In the assumptions A is taken to be a positive number not depending on either T or N. The notation $||B|| = \text{trace}(B'B)^{1/2}$.

Both the factors and the idiosyncratic components can be integrated or stationary, so that short- and long-run dependence can be modeled both via the common factors and also the idiosyncratic components. However, in our discussion we assume that in (13.7) the idiosyncratic terms are taken to be independent across i, which is slightly stronger than the assumptions necessary for applicability of the Bai and Ng (2004) methods.

The heart of the unit root analysis consists of making the decomposition (between common factors and idiosyncratic terms) and then testing each of these components for a unit root. Thus, returning to the set-up described by (13.5), let:

$$y_{i,t} = \mu_i + \pi_i' F_t + e_{i,t},$$

where F_t is an $r \times 1$ vector of "common factors." The model can be rewritten in first differences:

$$\Delta y_{i,t} = \pi_i' f_t + z_{i,t}, \quad i = 1, 2, \ldots, N; \; t = 2, 3, \ldots, T,$$

where:

$$f_t = \Delta F_t, \; t = 2, 3, \ldots, T$$
$$z_{i,t} = \Delta e_{i,t}, \; i = 1, 2, \ldots, N; \; t = 2, 3, \ldots, T.$$

Next, define:

$$Y = (y_1, y_2, \ldots, y_N),$$

as the $T \times N$ matrix of all observations, where:

$$y_i = (y_{i,1}, y_{i,2}, \ldots, y_{i,T})',$$

and:

$$\tilde{y} = \Delta Y = (\Delta y_1, \ldots, \Delta y_N),$$

is the corresponding $(T-1)\times N$ matrix of first differences. The principal component estimator $\hat{f}$ of $f = (f_2, f_3, \ldots, f_T)'$ is $\sqrt{T-1}$ times the r eigenvectors corresponding to the r largest eigenvalues of the $(T-1) \times (T-1)$ matrix $\tilde{y}\tilde{y}'$ and the estimated factor loading matrix given by $\hat{\pi} = (\hat{\pi}_1, \ldots, \hat{\pi}_N)'$ is obtained from the relationship

$\hat{\pi} = \tilde{y}'\hat{f}/(T-1)$ under the normalization $\hat{f}'\hat{f}/(T-1) = I_r$, where I_r is the $r \times r$ identity matrix.

The estimated factors can now be recovered by summation:

$$\hat{F}_t = \sum_{s=2}^{t} \Delta\hat{f}_s, t = 2, \ldots, T.$$

If r= 1, this single factor can be tested for a unit root using an augmented Dickey–Fuller test with an intercept.

If (13.5) contains a linear trend in addition to an intercept, the method of principal components is applied to the *demeaned* and *differenced* data and the ADF test for the factor contains an intercept and a trend. The critical values for both these sets of tests are as provided by Dickey and Fuller (1979).

When the number of common factors r is greater than 1, Bai and Ng (2004) also develop tests for the number of linearly independent $I(1)$ common trends (equivalently the cointegrating rank) contained in the common factors. After an appropriate basis change the number of stationary factors is given by r_0, and there are r_1 linearly independent integrated factors or common trends, such that, as always in the $I(1)$ framework, $r_0 + r_1 = r$.

The two test statistics ($MQ_c(m)$ and $MQ_f(m)$) follow, up to a transformation to ensure real valued test statistics, Stock and Watson (1988). The test statistics for testing the null hypothesis of m common trends in the common factors are computed recursively with the first test statistic based on $r = m$ common factors. The statistic $MQ_c(m)$ is based on estimating a VAR(1) process for $\hat{Y}_t$, where $\hat{Y}_t = \hat{\beta}_{ORTH}\tilde{F}_t$, and where, in the first step, $\tilde{F}_t$ is the m-dimensional vector of factors computed from the demeaned, respectively demeaned and detrended observations, while $\hat{\beta}_{ORTH}$ is the matrix of m eigenvectors associated with the m eigenvalues of the matrix given by $\frac{1}{T^2}\sum_{t=2}^{T}\tilde{F}_t\tilde{F}_t'$. The statistic $MQ_f(m)$ is constructed similarly, except that a pth order VAR is fitted first to get $\hat{y}_t = \hat{\Pi}(L)\hat{Y}_t$ and the test is based on the filtered $\hat{y}_t$ series.

