional distributions. However, Zimmer and Trivedi show how the estimates can be used to derive the conditional distribution and hence compute the ATE of insurance coverage on health care use.

12.7 Evaluation of treatment effects

12.7.1 Matching

Matching provides a general approach to deal with selection on observables. It addresses the problem that, in the observed data, confounding factors may be non-randomly distributed over the treated and controls. Rosenbaum and Rubin (1983) showed that, rather than matching on an entire set of observable characteristics (x), the dimensions of the problem can be reduced by matching on the basis of their probability of receiving treatment, $P\left(d = 1|x\right)$, known as the propensity score. In practice, propensity score matching (PSM) estimators do not rely on

exact matching and instead weight observations by their proximity, in terms of the propensity score.

An important requirement is that the model for treatment, used to construct the propensity score, should only include variables that are unaffected by participation in the treatment, or the anticipation of participation. The matching variables should be either time invariant characteristics or variables that are measured before participation in the treatment and that are not affected by anticipation of participation. The crucial condition for identification of treatment effects using the matching approach is that the selection into treatment should be ignorable, conditional on the observed covariates.[3]

Jones *et al*. (2007a) use the ECHP to estimate the impact of private health insurance coverage on the use of specialist visits in four European countries that allow supplementary coverage. The results show that the probability of having private insurance increases with income and with better reported health. Private insurance has a positive effect on the probability of specialist visits in all countries, although the magnitude is sensitive to the choice of estimator. They match treated individuals with non-treated individuals inversely weighted for the distance in terms of estimated propensity scores, with weights constructed using kernel smoothed distance weighting. They ensure that all cases are supported by controls. The quality of the matching can be assessed by computing the reduction of the pseudo R^2 of the insurance regression before and after matching. To evaluate the extent to which matching on propensity scores balances the distribution of the *x*s between the insured and the uninsured group, they compute the bias reduction due to matching for each of the *x*s.

Dano (2005) uses a 10% sample of the Danish population, drawn from register data, to give a panel for 1981–2000. She estimates the impact of injuries sustained in road traffic accidents on economic outcomes. Although these accidents are unanticipated health shocks, their incidence varies with observable and unobservable characteristics that can be associated with the outcomes and the estimates of the treatment effect need to be adjusted for this. Due to the large sample size, one-to-one matching without replacement is used, with matching on the linear index from the propensity score. The matching is combined with a difference-in-differences approach to control for time invariant unobservables. The study finds an impact of injuries on earned income for older and low-income individuals, but also shows the compensating effects of public transfers in the Danish system.

García-Gómez and López-Nicolás (2006) adopt a matched panel data difference-in-differences estimator. They use panel data from the Spanish component of the ECHP to explore the impact of health shocks on employment and of employment shocks on health. Their strategy is to match exactly on pre-treatment outcomes, in order to control for time invariant observables. This means that controls are restricted to those individuals who were identical to the treated in terms of their pre-treatment outcomes. In order to define the treated and the controls, a three-year window is adopted. In the case of health shocks, the treated are those who are in good health in the first year and then move to bad health in the next two years, and who are in employment for the first two years. The controls remain in good

health throughout the period and are also in employment in the first two years. The outcome is employment status in the third year. In addition to matching on pre-treatment outcomes, PSM is used to make the treated and controls comparable in terms of their observed characteristics. Four methods of matching are compared: nearest neighbor matching on the propensity score; kernel matching on the propensity score; matching of the four nearest neighbors on a set of explanatory variables; and simple matching on the four nearest neighbors according to the propensity score.

Other studies that use matching are summarized in Table 12.2.

12.7.2 Regression discontinuity

The regression discontinuity (RD) design exploits situations where the assignment to treatment changes discontinuously with respect to a threshold value of one or more exogenous variables. The contrast between individuals on either side of the discontinuity is used to identify the treatment effect. In a sharp regression discontinuity design, passing the threshold completely determines the allocation of treatment. In a fuzzy design, which is more likely in practice, the allocation of treatment is stochastic and the threshold creates a discontinuity in the probability of treatment. The discontinuity design relies on a comparison of observations "before and after" the threshold and does not have a separate control group. For this reason, applications typically use a narrowly defined neighborhood around the discontinuity to try and ensure that the treated and untreated observations are comparable in other respects. Studies that use a discontinuity design were described in section 12.2 above (Almond, 2006; Lleras-Muney, 2005; Pop-Eleches, 2006).

12.7.3 Difference-in-differences

The difference-in-differences, or diff-in-diff (DD) approach to evaluation with non-experimental data has been applied extensively in the health economics literature. The method is based on a before and after (pre–post) design with a control group. It can be used with both panel data and repeated cross-sections and requires treatment and control groups to be specified.

The basic form of the DD estimator of the average treatment effect compares mean outcomes for the treated (1) and controls (0) before (B) and after (A) the treatment:

$$ATE_{DD} = (\bar{y}_A^1 - \bar{y}_B^1) - (\bar{y}_A^0 - \bar{y}_B^0). \tag{12.39}$$

With individual panel data, the DD estimator can be computed using a two-way fixed effects specification:

$$y_{it} = \gamma(T_i P_t) + x_{it}'\beta + \nu_t + u_i + \varepsilon_{it}. \tag{12.40}$$

The treatment effect is identified by the parameter (γ) on the interaction term between the indicator for whether the individual is in the treated group (T) and the indicator for the post-treatment period (P).[4] The observed regressors (x) control for any observable differences between the treated and controls and the individual effects (u) control for any time invariant unobservable differences that may be

Table 12.1 Studies that use matching estimators

Study	*Outcome*	*Treatment*	*Method*	*Comment*
Dano (2005)	Earnings, annual employment rate, disposable income, public transfer income	Road traffic accidents	Uses difference-in-differences matching estimator with panel constructed from register data. One-to-one matching without replacement based on linear index from propensity score. Checks for balancing	Finds an impact on earned income for older and low income individuals. Also shows compensating effects of public transfers in the Danish system
Frolich *et al*. (2004)	Labor market outcomes: reintegration into the labor force	Vocational rehabilitation program in western Sweden	Multiple treatments with matching based on multivariate balancing scores computed from multinomial probit models. Uses nearest neighbours with replacement. Checks for balancing of covariates after matching	Finds a negative effect of rehabilitation. Many of the effects are insignificant: many controls are used repeatedly in the matching
García-Gómez and López-Nicolás (2006)	Employment, income, SAH	Health shocks and employment shocks	Use matched difference-in-differences estimator. Combine exact matching on pre-treatment outcomes with propensity score matching. Use both nearest neighbor and kernel-smoothed matching	Find effects of health shocks on employment and activity. Also find an effect of transition to unemployment on SAH

Girma and Paton (2006)	Teenage pregnancy rates	Free over-the-counter access to emergency birth control for teenagers at pharmacies in England	Use difference-in-differences matching estimator with panel data Matching based on nearest neighbors. Impose common support and test for balancing	No evidence that policy leads to lower teenage pregnancy rates
Jalan and Ravallion (2003)	Prevalence and duration of diarrhea in children aged under five in rural India	Piped water supply	Propensity score matching using logit, matching to five nearest neighbors	Finds that matching on household- as well as village-level controls makes a difference. Average effects are misleading as there is a lot of heterogeneity in the treatment effects, with little impact on poorer and less-educated mothers

correlated with the outcome and with the allocation of treatment. In this sense, the DD estimator combines selection on unobservables with selection on observables, so long as the unobservables are time invariant. The time effects (ν) take account of any time trend in the data that is common to both the treatment and control groups. This implies a "parallel trend" assumption. When the DD estimator is applied to repeated cross-section data a further assumption is required: that the composition of the treatment and control groups remains stable over time.

The DD estimator in equation (12.40) is defined above by using the interaction between the post-treatment period (P) and belonging to the treatment group (T). In some applications exposure to treatment may be defined by the interaction between more than two factors. For example, in Schmidt's (2007) evaluation of the impact of infertility insurance mandates on birth rates in the US, an indicator of whether states have mandates is interacted with whether or not women are over 35, as those over 35 are most likely to suffer infertility. Multiple interactions can be used to define exactly who is exposed to treatment and also to allow for heterogeneity in the size of the treatment effect. This approach is often labeled difference-in-difference-in-differences (DDD).

Chalkley and Tilley (2006) show how economic incentives can influence dental practice. This study exploits the comparison between self-employed and salaried dentists working for the NHS in Scotland to show that the financial incentives of FFS increase the intensity of treatment by around 21%. Using a DD approach, the paper finds that self-employed dentists treat exempt patients, who are assumed to be more likely to be influenced by supplier inducement, more intensively than non-exempt patients, relative to salaried dentists who do not face the financial incentive of FFS. These findings are based on an administrative database, the Management Information and Dental Accounting System (MIDAS), that records claims for self-employed and salaried dentists. The database provides a panel of dentists and patients and can be used to control for the practice style of individual dentists as well as measures of patient need.

In January 1994 the health authorities in Belgium increased co-payment rates for home and office visits to GPs and for visits to specialists. The increases were substantial: 35% for GP home visits, 45% for GP office visits and 60% for specialist visits. Cockx and Brasseur (2003) use this change in prices as a natural experiment. To create a control group they use those who were exempt from charges due to low income among widows, orphans, the disabled and retired. This means that identification relies on the treatment and control groups being comparable and the authors note that identification can only be achieved for low-income groups. A DD estimator is applied to the logarithm of utilization and the model is extended to a Rotterdam demand system to accommodate substitution effects induced by the change in relative prices. Interaction terms are used to allow for heterogeneity in the treatment effects. A similar set of reforms in Germany is used as a natural experiment by Winkelmann (2004b). In this case co-payments for prescription drugs increased by 6 DM on July 1, 1997, leading to relative price increases of up to 200% depending on the pack size. The policy is evaluated using data from the GSOEP for the years around the reform, 1995–96 and 1998–99. The control group

here is those exempt from these charges, made up of those with private insurance, co-insured children and low-income households. A DD strategy is adopted, with the effect of the co-payments on doctor visits identified by the interaction between the timing of the reform and exemption from charges. Winkelmann argues that the assumption of a common trend, which is essential for identification, is plausible in this context.

The use of a control group in DD methods help avoids the spurious inferences that can arise in a simple before and after comparison. For example, in Wagstaff and Yu's (2007) evaluation of the impact of the World Bank's Health VIII project in Gansu province in China they find only a small reduction in out-of-pocket spending on health care in counties exposed to the program. A before-and-after comparison would suggest that there was no significant improvement in this outcome. However, the trend in the control group of counties shows a rise in out-of-pocket payments, so the DD estimate reveals better outcomes among the treated relative to the controls. An important caveat is that the validity of the DD estimates relies on the comparability of the treated and controls in terms of the underlying trend in the outcomes. The comparability of treatment and control groups can be enhanced by combining the DD approach with matching estimators (as in Dawson *et al.,* 2007; Galiani *et al.,* 2005; Wagstaff and Yu, 2007). In Wagstaff and Yu (2007), the unmatched DD estimate for the impact of Health VIII on the availability of medical equipment in township health centers does not show a significant effect, but when the controls are matched with treated counties an effect is revealed. This is because the counties selected for the project tended to be poorer than the average among the controls so that, on average, the funds available to invest in equipment in the control counties lead to higher rates of increase. Matching with control counties that face the same sort of financial constraints allows a reliable comparison to be made.

The careful use of matching estimators, which should include tests of whether the treated cases and selected controls are balanced in terms of their observed characteristics, provides a link to strategies for testing the robustness of the identification assumptions that are built into the DD approach. The comparability of the treatment and control groups can be assessed by comparing their observed characteristics prior to treatment and, in particular, by testing the parallel trend assumption prior to treatment. A good example of this is Galiani *et al.* (2005). They use a DD strategy applied to panel data on municipalities in Argentina. The treatment of interest is the privatization of local water services that took place in the 1990s and the outcomes are measures of general and cause-specific child mortality. There is sufficient data for the pre-treatment period to do graphical analysis of the trends in the treatment and control groups. More importantly, it is possible to estimate the two-way fixed effects specification for mortality rates only using the data from the pre-treatment period, but including an indicator of which municipalities would go on to be treated. Evidence that this indicator is significant would undermine the parallel trends assumption and mean that areas that privatized their water supply were systematically different in terms of (trends in) mortality. In fact, Galiani *et al.* find that the common trend assumption is not rejected. Their DD

estimators are refined using a PSM approach. The results show a significant reduction in deaths from infectious and parasitic diseases and suggest that privatization helped to reduce health inequalities. Other studies that combine DD with matching are Dano (2005), García-Gómez and López-Nicolás (2006), Girma and Paton (2006) and Marini *et al.* (2008).

Numerous studies in health economics use the DD strategy. Some of these are summarized in Table 12.3.

12.7.4 Instrumental variables

The DD design is often applied in the context of natural experiments. Natural experiments and natural controls also form the basis for the IV approach, which is intended to capture "selection on unobservables" (see, e.g., Auld, 2006b). This approach relies on the variation in treatment that can be attributed to variation in an exogenous variable, or instrument; assigning individuals to treatments on the basis that the instrument mimics the random assignment of an experimental design. This approach is often hard to apply in practice as instruments should be both powerful predictors of treatment and have no direct effect on outcomes. The search for convincing instruments is therefore fraught with difficulty.

There are two broad estimation strategies. The FIML approach specifies a complete system of equations for the outcomes and treatments and estimates them jointly, allowing for common unobservable factors and identifying the model through exclusion restrictions. Estimation can be by MLE, MSL, MCMC, DFM or copulas, as described in section 12.6 above. The more commonly used approach is the limited-information or single equation approach, using IV estimators, such as 2SLS, GMM and 2SCML. Some studies that use instrumental variables were described in section 12.2 above (Arendt, 2005; Auld and Sidhu, 2005; Evans and Lien, 2005; Gardner and Oswald, 2007; Lakdawalla *et al.,* 2006; Lindahl, 2005). Other applications are too numerous to describe in detail here (some examples are Cawley *et al.* 2006; Contoyannis *et al.,* 2005; Dubay *et al.,* 2001; Dusheiko *et al.,* 2004, 2007; Elliott *et al.,* 2007; Guaraglia and Rossi 2004; Hadley *et al.,* 2003; Jewell and Triunfo, 2006; Kessler and McClellan, 2002; Lindrooth and Weisbrod, 2007; Meer *et al.,* 2003; Sasso and Buchmueller, 2004; Schellhorn, 2001; Sloan *et al.,* 2001; Van Houtven and Norton, 2004; Yelowitz, 2000).

In section 12.1 it was emphasized that, when treatment effects are heterogeneous, the IV estimator identifies a local average treatment effect (LATE) and that this estimate is conditional on the set of instruments that are used. In a recent paper, Basu *et al.* (2007) apply Heckman and Vitlacyl's (1999) LIV estimator which identifies MTEs over the support of the propensity score $p(d = 1|x, z)$. Computation of the LIV estimator involves regressing the outcome y on the observed regressors $x$and on a flexible function of the propensity score, which is estimated using x and the instruments z. The model could be estimated semiparametrically, for example, by using a partially linear model, or, as in Basu *et al.*, by adding polynomial and interaction terms between x and $p(d = 1|x, z)$. The LIV estimator of the $MTE(x,u_d)$

Table 12.3 Studies that use DD

Study	*Outcome*	*Treatment*	*Treated/controls*	*Comments*
Adams (2007)	Relative wages for older workers	Introduction of pure community rating among small group health insurers in New York in 1993	(i) Data for small and large firms in New York only: time interacted with older workers and employment in small firm (ii) Data for small firms in all states: time interacted with older workers and New York	Uses two sets of DDD estimates. Finds an increase in relative wages of older workers in small firms
Carpenter (2004)	Self-reported alcohol use and drunk driving	Zero tolerance drunk driving laws	In DDD estimators zero tolerance laws interacted with age 18–20, the group affected by the laws, and age 22–24	Finds an effect on episodic drinking among males, but for other outcomes
Chalkley and Tilley (2006)	Intensity of dental treatment	Remuneration of dentists, FFS or salary	Interacts salaried versus self-employed dentists with exempt versus non-exempt patients	Find that self-employed dentists treat exempt patients more intensively
Chen *et al*. (2007)	Use of outpatient and inpatient care and health status among the elderly	Introduction of NHI in Taiwan in 1995	Those who became insured under NHI/those already insured	Find an impact on use of care, which is larger for those on low incomes, but not on health
Chen and Zhou (2007)	Height, labor supply, earnings	1959–61 famine in China	Birth cohorts interacted with regional differences in severity of famine (proxied by excess mortality)	Find worse outcomes for those exposed to the famine
Cockx and Brasseur (2003)	Demand for physician services	Increase in co-payments	Non-exempt/exempt	DD applied to a Rotterdam demand system

Continued

Table 12.3 Continued

Study	*Outcome*	*Treatment*	*Treated/controls*	*Comments*
Currie and Hotz (2004)	Childhood accident requiring medical attention	Child care regulations	Aged 0–4/aged 5–9	
Davidoff *et al.* (2005)	Employer-sponsored insurance coverage	Reforms of state regulations of small group insurance market in US	Interacts indicators for reform with high/low risk and small/large firms	Uses DD and DDD estimates with repeated cross-sections
Dawson *et al.* (2007)	Waiting times in ophthalmology	London patient choice experiment (LPCP)	LCPC hospitals/three comparator groups: all hospitals in rest of England; a matched control group; all hospitals from four large metropolitan areas	DD combined with PSM. The results show a small reduction in average waiting times and reduced dispersion within the LPCP hospitals
Dranove *et al.* (2003)	Health care expenditures and health outcomes for patients receiving coronary artery bypass graft (CABG)	Mandatory CABG report card laws adopted in New York State in 1991 and Pennsylvania in 1993	Hospitals affected by reform/hospitals in other states	Use DD estimators in both hospital level and patient level analyses. Find an adverse effect of report cards on outcomes, due to the patient selection they induce. The validity of the DD strategy is assessed by using a cohort of acute myocardial infarction (AMI) patients who, as emergency admissions, should not be subject to patient selection
Dusheiko *et al.* (2006)	Admissions to hospital (chargeable elective, non-chargeable elective and emergency)	Abolition of GP fundholding in England	(Ex-)fundholders/ non-fundholders	Find that abolition of fundholding increased admissions

Finkelstein (2004)	Private insurance coverage for prescription drug expenditure	Medicare coverage	Those aged 63–64 at start of HRS panel survey, who became eligible for Medicare/(younger controls) those aged 60–62 who were never eligible, (older controls) those aged 65–67 who were eligible throughout	Finds no evidence that Medicare is associated with levels of private coverage for drug expenditures
Galiani *et al*. (2005)	Child mortality (general and cause-specific)	Privatization of local water services in Argentina	Privately provided water services/publically provided	Includes careful analysis of robustness of results to "parallel" trends assumption, matching methods and use of cause-specific mortality to assess validity of findings
Jensen and Richter (2004)	Poverty, nutrition, use of medical care	1996 pensions crisis in Russia	In arrears/those who received pensions	
Liu *et al*. (2004)	Hospital length of stay and charges	Postpartum discharge laws in US states	States that enacted the laws/states that did not	Find heterogeneity in the effects depending on how the laws were implemented

Continued

Table 12.3 Continued

Study	*Outcome*	*Treatment*	*Treated/controls*	*Comments*
Marini *et al.* (2008)	Retained surplus/deficit and Reference Cost Index (RCI)	Introduction of Foundation Trusts in England in 2004	Foundation Trusts/three comparator groups: all hospitals in rest of England; a matched control group; all hospitals eligible for Foundation status	Difference in differences combined with PSM. The results show a small increase in surplus and a small decrease in the RCI within Foundation Trusts
Propper *et al.* (2002)	Waiting times for hospital admissions in England (North West Anglia region)	GP fundholding	Fundholders' patients/non-fundholders' patients	Effects on waiting only applied to a limited set of patients and of procedures
Schmidt (2007)	Infertility (first birth rates)	Infertility insurance mandates in US states	Uses interaction between time, whether states have a mandate and age of women (over 35)	Uses DDD estimates. Finds that mandates significantly increase birth rates for women over 35
Wagstaff and Yu (2007)	Use of services, catastrophic expenses, health outcomes	World Bank's Health VIII project, Gansu province, China	Project/non-project counties	DD combined with PSM
Winkelmann (2004a)	Doctor visits	Increase in co-payments for prescription drugs	Non-exempt/exempt	
Wolfe *et al.* (2006)	Public health care coverage of "welfare leavers"	Wisconsin BadgerCare Program (expanded public health insurance eligibility)	(i) Between cohort strategy: 1997 cohort/1995 cohort of leavers (ii) Within cohorts: newly eligible/continuously eligible	DD estimates suggest that BadgerCare increased public coverage by 17–25 percentage points

is then:

$$LIV = \left[\frac{\partial E(y|x, p(x,z))}{\partial p(x,z)} \right]_{1-p(x,z)=u_d} . \tag{12.41}$$

This can be used to test for heterogeneity in the treatment effect and to construct estimates of the other treatment effects of interest, such as the ATE and ATET.