The testing procedure consists of constructing a sequence of these MQ statistics, starting with testing the null hypothesis $m = r$ (that is, r stochastic trends) against the alternative hypothesis $m = r - 1$, and testing down until the first non-rejection of the null hypothesis occurs; for example, in the second step, the test statistic is based on only $r-1$ eigenvectors $\hat{\beta}_{ORTH}$ corresponding to the $r-1$ largest eigenvalues (for a detailed description see Bai and Ng, 2004, pp. 1133–4).

Two versions of these statistics are considered by the authors to allow for demeaning and/or detrending of the observations, depending upon the model considered. Critical values are provided by them for up to six stochastic trends.

Similarly, the estimated idiosyncratic components can also be tested for unit roots. These are obtained from $\hat{e}_{i,t} = \sum_{s=2}^{t}\Delta\hat{z}_{i,s}$, $i = 1, 2, \ldots, N$; $t = 2, \ldots, T$, with $\Delta\hat{z}_{i,s} = \Delta\hat{y}_{i,s} - \hat{\pi}_i'\hat{f}_s$. The additional complication here is that the estimates that are available are not, in general, cross-sectionally independent in finite samples due to their dependence upon the estimated factors and loadings. We believe that

this issue, which complicates the use of first-generation panel unit root tests on estimated de-factored data, is not considered carefully enough in the literature.

Bai and Ng derive the asymptotic behavior of tests paralleling those of Choi (2001) and Maddala and Wu (1999), henceforth referred to as BN_N and BN_{χ^2}, under the assumption of cross-sectional independence of the idiosyncratic components.

The Choi (2001)-type test is constructed as follows. Denote the p-value associated with the ADF test on the residual series from the ith unit, $\hat{e}_{i,t}$, $i = 1, 2, \ldots, N$, by $p_{\hat{e}}(i)$. Then the following result:

$$BN_N = \frac{-2\sum_{i=1}^{N} \log p_{\hat{e}}(i) - 2N}{\sqrt{4N}} \Rightarrow N(0, 1),$$

can be established by careful analysis, paralleling the type of panel unit root test proposed by Choi (2001) for cross-sectionally independent panels. The test statistic BN_{χ^2} is, of course, given by $-2\sum_{i=1}^{N} \log p_{\hat{e}}(i) \sim \chi^2_{(2N)}$.

Note that simple sequential limit theory with first $T \to \infty$ followed by $N \to \infty$, as used in the panel unit root tests for cross-sectionally independent data, does not apply here. This stems from the fact that consistent estimation of factors and loadings is based on joint limit theory with minimum rate restrictions for both dimensions of the panel, which implies that the observed $\hat{e}_{i,t}$ are, in general, not cross-sectionally independent for finite samples even under the assumption that the $e_{i,t}$ are independent. The panel unit root test result is established both when the factors are computed after differencing (intercept only case) and after differencing and demeaning (intercept and trend), and requires that the idiosyncratic terms be independent across i. It should be noted, however, that the main results of the Bai and Ng (2004) paper (consistent estimation of the factors and loadings and testing for common trends in the common factors) allow for weak cross-sectional correlation of the idiosyncratic errors.

Two general observations should be made of the Bai and Ng method. First, it is sufficient that at least one integrated factor be present for all the $y_{i,t}$ series to have unit roots, if this factor is loaded into all series. Bai and Ng (2004) call this integration or non-stationarity due to "a pervasive source." The integration properties of the idiosyncratic components, however, feed, under the assumption of their cross-sectional independence, uniquely into each series. That is, if all common factors are stationary the series $y_{i,t}$ has a unit root if and only if $e_{i,t}$ has a unit root. This is referred to as a "series specific source" and may be thought to be a measure of the existence or otherwise of a unit root in a given unit of a panel once account has been taken of all the common trends driving the data (and describing the dependence). The judgment on which is the more important source depends upon the phenomenon being studied – that is, whether each series has its "own root" or whether it comes from the same factor(s).