12.8 Future prospects

Like other areas that are rooted in applied microeconomics, such as development, environmental and labor economics, modern empirical analysis in health economics is dominated by the tools of microeconometrics and the use of individual-level data drawn from social surveys and administrative sources. The trend is towards complex longitudinal and multilevel data structures, with increasing reliance on linkage of a variety of sources. Health economists have exploited the full range of microeconometric techniques, and applications to health data have driven methodological innovations in the context of variables with skewed and heavy-tailed distributions, multinomial choices, count data and mixture models.

Much of the empirical analysis done by health economists seeks to estimate causal effects and fits within the treatment–outcomes framework. A challenge for successful applied work is to find appropriate sources of variation to identify the treatment effects of interest. Estimation of causal effects can be prone to selection bias, when the assignment to treatments is associated with the potential outcomes of the treatment. Overcoming this selection bias requires variation in the assignment of treatments that is independent of the outcomes. One source of independent variation comes from randomized controlled experiments. These are the norm in the evaluation of new clinical therapies, but their use for the evaluation of broader health and social programs remains relatively rare.

Applied researchers in health economics face a twin challenge. The first is to make the best possible use of the available non-experimental data by combining robust econometric methods, such as those presented in this chapter, with imaginative and convincing sources of identification. The second is to seek opportunities to encourage the agencies responsible for designing and funding health and social programs to collect new and comprehensive longitudinal datasets, to facilitate the linkage of different datasets and to make greater use of randomized designs in the evaluation of new initiatives.

Acknowledgments

This chapter draws on joint work with Teresa Bago d'Uva, Silvia Balia, Paul Contoyannis, Cristina Hernández Quevedo, Xander Koolman, José Labeaga, Miaw-chwen Lee, Roberto Leon Gonzalez, Nigel Rice, Stefanie Schurer, Eddy van Doorslaer and John Wildman, and by Casey Quinn. I am grateful for comments from Giorgia Marini, Edward Norton, Pedro Rosa Dias and João Santos Silva.

Notes

1. This chapter uses the "treatment-outcome" terminology that is commonplace in the evaluation literature. In practice many treatments are broad policy reforms associated with the financing and delivery of health care rather than specific clinical interventions. Treatment effects are defined here in terms of a binary treatment with just two regimes – the treated and the controls. In practice there may be multiple treatments and varying intensities of treatment.
2. In health economics, latent class models (LCMs) have typically been applied in the context of nonlinear regression models, to allow for the role of unobserved heterogeneity in the relationship between an observed outcome and a set of regressors. In the statistics literature, LCMs are more commonly applied in the context of latent structural variables and a set of observed indicators, such that the indicators are orthogonal conditional on class membership.
3. Comparisons of treatment effects estimated using randomized experiments with those estimated by matching methods in the labor economics literature cast considerable doubt on the validity of such ignorability conditions and hence on the matching approach (e.g., Agodini and Dynarski, 2004; LaLonde, 1986; Smith and Todd, 2001).
4. Bertrand *et al*. (2004) highlight the risk of making misleading inferences using the standard DD estimator if there is serial correlation in the outcomes and the standard errors are not adjusted to take account of it.

Panel Methods to Test for Unit Roots and Cointegration

Anindya Banerjee and Martin Wagner

Abstract

We provide an up-to-date analytical survey of methods which have been developed to deal with estimation and inference in non-stationary panels. The chapter provides information not only on the tools but also interprets the literature and highlights the important challenges that remain. We discuss the difficulties involved in formulating hypotheses within a panel framework with unit roots and cointegration. These issues include incorporating cross-sectional dependence and structural breaks in the data. Both these features are widely prevalent in the panels and lead to complications in estimation and inference. For example, factor models are a widely used class of methods used to deal with dependence but constitute only one of several ways of formulating the problems involved. We argue that the links between cointegration and factor models in panels need to be considered adequately and the asymptotic theory put on a firmer footing in many respects. The study of cross-sectional dependence, breaks, and multiple cointegrating vectors, all of which are in their relative infancy, mark the way for productive research in the years ahead.

13.1 Introduction

Taking a look at the web page of the Groningen Growth Development Centre (http://www.ggdc.net) is a salutary experience. The Centre is devoted to the "comparative analysis of levels of economic performance and differences in growth rates in the world," both in the short and long durée, and the data resources it brings to this analysis are formidable.

Here in its pages are data for population, employment, annual working hours, gross domestic product (GDP) per capita, GDP per person engaged, and GDP per hour, for nearly 125 countries from 1950 onwards. Many of these series utilize the Maddison (2007) historical series, which can also be used to go back to the nineteenth century and in some cases even further into the past.

The 60-Industry Database provides an equally comprehensive dataset on industrial performance. The coverage is at a detailed industry level for Organization for Economic Cooperation and Development (OECD) countries and Taiwan, and the variables studied include: value added in current and constant prices, value added deflators, persons engaged, hours worked and labor productivity. The data cover industries for the period 1979–2003.

Finally, the Industry Growth Accounting Database provides information on labor skills in three categories and on investment and capital services (three information and communications technologies (ICT) asset categories and three non-ICT categories). The countries covered are Australia, Canada, the United States and four European countries (France, Germany, the Netherlands and the United Kingdom). The information is provided in order to allow for a decomposition of output growth into the contributions of labor and capital and total factor productivity using the growth-accounting methodology.

This chapter deals with particular aspects of the study of such large economic datasets, with a view to using this data to analyze economic hypotheses of interest.

13.1.1 An example: economic convergence in the sense of Evans and Karras (1996)

The available large datasets, containing income and other macroeconomic variables, lead us to choose economic convergence as a motivating example. This allows us to discuss some of the possibilities that macro-panel data offer and some issues that arise.[1]

There is an abundance of definitions of convergence in the literature. Given that we consider panel data, we focus on those put forward in Evans and Karras (1996) (abbreviated henceforth as EK). These essentially coincide with the definitions of Bernard and Durlauf (1995, 1996), formulated within a time series context.[2] Three features of EK are of interest to us, within the context of this chapter. First, that the paper studied convergence within the framework of a dataset in which the cross-section dimension N and time series dimension T were both used (in contrast to using only the T dimension and investigating the hypothesis on a country-by-country basis or only along the cross-sectional dimension). Second, the data could be taken to be integrated of order one (or, loosely speaking, needing first-differencing for stationarity). And third, and most importantly, the hypothesis of interest could be formulated in terms of testing for a unit root, in this case at least, in an autoregressive model. This threefold combination of a so-called macro-panel of data (involving gathering together time series information on a variable or a set of variables with the cross-sectional or cross-country information on these variables) with the problem of testing for a non-stationary root, where the hypothesis is formulated as such, gives our chapter its name and decides its focus.

Thus, denote log per capita GDP by $y_{i,t}$, referred to for simplicity as income, in country i in year t, considered to be valued at constant and common international prices. This variable is observed for a collection of $i = 1, \ldots, N$ countries over the years $t = 1, \ldots, T$. Several underlying theoretical formulations of growth models lead to balanced growth paths for each of the economies to which each of the economies converges in the long run. Under some additional assumptions the balanced growth paths of the economies are parallel to each other. Such a set-up is the starting point of EK's statistical definition of economic convergence, which we give below:

Definition (general): Denote by $y_{i,t+j}$ income in country i at time $t + j$ and assume that there exists a process a_t and finite parameters $\mu_1, \ldots, \mu_N$ for which it holds

that $\lim_{j\to\infty} E\left(y_{i,t+j} - a_t\right) = \mu_i$ for all $i = 1, \ldots, N$. Then the economies are said to converge. Convergence is called conditional if not all $\mu_1, \ldots, \mu_N$ are equal to 0 and is called absolute if all $\mu_1, \ldots, \mu_N$ are equal to 0.

This definition of convergence *potentially* leads to several interesting implications for non-stationary panel analysis since it presumes the existence of one joint trend process a_t (which is typically unobservable and is related to technology), such that the limits of the expected values of the deviations from this trend exist and are constant. Given that income is often found to be a unit root non-stationary process, this allows us to reduce or specialize the general formulation given in the definition above to an $I(1)$ context.

Thus, we consider henceforth the income series in the N countries to be jointly described by a vector $I(1)$ process.[3] In this case the EK definition of convergence implies that the deviations from the trend process a_t are asymptotically stationary. It implies furthermore that the cross-section members will not be independent of each other, given their relation to the single common trend a_t. Clearly, if we assume that the income series are $I(1)$, but the deviations from a_t are stationary, this implies that a_t is also an $I(1)$ process. Thus the panel exhibits within this framework cross-sectional dependence via the stochastic component of the common trend a_t. Cross-sectional dependence is discussed in detail in Appendix B. We can already foresee, given that we formulate the discussion here within an $I(1)$ modeling framework, that the specific formulation of the convergence definition of EK has strong cointegration implications which we detail next.

If we keep, for the moment, the cross-sectional dimension as fixed, the joint vector process $y_t = \left(y_{1,t}, \ldots, y_{N,t}\right)'$ is – under appropriate assumptions – also jointly an $I(1)$ vector process and thus has a Granger-type representation, where for simplicity we abstract from detailing the initial values and their effects, given by:

$$\begin{bmatrix} y_{1,t} \\ \vdots \\ y_{N,t} \end{bmatrix} = \begin{bmatrix} C_1 \\ \vdots \\ C_N \end{bmatrix} \eta_t + \begin{bmatrix} D_1 \\ \vdots \\ D_N \end{bmatrix} T_t + c^*(L)\varepsilon_t, \tag{13.1}$$

with $\eta_t \in R^r$ the $r \geq 1$ linearly independent common stochastic trends, $T_t \in R^s$ the deterministic components of the data-generation process (DGP) and $c^*(L)\varepsilon_t$ the stationary part, with L denoting the backward shift operator, that is, $L\left(x_t\right)_{t\in Z} = \left(x_{t-1}\right)_{t\in Z}$ and $c^*(L) = \sum_{j=0}^{\infty} c_j^* L^j$ such that $c^*(L)\varepsilon_t$ is a stationary process.

In particular, in an $I(1)$ setting, the EK definition implies that the cointegrating space for the N-dimensional vector of income series is of dimension $N - 1$. This follows immediately from the fact that any pair-wise difference of income between countries in which the unit root process a_t is annihilated is stationary. Note here that this already implies that all non-constant deterministic components are also annihilated by taking pair-wise differences. Consequently, the definition not only specifies the dimension of the cointegrating space but also fully determines the space itself (that is, a basis of the cointegrating space). Note, furthermore, that by the same argument it is also true that the deviations of any individual income

series from the cross-sectional average are stationary, that is, any of the N series $y_{i,t} - \bar{y}_t$ with $\bar{y}_t = \frac{1}{N}\sum_{i=1}^{N} y_{i,t}$ is also stationary, with mean 0 in the case of absolute convergence. Thus, the definition of convergence in the $I(1)$ context of EK is given by:

Definition (I(1) framework): If each income series $y_{i,t}$ is described by an $I(1)$ process, but all series $y_{i,t} - \bar{y}_t$ are stationary, the set of N economies is said to converge. Convergence is said to be absolute if the means of all the series $y_{i,t} - \bar{y}_t$ are equal to 0 and relative otherwise. The economies are said to diverge if all series $y_{i,t} - \bar{y}_t$ are non-stationary.[4]

Given our Granger representation in (13.1) above, we may ask about the restrictions imposed by this representation, that is, under what conditions are all series $y_{i,t} - \bar{y}_t$ stationary? Computing the cross-sectional average, we obtain:

$$\bar{y}_t = \frac{1}{N}\sum_{i=1}^{N} c_{i,1}\eta_{1,t} + \cdots + \frac{1}{N}\sum_{i=1}^{N} c_{i,r}\eta_{r,t} + \frac{1}{N}\sum_{i=1}^{N} d_{i,1}T_{1,t} + \cdots + \frac{1}{N}\sum_{i=1}^{N} d_{i,s}T_{s,t} + \bar{c}^*(L)\varepsilon_t, \tag{13.2}$$

where we use the notation $C_i = \left[c_{i,1}, \ldots, c_{i,r}\right]$ and $D_i = \left[d_{i,1}, \ldots, d_{i,s}\right]$, and $\bar{c}^*(L)\varepsilon_t = \frac{1}{N}\sum_{i=1}^{N} c_i^*(L)\varepsilon_{i,t}$ is stationary.

Now, in order to have convergence in the EK sense, each of the deviations of the income series from the cross-sectional average has to be stationary. This necessitates that all stochastic trends have to be annihilated – as well as all non-constant deterministic components. Consequently, for all $i = 1, \ldots, N$, it has to hold that:

$$c_{i,k} - \frac{1}{N}\sum_{i=1}^{N} c_{i,k} = 0, \tag{13.3}$$

which implies that $c_{i,k} = c_k$ for all $i = 1, \ldots, N$ and for all $k = 1, \ldots, r$. This in turn implies that only one common stochastic $I(1)$ trend, given by $\eta_t = \sum_{k=1}^{r} c_k \eta_{k,t}$, is present and identifiable in the data.[5] This is, of course, not a surprise given that the EK definition implies the presence of $N - 1$ cointegrating relationships (hence of only one stochastic trend), which is furthermore loaded with the same weight into each series. Similar arguments apply to all non-constant elements in the deterministic component: the coefficient to each non-constant deterministic variable has to be equal for each series; thus, for example, if present in the data, all linear trend slopes need to be identical for relative convergence to prevail. For absolute convergence to hold, in addition, all intercepts need to coincide.

Thus, we see that the EK definition of convergence imposes a lot of structure and hence testable restrictions on the panel of time series. Furthermore, as mentioned previously, it also implies that there is long-run cross-sectional dependence in the panel as defined in Appendix B.

It is worth observing at this stage that if one had enough observations to perform a multivariate time series analysis, in relation to the considerations above, one

would not need to resort to panel techniques. However, this is typically not the case and we therefore turn more specifically to the panel (unit root) implications of the convergence definition. In the case of convergence, each of the series $y_{i,t} - \overline{y}_t$ is stationary and divergence has been defined by EK as (unit root) non-stationarity of all the N series $y_{i,t} - \overline{y}_t$. Thus, the null hypothesis of convergence can be tested by a panel stationarity test, as presented, for example, in section 13.2.1.4. More often, however, the null hypothesis of divergence is tested against the alternative of convergence by using panel unit root tests that are specified against the alternative that all series are stationary. Under appropriate assumptions on the DGP, this can be done within panel Dickey–Fuller-type regressions of the form (with individual-specific autoregressive orders p_i):

$$\Delta\left(y_{i,t} - \overline{y}_t\right) = \delta_i + \rho_i\left(y_{i,t-1} - \overline{y}_{t-1}\right) + \sum_{k=1}^{p_i} \varphi_{i,k}\Delta\left(y_{i,t-k} - \overline{y}_{t-k}\right) + u_{i,t}, \qquad (13.4)$$

with $u_{i,t}$ denoting here the residual process of the autoregression. When the cross-sectionally demeaned data are described by an autoregression of the corresponding order, the processes $u_{i,t}$ are white-noise processes. Note here that EK, despite testing the null hypothesis of divergence, proposed such testing in a Dickey–Fuller-type regression including only intercepts and no other deterministic components, which are in fact not restricted under the divergence hypothesis by EK. Thus, in effect, what EK proposed was to test the null hypothesis of divergence with respect to the stochastic trend whilst allowing only for individual specific intercepts and linear trends. This restriction of the deterministic components needs to be investigated statistically, not least to prevent misspecification of the panel Dickey–Fuller-type regression above.

With the specified restriction, the null hypothesis of divergence is given by $H_0 : \rho_i = 0$ for all $i = 1, \ldots, N$ against the alternative hypothesis $H_A : \rho_i < 0$ for all $i = 1, \ldots, N$, where, as is usual in unit root testing, we really consider only stationary alternatives, which imposes restrictions on ρ_i under the alternative that depend upon the unknown coefficients $\varphi_{i,k}$ in case the data are really described by an autoregression and $u_{i,t}$ is white noise. In general there are no simple links between the innovations ε_t from the Granger representation above and the univariate regression errors $u_{i,t}$, with the latter being a function of the former. Generally, unless very strong restrictions are imposed, the errors $u_{i,t}$ will be cross-sectionally dependent. Issues are, however, even more problematic when testing the null hypothesis of divergence. Under divergence, when there are no restrictions on the stochastic trends present in the panel, the deviations from the cross-sectional averages will also in general be linked by stochastic trends, and these deviations can thus be cross-unit cointegrated.[6] Thus, the discussion here highlights strongly that in general we will need to consider panel unit root (and to a certain extent panel stationarity) tests that allow for cross-sectional dependencies, where in particular cross-sectional dependencies may enter via the errors or may arise via common factors. This is a theme to which we shall return in detail during the course of our chapter.

Clearly, if the panel is characterized by several independent stochastic trends, simple cross-sectional demeaning will not be able to remove all these non-stationary components. Allowing for such a situation – bearing in mind that a full systems analysis will typically not be feasible due to data limitations – is one of the major motivations for considering so-called factor models in the non-stationary panel literature. Factor models, by assuming that the data are generated by the sum of two components, common factors and idiosyncratic components, allow for modeling by putting restrictions on the spectrum of the jointly stationary process Δy_t.[7]

To explain further, let us consider the simplest case in relation to our convergence discussion. Ignoring deterministic components for simplicity, assume that each income series can be written as $y_{i,t} = a_t + \nu_{i,t}$, where the processes a_t and $\nu_{i,t}$ are all independent, and both components are either stationary or $I(1)$ processes. Due to the assumption that a_t and $\nu_{i,t}$ are independent, all series $y_{i,t}$ are also either stationary or integrated. The deviations from the cross-sectional averages are given by $\tilde{\nu}_{i,t} = \nu_{i,t} - \frac{1}{N}\sum_{j=1}^{N} \nu_{j,t} = \left(1 - \frac{1}{N}\right)\nu_{i,t} - \frac{1}{N}\sum_{j=1, j\neq i}^{N} \nu_{j,t}$. Now, in the case of convergence, the second term in this equation converges to 0 (under appropriate technical conditions); whereas in the case of divergence, the second term does not converge to 0. This shows that even if we start with cross-sectionally independent processes $\nu_{i,t}$, the processes $\tilde{\nu}_{i,t}$ describing the deviations from the cross-sectional averages are asymptotically independent as $N \to \infty$ only when convergence prevails, but need not be even asymptotically independent in the case of divergence.

The above example shows that, in general, if one is confronted with unobserved factors, cross-sectional averaging will not necessarily lead to asymptotically cross-sectionally independent series by studying the deviations from the cross-sectional averages. In our example above, due to the unobserved factor a_t being *loaded* in all series with the same weight, considering the deviations from the cross-sectional averages in fact allows elimination of this common factor. However, dependencies are introduced via the series $\tilde{\nu}_{i,t}$ that persist when the series are integrated. These remarks all hold similarly in cases where more than one common factor is considered or the factors do not enter all series with the same weights.

Therefore, when focusing only on the set of joint $I(1)$ processes that can be characterized by factor models, the need for appropriate estimation and inference techniques arises. Such techniques should deliver, again formulated for the convergence example considered here, the following: first, they need to construct consistent estimates of the common factor a_t as well as tests for stationarity (respectively unit root) behavior of this series. Second, the procedures need to establish panel unit root tests for the de-factored series, $y_{i,t} - \hat{a}_t$, where the circumflex indicates that only estimates of the unobservable factor are available. With these tools, convergence in the sense of EK can be tested by establishing first that a_t is an integrated process, and all series $\tilde{\nu}_{i,t}$ are stationary. Essentially these tools, allowing for multiple factors and heterogeneous loadings, have been developed by Bai and Ng (2004).

Note, furthermore, that for many empirical applications it may be necessary to also allow for structural change, which is most often modeled in the deterministic component of the processes. In this chapter we put particular emphasis on structural change and present some evidence that allowing for structural change may alter conclusions drastically. This fact is to a certain extent well-established in the time series unit root literature, starting with Perron (1989), but has found less attention in the non-stationary panel literature.

In section 13.2 we start with a general formulation of testing for a unit root in a panel data setting. This is first specialized to the case of panels with cross-sectionally independent members, but is then extended to a discussion of a more general framework, considering both cross-sectional dependence and structural change. Several sub-sections discuss the results of simulation and empirical studies to evaluate the properties of the tests devised for unit roots. As mentioned above, we illustrate the methods by an empirical study of purchasing power parity and the environmental Kuznets curve. Section 13.3 offers an analogous discussion of testing and estimation for cointegration, and as an additional empirical study, contains an analysis of exchange rate pass-through in the euro-area. In this application issues such as structural stability of the import pass-through equations (in the face of policy changes in the euro-area) are studied with reference to the core problem of testing for cointegration. Section 13.4 concludes.