Second, the importance of the Bai and Ng (2004) analysis is in showing that, by applying the method of principal components to first-differenced data, it is possible to obtain consistent estimators of the factors and the idiosyncratic terms regardless

of the dynamic properties of these series (under the assumptions posited above). That is, the tests for the number of common stochastic trends do not depend on whether the idiosyncratic components are stationary, while the tests for whether the errors are stationary do not depend on the presence or absence of common stochastic trends.

To be set off against these advantages are the restrictions (for example, the restrictions with respect to cointegration discussed Appendix B) implied by modeling dependence via common factors – and whether alternative approaches such as GVAR models should be considered. In addition the finite sample properties of factor-based methods, which have not always been shown to be encouraging, need to be considered in more detail.

13.2.2.3 Specializations of the Bai and Ng (2004) framework

Three specializations of the Bai and Ng procedure may be considered briefly, since they serve to illustrate some principles for dealing with cross-sectional dependence, which have been explored in more general contexts (see, for example, Pesaran, 2006).

Pesaran (2007)

The first specialization, due to Pesaran (2007), allows for the dependence among the cross-sectional units of the panel to derive only from one *stationary* common factor in the disturbances of each unit, with this common factor entering into the units with heterogeneous loadings.

His DGP takes the following form:

$$\begin{aligned} y_{i,t} &= (1-\varphi_i)\mu_i + \varphi_i y_{i,t-1} + u_{i,t} \\ u_{i,t} &= \pi_i f_t + \varepsilon_{i,t} \\ & i = 1, 2, \ldots, N;\ t = 1, 2, \ldots, T. \end{aligned}$$

The following assumptions are put in place:

(i) The idiosyncratic errors $\varepsilon_{i,t}$ are independently distributed across both i and t, have mean zero, variance σ_i^2 and finite fourth-order moment.
(ii) The common factor f_t is serially uncorrelated with mean zero, constant variance σ_f^2 and finite fourth-order moment.
(iii) $\varepsilon_{i,t}, f_t$ and π_i are mutually independent groups.

The assumption of serially uncorrelated error $u_{i,t}$ can be relaxed (see Pesaran, 2006, for details).

The null and alternative hypotheses are as for the IPS test (remember that $\rho_i = \varphi_i - 1$). Under the null hypothesis ($\varphi_i = 1, \rho_i = 0$) there is no trend in the data. With this rather restrictive specification, Pesaran proposes the use of a cross-sectionally augmented version of the IPS_t test described above. The procedure consists of including cross-sectional averages of the level and of lagged differences

in the IPS-type regressions, where the former are taken to act as a proxy for the single common factor for N sufficiently large. Lags of the cross-sectional averages may be utilized if necessary to take account of serial correlation in the $u_{i,t}$ process.

Thus, using (for the case without linear trend),

$$\Delta y_{i,t} = \mu_i + \rho_i y_{i,t-1} + c_i \bar{y}_t + d_i \Delta \bar{y}_t + \sum_{k=1}^{p_i} \varphi_{ik} \Delta y_{i,t-k} + v_{i,t}, \; i = 1, 2, \ldots, N; \; t = p_i + 2, \ldots, T, \tag{13.12}$$

where the cross-sectional average of the $y_{i,t}$ terms is:

$$\bar{y}_t = \frac{1}{N} \sum_{i=1}^{N} y_{i,t}, \text{ and}$$
$$\Delta \bar{y}_t = \frac{1}{N} \sum_{i=1}^{N} \Delta y_{i,t},$$

the $CIPS_t$ test is given by:

$$CIPS_t = \frac{1}{N} \sum_{i=1}^{N} CADF_i,$$

with $CADF_i$ denoting the Dickey–Fuller t-statistic for testing $H_0 : \rho_i = 0 \; \forall \; i$ in (13.12). This test harks back both to the idea of using group mean tests to allow for heterogeneity of the autoregressive root under the alternative hypothesis and of using cross-sectional averaging to allow for cross-sectional dependence across the units. The latter may not be effective, depending on the nature of the dependence being modeled.