Three appendices follow the main text. In Appendix A we collect some details on the datasets employed in this chapter; Appendix B contains a brief discussion on cross-sectional dependence; and Appendix C mentions a few aspects with respect to limit theory in non-stationary panels.

It is helpful, perhaps, before starting on the main account, to discuss here briefly how our study differs from some of the excellent studies which are already available; see, for example, Breitung and Pesaran (2008) or the special issue of the *Journal of Applied Econometrics* (2007) devoted to the topic of heterogeneity and cross-sectional dependence in panel data models, or more particularly the chapter by Choi (2006b) in the first volume of this handbook. Some of the material which appears in those sources finds some repetition here, since many of the themes which we deal with cannot be presented without context or introduction. Nevertheless, we believe our chapter contributes to the literature in three distinct and important ways. First, it presents a unified and general formulation of testing for unit roots and cointegration in panel data. Second, in doing so, almost uniquely this chapter pays considerable attention to the role of structural change in panel unit root and cointegration analysis. Structural change has been found to be a substantial issue in the time series context and continues to be so in the panel setting. Finally, by presenting a range of evidence on the performance of the methods, based on both simulation and empirical evidence using a variety of data sources, this chapter attempts to demonstrate unit root and cointegration analysis in panels in action. The material collected in Appendices B and C will also be of some interest by adding to the discussion both on modeling and accounting for dependence and on some key concepts of limit theory for integrated panels.

13.2 Unit root analysis in non-stationary panels

In order to highlight the potential advantages that panel data offer, some appropriate assumptions have to be made. Without any restrictions non-stationary panel data, or, to be more precise, integrated panel data, can be written as:

$$y_{i,t} = D_{i,t} + u_{i,t},$$

where $D_{i,t}$ denotes the deterministic part of the process generating the data, $u_{i,t}$ is the stochastic part, $i = 1, \ldots, N$ is the cross-sectional index and $t = 1, \ldots, T$ is the time index. Now, without any restrictions on the joint stochastic behavior of the $u_{i,t}$ series, no gains from pooling the data (that is, the cross-sectional and time series information), for example by constructing a test statistic, can be expected. Essentially, for the approach to be valuable, parsimonious representations of the joint DGP of the processes $u_{i,t}$ are required. The most parsimonious is given by assuming that the stochastic components $u_{i,t}$ are cross-sectionally independent, which is – especially for macroeconometric questions – too strong an assumption. Thus, in order to allow for cross-sectional dependence in a parsimonious way, so-called (approximate) factor models have gained popularity. These model the individual series $u_{i,t}$ as the sum of two components, namely some common factors F_t and an idiosyncratic component $e_{i,t}$, thus arriving at $u_{i,t} = \pi_i' F_t + e_{i,t}$ with π_i denoting the so-called factor loadings. In this set-up the panel unit root testing problem can formulated for the following data-generating process:[8]

$$y_{i,t} = D_{i,t} + \pi_i' F_t + e_{i,t} \tag{13.5}$$

$$(1 - L)F_t = C(L)\eta_t \tag{13.6}$$

$$(1 - \varphi_i L)e_{i,t} = H_i(L)\varepsilon_{i,t}, \tag{13.7}$$

observed for $t = 1, 2, \ldots, T, i = 1, 2, \ldots, N$, with $C(L) = \sum_{j=0}^{\infty} C_j L^j$ and $H_i(L) = \sum_{j=0}^{\infty} H_{i,j} L^j$. In the general case, F_t is an $r \times 1$ vector of "common factors," generated by some multivariate white noise process η_t, which accounts for the dependence that exists across the units of the panel. The unit-specific idiosyncratic terms $e_{i,t}$ are sometimes considered to be cross-sectionally independent, under the assumption that all cross-sectional dependencies are captured by the common factors. In case the idiosyncratic components are not assumed to be cross-sectionally independent, the above model is known as an approximate factor model. For the statistical analysis of the model as outlined above, appropriate assumptions have to be made both for identification as well as to establish the asymptotic behavior of estimators and test statistics. We discuss one set of possible assumptions when describing the method of Bai and Ng (2004) in section 13.2.2.2.

The properties of the functions $C(L)$ and $H_i(L)$ (see the detailed assumptions in section 13.2.2.2) determine the time series properties of the F and e series. For example, if $C(1) = 0$, F_t will be $I(0)$. If, on the other hand, $C(1)$ is of full rank, F_t is an $I(1)$ process composed of r linearly independent stochastic trends. For intermediate

ranks of $C(1)$ the process F_t is a cointegrated $I(1)$ process with the corresponding number of cointegrating relationships and common trends.

One of the key issues to consider is that both the common part of the processes (modeled via the factors) and the idiosyncratic parts are allowed to be integrated or stationary. This implies that determining the time series properties of the $y_{i,t}$ series requires not only consistent estimation but also inference on the properties of the constituent parts. We may, for example, think of these processes as being integrated "unconditionally" if either the factors or the idiosyncratic parts (or both) are integrated of order one, while conditional on taking account of the factors (that is, the dependence across the units of the panel), the $y_{i,t} - \hat{\pi}_i' \hat{F}_t$ series may be tested for integration or stationarity. The circumflexes above the factor loadings and the factors indicate that, for testing, estimates of these unobserved quantities have to be obtained. Note also that when we talk about stationarity of series, we consider stationarity of the stochastic part of the series, whilst also allowing for the presence of deterministic components $D_{i,t}$.

In general, cross-sectional dependence can arise through the unit-specific idiosyncratic terms as well as through the common factors. Both of these channels in general may lead to cointegration between the cross-section members. To make the discussion more precise, we define the concepts of short- and long-run cross-sectional dependence, as well as of cross-unit cointegration, in detail in Appendix B. There we also discuss in some detail the cointegration implications of the (approximate) factor model. For example, the papers of Banerjee, Marcellino and Osbat (2004, 2005) have highlighted that failing to account properly for cross-unit cointegration may severely distort panel cointegration testing. Further simulation evidence in this respect is contained in Wagner and Hlouskova (2007).

Formulating the discussion in terms of (13.5)–(13.7) above allows us to highlight specific important aspects of the theory of testing for unit roots in panels, summarized as follows.

Deterministics and breaks

For example, a typical formulation of the deterministic part of the process in unit root and cointegration analysis is to consider:

$$D_{i,t} = \mu_i + \delta_i t, i = 1, 2, \ldots, N, \tag{13.8}$$

where the i index denotes unit specificity of the deterministic components. This formulation allows for deterministic unit specific intercepts and trend growth rates, but a generalization allows for breaks in intercept and trend. For example, allowing for up to l_i breaks in the intercept and m_i breaks in trend in unit i gives:

$$D_{i,t} = \mu_i + \delta_i t + \sum_{j=1}^{l_i} \theta_{i,j} DU_{i,j,t} + \sum_{k=1}^{m_i} \gamma_{i,k} DT^*_{i,k,t}, i = 1, 2, \ldots, N, \tag{13.9}$$

where the dummy variables are defined as $DU_{i,j,t} = 1$ for $t > T^i_{a,j}$ and 0 elsewhere, and $DT^*_{i,k,t} = (t - T^i_{b,k})$ for $t > T^i_{b,k}$ and 0 elsewhere. In other words, $T^i_{a,j}$ and $T^i_{b,k}$

denote the date of the *j*th break in the intercept and the *k*th break in the trend slope for the *i*th unit. As in the empirical example in section 13.3.1.5, the specification can be simplified by setting $l_i = m_i = 1 \; \forall \; i = 1, 2, \ldots, N$, but the theory is available for the general case (see, for example, Bai and Carrion-i-Silvestre, 2007).

Cross-sectional dependence

The matrix F_t collects the common effects that are present across the cross-section dimension. The non-stationarity (or integration) of F_t will mean that all the units in the panel have common non-stationary (or integrated) components entering into each individual unit $y_{i,t}$ with loadings of magnitude π_i. Within the context of the Evans and Karras (1996) example, the π_i's are all equal to one, and the single common factor is concentrated out of the problem by cross-sectional demeaning – that is, by constructing the variable $y_{i,t} - \frac{1}{N}\sum_{i=1}^{N} y_{i,t}$, so that the focus then lies on testing the null hypothesis of a unit root in the regression model given by (13.4) above. As mentioned above, however, the simple cross-sectional averaging in general introduces correlations in the error terms describing the deviations from the cross-sectional averages.

As alluded to already in the convergence example, the presence of one or more common stochastic factors with heterogeneous loadings necessitates new testing and estimation strategies. One of these approaches, which is given in the work of Bai and Ng (2004) and Pesaran (2006), considers a general alternative to factor extraction by allowing cross-sectional averages (as $N \to \infty$) to approximate the effects of the unobserved or latent common factors. In this way, the need to estimate the factors and their loadings is avoided. The Pesaran approach, in the context of testing for unit roots, is discussed in section 13.2.2.3.

A further very interesting approach has been introduced in Pesaran, Schuerman and Weiner (2004) and Garratt *et al.* (2006) who introduce the concept of global vector autoregressions (GVARs), which consists of specifying VAR models for each cross-sectional member of the panel, including specifically constructed averages of the other cross-section members' variables as exogenous variables. This approach, feasible whenever the data permit VAR modeling for each cross-section member, is a parsimonious way of combining the information of all cross-section members. The construction of the weighted cross-sectional averages of the other countries' variables is a key issue in this modeling approach. One example considered by the authors is to use trade shares as weights. Obtaining further understanding of appropriate weighting schemes, which in general will depend upon the application considered, as well as the performance of these methods, is an important task. Under certain assumptions the joint system can be solved for based on the individual specific VAR models with exogenous variables. Given that a recent book-length discussion of this approach by Garratt *et al.* (2006) is available, we abstain from including this approach here.

Cross-sectional dependence can also emerge through correlations among the $e_{i,t}$ via the $\varepsilon_{i,t}$ variables across the units *i*, as in models of spatial correlation considered in a paper by Baltagi, Bresson and Pirotte (2007) or in purchasing power parity examples such as O'Connell (1998) discussed below. Note that we discuss in detail

in Appendix B the implications of correlation in the variables $e_{i,t}$, which also can lead to long-run cross-sectional dependencies.

In the simplest case of models (13.5)–(13.7), we could think of switching off cross-sectional dependence by setting $\pi_i = 0$ for all the units, specifying that the $\varepsilon_{i,t}$ are independent over i, and allowing specifications for the deterministic process to be given by (13.8) (that is, without breaks).[9] When $\varphi_i = 1$, and hence $\rho_i = 0$, the series $y_{i,t}$ contains a unit root.

13.2.1 Tests without cross-sectional dependence or structural breaks

Several tests, depending on the specification of the null and alternative hypotheses, have been developed to test for unit roots in panels.

13.2.1.1 Levin, Lin and Chu (2002)

As discussed in the many excellent descriptions in the literature (see, for example, Hlouskova and Wagner, 2006), the test is based on running augmented Dickey–Fuller regressions:

$$\Delta y_{i,t} = \mu_i + \delta_i t + \rho_i y_{i,t-1} + \sum_{k=1}^{p_i} \varphi_{i,k} \Delta y_{i,t-k} + v_{i,t}, i = 1, 2, \ldots, N; t = p_i + 2, \ldots, T. \tag{13.10}$$

Here we denote by $v_{i,t}$ the error process corresponding to the autoregressive specification to which the ADF set-up corresponds. Only if the data are really generated by autoregressions of orders $p_i + 1$ will the $v_{i,t}$ be white-noise processes. In practice this implies that lag length selection will be an issue (see below). Three sub-cases concerning the specification of the deterministic component are considered by Levin, Lin and Chu (2002) (henceforth referred to as LLC):

1. no deterministic terms;
2. intercept only;
3. intercept and linear trend.

We index the specification of these three deterministic components with $m = 1, 2, 3$. The null hypothesis of the LLC test is $H_0 : \rho_i = 0 \, \forall i = 1, 2, \ldots, N$ against the homogeneous alternative hypothesis $H_A : \rho_i = \rho < 0 \, \forall i = 1, 2, \ldots, N$.[10] This formulation of the null and alternative hypotheses allows for the construction of pooled tests (once appropriate corrections are made for the cross-sectional heterogeneity arising from other features of the DGP). Pooling may be made in both the within and between dimensions and gives rise to the tests (LLC and IPS, respectively) described below.

As mentioned above, selection of the lag length in (13.10) is an issue. In case the data are not described by finite-order autoregressive processes, the lag lengths have to increase as a function of the T-dimension of the panel (as was first studied by Said and Dickey, 1984, in the time series context) and LLC propose specifically that $p_i(T)$ grows at rate $T^{\kappa}, 0 < \kappa < 0.25$. Careful lag length selection is necessary to

ensure consistency of estimation by choosing the lag lengths in order to eliminate serial correlation in the error terms; that is, to have, at least asymptotically, white-noise processes $v_{i,t}$. In practice this typically means that information criteria are used to choose the lag lengths to ensure that the estimated residuals $\hat{v}_{i,t}$ show no evidence of serial correlation.[11]

In order to construct the LLC test, for chosen lag lengths p_i, two auxiliary regressions are initially estimated – the first consists of regressing $\Delta y_{i,t}$ on its lags $\Delta y_{i,t-k}, k = 1, 2, \ldots, p_i$, and the deterministic terms; denote the residuals from this regression by $\tilde{e}_{i,t}$. The second consists of regressing $y_{i,t-1}$ on the same set of regressors, to yield residuals denoted by $\tilde{f}_{i,t-1}$. Finally, $\tilde{e}_{i,t}$ is regressed on $\tilde{f}_{i,t-1}$ and the regression standard error from this equation, denoted $\hat{\sigma}_{v,i}$, is used to construct the standardized residuals $\hat{e}_{i,t} = \tilde{e}_{i,t}/\hat{\sigma}_{v,i}$ and $\hat{f}_{i,t-1} = \tilde{f}_{i,t-1}/\hat{\sigma}_{v,i}$. This standardization is needed to remove the effects of cross-sectional heterogeneity of the processes $v_{i,t}$ in (13.10) on the limiting distributions.

The next step is to estimate the long-run variance of $\Delta y_{i,t}$. Recall that under the null hypothesis,

$$\Delta y_{i,t} = \mu_i + \delta_i t + \sum_{k=1}^{p_i} \varphi_{i,k} \Delta y_{i,t-k} + v_{i,t}, i = 1, 2, \ldots, N; t = p_i + 2, \ldots, T,$$

so that a direct estimate of the long-run variance of $\Delta y_{i,t}$ is given by: $\hat{\sigma}^2_{v,i}(1 - \sum_{k=1}^{p_i} \hat{\varphi}^2_{i,k})^{-2}$.

In practice the following estimate is preferred in order to improve the size and the power of the test in finite samples. Denoting by $\hat{u}_{i,t} = \Delta y_{i,t} - \hat{\delta}_{mi} d_{mt}$, where d_{mt} denotes the specification of the deterministic terms, the long-run variance is estimated by $\hat{\sigma}^2_{LR} = T^{-1} \sum_{t=1}^{T} \hat{u}^2_{i,t} + \frac{2}{T} \sum_{j=1}^{L} w(j, L) \sum_{t=j+1}^{T} \hat{u}_{i,t} \hat{u}_{i,t-j}$, with the lag truncation parameter chosen by criteria given in Andrews (1991) or Newey and West (1994). The weights $w(j, L)$ are, in most applications, given by $w(j, L) = 1 - \frac{j}{L+1}$, referred to as the Bartlett kernel. For future reference, define $\hat{s}^2_i = \hat{\sigma}^2_{LR}/\hat{\sigma}^2_{v,i}$ and $\hat{S}_{N,T} = N^{-1} \sum_{i=1}^{N} \hat{s}_i$.

The essential component of the LLC test statistic (under all three deterministic specifications) is given by:

$$\hat{\rho} = \frac{\sum_{i=1}^{N} \sum_{t=p_i+2}^{T} \hat{e}_{i,t} \hat{f}_{i,t-1}}{\sum_{i=1}^{N} \sum_{t=p_i+2}^{T} \hat{f}^2_{i,t-1}},$$

computed from the pooled regression of $\hat{e}_{i,t}$ on $\hat{f}_{i,t-1}$. The t-form of this statistic, to test the null hypothesis $H_0 : \rho = 0$, is given by standardizing $\hat{\rho}$ by the standard deviation of $\hat{\rho}$, denoted $STD(\hat{\rho})$, from the pooled regression.

For the case with no deterministic terms, $t_{\rho=0} \Rightarrow N(0, 1)$ as $T \to \infty$ followed by $N \to \sigma$.[12] However, when either a constant or trend (or both) is present in the model, the t-statistic diverges (due to the presence of the so-called Nickell bias; see Nickell, 1978) to minus infinity (even under the null) and consequently needs to

be re-centered and re-normalized for convergence to a well-behaved distribution. Therefore,

$$t_{\rho *} = \frac{t_\rho - N\tilde{T}\hat{S}_{N,T}STD(\hat{\rho})\mu_{mT}}{\sigma_{mT}} \Rightarrow N(0,1).$$

Here $\tilde{T}$ denotes the effective average sample size, to take into account individual specific numbers of lagged terms across the individual units, while μ_{mT} and σ_{mT} denote the mean and variance corrections for the three different specifications of the deterministic terms. The latter are tabulated by LLC for various dimensions of N and T.

These are interesting results, deriving from the application of sequential (with first $T \to \infty$ followed by $N \to \infty$) central limit theorems, applicable under the assumption of *independent* cross-sectional units whenever the individual building blocks, which are identically distributed once T has passed to infinity, have finite second moments. As we show below, violations of this assumption can lead to severe difficulties, which may be soluble for a number of cases using a range of additional techniques.

Various modifications of the LLC procedure have been proposed, *inter alia*, by Harris and Tzavalis (1999), who derive asymptotic results for fixed T, allowing only the N dimension to tend to infinity, with closed form expressions for the correction factors for serially uncorrelated errors. As for LLC above, appropriately scaled and re-centered t-statistics tend to $N(0,1)$ densities as N tends to infinity, leading to tests which have better properties when the T dimension is relatively small and little or no serial correlation is permitted in the $v_{i,t}$ processes. Breitung (2000) develops, by means of appropriate variable transformations, a modified LLC test which, while coinciding with the LLC test when no deterministic terms are present, does not require bias correction factors for the cases where a constant or trend is present.

Several features of the testing framework above lend themselves to extensions and we shall try to deal with each of these in turn in the sections which follow:

1. relaxing homogeneity;
2. relaxing cross-sectional independence;
3. relaxing structural stability of the deterministic component.

13.2.1.2 Relaxing homogeneity – Im, Pesaran and Shin (2003)

Im, Pesaran and Shin (2003) (henceforth IPS), propose a class of group-mean panel unit root tests to allow for a heterogeneous alternative specified as:

$$H_A^1 : \rho_i < 0 \text{ for } i = 1, 2, \ldots, N_1 \text{ and } \rho_i = 0 \text{ for}$$
$$i = N_1 + 1, \ldots, N, \text{ where } \lim_{N\to\infty} \frac{N_1}{N} = k > 0.$$

IPS present two tests for the case of serially uncorrelated and correlated errors, and for specifications of the deterministic terms allowing for a constant and a constant and linear trend. The two tests are (i) a t-test based on ADF regressions, denoted IPS_t, and (ii) a Lagrange multiplier test, denoted IPS_{LM}. We concentrate here on (i),

where individual specific serial correlation structures are allowed in (13.10), with the assumption that the $y_{i,t}$ follow $AR(p_i + 1)$ processes.

We start by establishing some notation, assuming for simplicity that all required lagged observations are available. From (13.10), let:

$$\begin{aligned}
\tilde{\varphi}_i &= (\varphi_{i,1}, \ldots, \varphi_{i,p_i})' \\
y_{i,-1} &= (y_{i,0}, y_{i,1}, \ldots, y_{i,T-1})' \\
\Delta y_{i,-s} &= (\Delta y_{i,1-s}, \Delta y_{i,2-s}, \ldots, \Delta y_{i,T-s})', s = 0, 1, \ldots, p_i \\
\Delta y_i &= \Delta y_{i,-0} \\
d_{2T} &= (1, 1, \ldots, 1)' \\
t_{VEC} &= (1, 2, \ldots, T)' \\
d_{3T} &= (d'_{2T}, t'_{VEC}) \\
Q_{i,m} &= (d_{mT}, \Delta y_{i,-1}, \ldots, \Delta y_{i,-p_i}), m = 2, 3 \\
M_{Q_{i,m}} &= I_T - Q_{i,m}(Q'_{i,m}Q_{i,m})^{-1}Q'_{i,m}, m = 2, 3 \\
X_{i,m} &= (y_{i,-1}, Q_{i,m}), m = 2, 3 \\
M_{X_i,m} &= I_T - X_{i,m}(X'_{i,m}X_{i,m})^{-1}X'_{i,m}, m = 2, 3.
\end{aligned}$$

Then:

$$t_{iT,m}(p_i, \tilde{\varphi}_i) = \frac{\sqrt{T - p_i - m}(y'_{i,-1}M_{Q_i,m}\Delta y_i)}{(y'_{i,-1}M_{Q_i,m}y_{i,-1})^{1/2}(\Delta y'_i M_{X_i,m}\Delta y_i)^{1/2}}, m = 2, 3.$$

As before, $m = 2$ refers to the specification with a constant but without a linear trend, while $m = 3$ includes both a constant and a linear trend.

IPS_t is based on the cross-sectional average of the corrected t-statistics, that is,

$$IPS_{t,m} = \frac{\sqrt{N}\{\bar{t}_m - \frac{1}{N}\sum_{i=1}^{N} E(t_{iT,m}(p_i, 0)|\rho_i = 0)\}}{\sqrt{\frac{1}{N}\sum_{i=1}^{N} \mathrm{var}(t_{iT,m}(p_i, 0)|\rho_i = 0)\}}} \Rightarrow N(0, 1), \quad m = 2, 3,$$

where:

$$\bar{t}_m = \frac{1}{N}\sum_{i=1}^{N} t_{iT,m}(p_i, \tilde{\varphi}_i),$$

and $E(t_{iT,m}(p_i, 0)|\rho_i = 0)$ and $\mathrm{var}(t_{iT,m}(p_i, 0)|\rho_i = 0)$ are the mean and variance of the Dickey–Fuller statistic respectively for finite T and depend on the nuisance parameters $\tilde{\varphi}_i$. As $T \to \infty$, this dependence disappears and $E(t_{iT,m}(p_i, 0)|\rho_i = 0)$ and $\mathrm{var}(t_{iT,m}(p_i, 0)|\rho_i = 0)$ converge to the mean and variance of the Dickey–Fuller density corresponding to the model estimated (with intercept or with intercept and linear trend).

IPS tabulate these so-called correction terms for a set of values for T and $p_i = p$ for both specifications of the deterministic terms. Use of these correction terms (for

non-asymptotic values of T) is therefore restricted to balanced panels and equal lag lengths in all units of the panel. For large values of T, the use of simulated critical values (specific to the nuisance parameters) can be avoided and the asymptotic critical values can be used instead.

Similar principles apply to the use of the IPS_{LM} test under the additional restriction that $\lim N/T = c > 0$, as first T and then $N \to \infty$.

13.2.1.3 Fisher tests – Maddala and Wu (1999) and Choi (2001)

Continuing to focus on cross-sectional independence, Maddala and Wu (1999) and Choi (2001) developed tests based on combining p-values, an idea due to Fisher (1932). Fisher started his considerations by observing that the p-values of a continuous test statistic are uniformly distributed over the unit interval. Combining this with the fact that minus two times the log of a uniform distribution over the unit interval is distributed as a $\chi^2_{(2)}$ random variable, panel unit root tests can easily be constructed for cross-sectionally independent panels. If the N units are independent, the sum of the p-values, $-2\sum_{i=1}^{N} \log p_i \sim \chi^2_{(2N)}$, under the null hypothesis of a unit root in each unit of the panel. As long as p-values are computable for a test for a unit root on the individual units, either asymptotic, or via means of simulations or response surfaces (see, for example, MacKinnon, 1994, and MacKinnon, Haug and Michaelis, 1995, for augmented Dickey–Fuller tests), the Fisher test can be used to test for unit roots in panels. The key assumption remains that of cross-sectional independence, although its relaxation is possible in some cases (to allow for certain special forms of short-run dependence as described in section 13.2.2.1) by means of bootstrap techniques.

13.2.1.4 Tests with stationarity as the null hypothesis

Tests have also been developed which take as the null that of (heterogeneous) stationary roots against the alternative of a unit root in all cross-section members. Among this class of tests are those due to Hadri (2000) and Hadri and Larsson (2005), which apply the idea developed in Kwiatkowski *et al.* (1992) to the panel framework.

Looking at the specification where a linear trend is present under the null hypothesis, the LM-tests are based on looking at the partial sums of the residuals of the regressions (estimated for each unit):

$$y_{i,t} = \mu_i + \gamma_i t + u_{i,t}, \tag{13.11}$$

where, under the null hypothesis, and only for the sake of illustration, $u_{i,t}$ may be taken to be a serially uncorrelated stationary process.

Denoting by $\hat{u}_{i,t}$ the estimated residuals in (13.11), and their partial sums by $S_{i,t} = \sum_{j=1}^{t} \hat{u}_{i,j}$, the Hadri statistic, denoted by H_{LM}, is given by:

$$H_{LM} = \frac{1}{NT^2} \sum_{i=1}^{N} \sum_{t=1}^{T} \frac{S_{i,t}^2}{\hat{\sigma}_{u,i}^2},$$

where:

$$\hat{\sigma}_{u,i}^2 = \frac{1}{T}\sum_{t=1}^{T}\hat{u}_{i,t}^2.$$

Under the null, using sequential convergence (that is, as before, $T \to \infty$ followed by $N \to \infty$), the re-centered and re-scaled Hadri statistic is given by:

$$Z_{LM} = \frac{\sqrt{N}(H_{LM} - \xi)}{\zeta} \Rightarrow N(0, 1).$$

The correction terms depend on the specification of the deterministic process and are given by Hadri (2000). The extension to the case of serially correlated (but stationary under the null) errors is easily dealt with by using an estimator of the long-run variance of $u_{i,t}$.

Hadri and Larsson (2005) allow for fixed T by deriving the finite sample mean and variance of $\kappa_{i,T} = \frac{1}{T^2}\sum_{t=1}^{T}\frac{S_{i,t}^2}{\hat{\sigma}_{u,i}^2}$, so that, by a simple application of central limit theory, it follows that:

$$H_T = \frac{1}{\sqrt{N}}\sum_{i=1}^{N}\left(\frac{\kappa_{i,T} - \mathrm{E}\kappa_{i,T}}{\mathrm{var}(\kappa_{i,T})}\right) \Rightarrow N(0, 1) \text{ as } N \to \infty.$$

As before, the correction terms depend on the specification of the deterministic component and are given by Hadri and Larsson (2005). Note also that the closed form expressions for the correction factors derived in Hadri and Larsson are only correct for the case of serially uncorrelated errors, which limits the usefulness of the test to some extent.

13.2.1.5 A summary of simulation evidence (Hlouskova and Wagner, 2006)

We describe briefly here the results of a large-scale simulation study undertaken by Hlouskova and Wagner (2006) on many of the tests described above. For further details, we refer the reader to their paper, which provides a meticulous account of the behavior of the tests for unit roots in panels that are cross-sectionally independent as a function of numerous features of the DGP and estimation methods, including the dimensions of T and N, lag selection algorithms in the augmentation of the Dickey–Fuller tests, the presence of moving average terms in the error processes, and certain forms of cross-sectional correlation, given by either constant correlation or geometrically declining correlations by assuming the correlation matrix to be of Toeplitz form.

Hlouskova and Wagner conclude that the best performance in terms of power, where the evidence is based on simulations, for the case where the model has an intercept, is displayed by the LLC test or its modification proposed by Breitung (2000). For short panels, the Harris and Tzavalis (1999) modification of LLC offers some gains in panels where the errors are not serially correlated or the amount of serial correlation is small. They also observe that, when T is small

relative to N, the size and power properties of panel tests are affected adversely. The presence of moving average terms distorts the size of tests especially as the moving average coefficient θ in the process $v_{i,t} = \varepsilon_{i,t} + \theta\varepsilon_{i,t-1}$ tends to -1. This is a feature of tests for unit roots that is also evident in the time series case (see Molinas, 1986, or Schwert, 1989). Appropriate selection of the lag length in the ADF regressions is an issue here, since one way to account for the moving average dynamics is by sufficiently expanding the order of the autoregressions. As noted in a previous section, the impact of lag length selection, by various criteria such as AIC or BIC, is found to be ambiguous – beneficial in some cases and harmful in others. Evidence overall tends to suggest that, for θ close to zero, smaller lag lengths than those selected by the BIC tend to lead to better performance of the unit root tests, while the converse is true for values of θ close to -1.

13.2.2 Allowing for cross-sectional dependence

An important assumption underlying the so-called first-generation tests for unit roots in panel data, discussed in the previous section, is that of cross-sectional independence of the units of the panel. It is important, therefore, to assess the consequences of making this assumption when applying these techniques to datasets where it is not sustainable. As in our discussion of EK, in our view this appears to be relevant for many of the datasets for which one would have occasion to use unit root or cointegration tests in panels.

The motivation for the research presented next is to begin by analyzing, within the framework of some simulation studies, the consequences of departures from cross-sectional independence for the size and power properties of the first generation of commonly-used tests for unit roots in panels, and then to consider in detail the second generation of unit root tests that have emerged to allow for dependence. It is possible to generalize this framework to allow for structural breaks and we shall return to this issue in a later section.

Some particular examples of cross-sectional dependence are presented here, which we classify as short-run and long-run dependence according to the discussion and definition given in Appendix B. We distinguish between these two forms of dependence according to whether cross-unit cointegrating relationships, also defined in Appendix B, are present in the panel or not. While there are many ways of formulating dependence in panels, what is needed is the development of a general framework to incorporate the different possibilities and analyze their consequences. Appendix B contains a few simple observations.

13.2.2.1 Exemplifying the effects of cross-sectional dependence (O'Connell, 1998)

The study of O'Connell (1998) is a powerful demonstration of the oversizing of the LLC tests in the presence of short-run dependence. His simulation results have since been replicated and generalized, for example, by Hlouskova and Wagner (2006) and Baltagi, Bresson and Pirotte (2007). In the latter paper, cross-sectional dependence is derived from so-called spatial correlations. Describing some of this

research is the main motivation for this section, with a view to describing some of the general principles involved.

Our discussion is in several parts. We start by discussing O'Connell's contribution to the debate on testing for purchasing power parity in panels. By setting out the data-generation processes in some detail, we describe how O'Connell introduces short-run dependence into the panel. Second, we present some of O'Connell's results to describe the size distortions arising from this dependence. We discuss some solutions proposed to deal with that dependence. Based on this discussion, we then proceed in the following sub-sections to a discussion of the second generation of unit root tests aimed at modeling cross-sectional dependence, focusing on the work of Bai and Ng (2004) and other authors who have made use of factor models.

Consider, for illustration, the DGP given by:

$$\Delta y_{i,t} = \varepsilon_{i,t}, \quad i = 1, 2, \ldots, N; \quad t = 2, 3, \ldots, T,$$

where, for the purposes of the illustration, we may take $\varepsilon_{i,t} \sim$ i.i.d. $N(0, 1)$ without much loss of generality and where we also abstract from deterministic components. $y_{i,t}$ is therefore a simple random walk process. The model to be estimated is given by a simplified version of equation (13.10):

$$\Delta y_{i,t} = \mu_i + \rho_i y_{i,t-1} + \varepsilon_{i,t}, \quad i = 1, 2, \ldots, N; \quad t = 2, 3, \ldots, T.$$

The model is used to test:

$$H_0 : \mu_i = \rho_i = 0,$$

against the alternative:

$$H_A : \mu_i \neq 0; \quad \rho_i < 0,$$

although the results described below (taken from O'Connell, 1998) are based on looking only at the t-statistic for the estimate of the autoregressive parameter. It should be noted that, as usual within the LLC framework, ρ_i is restricted to be the same across all N units under both the null and alternative hypotheses. The testing framework can be augmented by polynomials of time, in particular by a linear trend t.

Now, under the normality and independent and identically distributed (i.i.d.) assumptions, cross-sectional dependence between the series is fully characterized by the *dynamic* covariance structure of the joint process $\varepsilon_t = \left(\varepsilon_{1,t}, \ldots, \varepsilon_{N,t}\right)'$. To make the discussion as simple as possible, consider a situation, like O'Connell (1998) does implicitly, where the joint random vector is also normally distributed and where the only correlations occur contemporaneously, in which case the dependence structure is fully characterized by $\Omega = E(\varepsilon_t \varepsilon_t')$. The joint vector of all disturbances $\varepsilon = \left(\varepsilon_1, \ldots, \varepsilon_T\right)'$ has its block-diagonal covariance, in our set-up

equal to the correlation, matrix given by:

$$\Sigma = \begin{pmatrix} \Omega & 0 & \dots & 0 \\ 0 & \Omega & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \dots & 0 & \Omega \end{pmatrix}.$$

In order to analyze the effect of cross-sectional dependence, O'Connell (1998) studied the effects of relaxing the assumption of diagonality of the matrix Ω on the performance of the LLC tests, using the original LLC correction factors and critical values derived under the assumption of cross-sectional independence. In particular, O'Connell considers the following simple shape of the correlation matrix, also used by Hlouskova and Wagner (2006) as one of their designs which they label, for obvious reasons, constant correlation:

$$\Omega = \begin{pmatrix} 1 & \omega & \dots & \omega \\ \omega & 1 & \ddots & \vdots \\ \vdots & \ddots & \ddots & \omega \\ \omega & \dots & \omega & 1 \end{pmatrix}.$$

This formulation imples that the "distance" between the cross-sectional disturbances is not considered relevant economically. Various justifications for such a covariance structure can be offered from examples dealing with spatial structures or for purchasing power parity based applications.[13] However, here it serves only for the purposes of illustration within the context of a Monte Carlo study. The simple O'Connell design also ensures that there is no long-run dependence for $-1 < \omega < 1$.

The simulations were conducted with the following choices of sample sizes and parameters in the DGP:[14]

$$N \in \{10, 50, 90\}$$
$$T \in \{20, 60, 100\}$$
$$\omega \in \{0, 0.3, 0.5, 0.7, 0.9\},$$

with the disturbances distributed as described above. It is worth pointing out that the $\{N, T\}$ combinations considered do have relevance for assessing the results of the simulations, since a number of the asymptotic results on the properties of unit root tests in panels impose joint conditions on N and T tending to infinity in order to prove the theorems. This is also a crucial issue that arises later when discussing factor estimation.

For given values of N, T and ω, the t-statistic $\hat{\rho}/\widehat{\sigma}_{\hat{\rho}}$ (denoted t_{OLS}) was computed and compared (for each of the 5,000 replications/panels) with critical values (at 1%, 5% and 10%) tabulated by LLC, designed for the case without correlation, that is, for $\omega = 0$.

The results, as reported in O'Connell (1998, p. 6, Table 1) for non-zero values of ω, were quite dramatic. He showed that, for example for T= 20, N= 10 and ω = 0.3, the true size of the test at 5% (respectively 10%) nominal size, if LLC critical values are used, was 9% (respectively 15%). These distortions increased as ω increased – for example, when $\omega = 0.9$, for the same configuration of T and N, the rejections of the true null hypothesis at 5% (respectively 10%) increased to 37% (respectively 43%). The size distortions were not affected significantly by increasing T for fixed N. Thus the configurations $T = 60$, $N = 10$, $\omega = 0.3$ and $T = 100$, $N = 10$, $\omega = 0.3$ give rejections of 9% (respectively 15%) at 5% (respectively 10%) nominal size, which are unchanged from their $T = 20$ values. The distortions, however, do increase with N for fixed T and ω. For $T = 20$, $N = 50$, $\omega = 0.3$, the rejection at 5% (respectively 10%) increases to 21% (respectively 28%) and to 31% (respectively 37%) when N is raised to 90, and these numbers are even higher when ω is also increased.

Adjusting the critical values to control for the size of the test leads to a severe reduction in power. For example, the power of the t-test to reject $H_0 : \rho_i = 0$ against the alternative $H_0 : \rho_i = -0.04$ (reported in O'Connell, 1998, p. 6), where this non-zero value of ρ_i gives a half-life of deviation from purchasing power parity of between four and five years and is coherent with empirical estimates, is 8% when $T = 20$, N = 10, 14% when T =20, N= 50, and 13% when $T = 20$, $N = 90$. ω here is 0.3 and the confidence level of the tests is 5%. For T = 60 and N = 50, power drops from 92% (when ω = 0) to 30% (when ω = 0.5) and to 9% (when ω = 0.9). Thus the necessity to counteract distortions neutralizes any beneficial effects of increasing N, the longitudinal dimension of the panel, and the loss of power involved – as a result of the necessary adjustment – is clearly a serious one. Indeed, the trade-off between the N and T dimensions, which is evident from both the asymptotic theory and the empirical implementation, is a topic which is relatively ill-studied in the literature.

In order to account for the non-zero off-diagonal terms in Ω, O'Connell proposed the following generalized least squares (GLS) estimator:

$$\hat{\rho}_{GLS} = \frac{tr(X'\Delta Y\Omega^{-1})}{tr(X'X\Omega^{-1})},$$

where ΔY is a $T \times N$ matrix of the first-differenced ys and X is a matrix of lagged ys. When $\omega = 0$, we recover the usual ordinary least squares (OLS) estimator. Thus:

$$\Delta Y_{T\times N} = \begin{pmatrix} \Delta y_{1,1} & \Delta y_{2,1} & \cdot & \cdot & \cdot\cdot & \Delta y_{N,1} \\ \Delta y_{1,2} & \Delta y_{2,2} & \cdot & \cdot & \cdot & \Delta y_{N,2} \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \\ \Delta y_{1,T} & \Delta y_{2,T} & \cdot & & & \Delta y_{N,T} \end{pmatrix}.$$

Computation of the feasible GLS estimator, denoted by $\hat{\rho}_{FGLS}$, requires a consistent estimator of Ω. Allowing only for contemporaneous correlation, a consistent

estimator of Ω is given by the (estimated) covariance matrix of the first differences of the vector y_t, that is,

$$\hat{\Omega} = T^{-1} \sum_{t=1}^{T} \Delta y_t \Delta y_t'$$

$$\Delta y_t = (\Delta y_{1t}, \Delta y_{2,t}, \ldots, \Delta y_{N,t})'$$

and, therefore,

$$\hat{\rho}_{FGLS} = \frac{tr(X' \Delta Y \hat{\Omega}^{-1})}{tr(X' X \hat{\Omega}^{-1})}.$$

Clearly, with this estimator not all correlations between the cross-section members need to be identical, as assumed by O'Connell to illustrate the issues in the simulation part of his paper. The results reported in O'Connell (1998, p. 12, Table 3) are encouraging because the rejection frequencies under both the null hypothesis (size) and the alternative hypothesis (power) are now invariant to the value of ω in the DGP, and depend on T and N alone. Provided T is much larger than N, the power of the FGLS test comes close to the OLS panel unit root test when the disturbances are independently and identically distributed. Efficiency losses ensue as N comes closer and closer to T, which Hlouskova and Wagner (2006) refer to as size divergence when N is "too large" compared to T.

The discussion above serves to introduce and illustrate some of the main issues involved, but is nevertheless too specialized, applying as it does to only one highly restrictive specification of cross-sectional dependence. More general methods for dealing with short-run cross-sectional dependence will be discussed below (including dealing with nonparametric methods for estimating the variance covariance matrix of the disturbances when there is dependence across the units).

13.2.2.2 Cross-sectional dependence via approximate factor models – Bai and Ng (2004)

An important class of tests developed to allow for long-run cross-sectional dependence is due to Bai and Ng (2004). Returning to the formulation given by (13.5)–(13.7), the basic idea is to think of the series comprising the panel as consisting of the sum of a set of deterministic terms, common factors and idiosyncratic components. The detailed assumptions made by Bai and Ng are given by:

(i) For non-random π_i, $||\pi_i|| \leq A$; for random π_i,

$E||\pi_i||^4 \leq A$, $\frac{1}{N} \sum_{i=1}^{N} \pi_i \pi_i' \to \Sigma_\Pi$, an $r \times r$ positive definite matrix, where $\to$ denotes convergence in probability.

(ii) $\eta_t \sim i.i.d.(0, \Sigma_\eta), E||\eta_t||^4 \leq A, \text{var}(\Delta F_t) = \sum_{j=0}^{\infty} C_j \Sigma_\eta C_j' > 0, \sum_{j=0}^{\infty} j||C_j|| < A$, $C(1)$ has rank r_1, $0 \leq r_1 \leq r$.

(iii) For each i,

$$\varepsilon_{i,t} \sim i.i.d.(0, \sigma_{\varepsilon_i}^2), E|\varepsilon_{i,t}|^8 \leq A, \sum_{j=0}^{\infty} j||H_{i,j}|| < A, \omega_i^2 = H_i(1)^2\sigma_{\varepsilon_i}^2 > 0;$$

$\varepsilon_{i,t}$ are independent over i.[15]

(iv) The errors $\varepsilon_{j,t}$, $\eta_{s,i}$ and the loadings π_i form three mutually independent groups for all (j, t, s, i).[16]

(v) $E||F_0|| \leq A$, and for all i =1,2,...,N, $E|e_{i,0}| \leq A$.