Pesaran (2007) investigates the asymptotic null distribution of the individual $CADF_i$ statistics as well as of the associated $CIPS_t$ test statistic. The former allows for the construction of p-values for the individual (that is, unit by unit) $CADF_i$ test statistics so that tests in the spirit of Maddala and Wu (1999) or Choi (2001) can be constructed. The asymptotic distributions are derived both for sequential asymptotics as well as joint asymptotics (N and T tending to infinity such that $N/T \to k$, where k is a fixed finite non-zero positive constant). Pesaran shows that the $CADF_i$ statistics do not depend on the factor loadings but are asymptotically correlated through their dependence on the common factor. This has the consequence that standard central limit theorems cannot be used to derive the asymptotic distribution of either $CIPS_t$ or of the pooled p-value tests. A truncated $CIPS_t$ test statistic, denoted $CIPS_t^*$, is also proposed with better properties. Critical values for both $CIPS_t$ and $CIPS_t^*$ are presented for the three main specifications of the deterministic components, and not just for the specification outlined here for illustration.

Moon and Perron (2004)

A second specialization, somewhat less restrictive than Pesaran, is due to Moon and Perron (2004), who consider a DGP of the following form (which may also be

rewritten in the form given by (13.5)–(13.7) above):

$$
\begin{aligned}
y_{it} &= \mu_i + y^0_{i,t} \\
y^0_{i,t} &= \varphi_i y^0_{i,t-1} + u_{i,t} \\
u_{i,t} &= \pi_i' f_t + e_{i,t} \\
i &= 1, 2, \ldots, N;\ t = 1, 2, \ldots, T.
\end{aligned}
$$

Note that f_t is an r-dimensional vector of common factors, taken here to be stationary, see assumptions (ii) and (v) below, where r may be taken to be known.[17]

Key assumptions within this framework include the following:

(i) $e_{i,t} = \sum_{j=0}^{\infty} d_{i,j}\varepsilon_{i,t-j}$, where $\varepsilon_{i,t}$ are i.i.d. (0,1) across i and over t, have finite eighth moment, $\inf_i \sum_{j=0}^{\infty} d_{i,j} > 0$ and $\overline{d}_j = \sup_i |d_{i,j}|$, $\sum_{j=0}^{\infty} j^m \overline{d}_j < M$ for some $m > 1$;

(ii) $f_t = \sum_{j=0}^{\infty} c_j \eta_{t-j}$, where c_j are $r \times r$ matrices of real numbers and the $r \times 1$ vectors $\eta_t = (\eta_{1,t}, \ldots, \eta_{j,t}, \ldots, \eta_{r,t})'$ are i.i.d. $(0, I_r)$, so that $\eta_{j,t}$ is i.i.d across j and over t. It is also assumed that $\sum_{j=0}^{\infty} j^m ||c_j|| < M$, for some $m > 1$;

(iii) $\varepsilon_{i,t}$ and $\eta_{i,s}$ are independent;

(iv) as $N \to \infty$, $\frac{1}{N}\sum_{i=1}^{N} \pi_i \pi_i' \to \Sigma_\Pi > 0$;

(v) as $T \to \infty$, $\frac{1}{T}\sum_{i=1}^{N} f_t f_t' \to \Sigma_f > 0$.

The unit root in the $y_{i,t}$ process comes solely from φ_i being equal to one. This is a key restriction from the overall Bai and Ng (2004) framework (which allows for integrated factors and integrated idiosyncratic components).

Following from above, the unit root null hypothesis of $H_0 : \varphi_i = 1\ \forall i$ is therefore tested against the heterogeneous alternative of $H_A : \varphi_i < 1$ for some of the units, as long as the number of these units remains a positive fraction of the total number of units as $N \to \infty$. The vector π_i determines the loadings of the factors into the ith unit and, if $r = 1$, the system simplifies to the DGP considered by Pesaran (2007).[18]

The procedure consists of first computing the pooled OLS estimator $\hat{\varphi}_{Pooled}$ (of φ), given by setting $\varphi_i = \varphi\ \forall i$ and calculating the residuals from the pooled regression as $\hat{u}_{i,t} = y_{i,t} - \hat{\varphi}_{Pooled} y_{i,t-1}$. Extracting the factors from the $\hat{u}_{i,t}$ series is the second step.

Next, we establish some notation:

$$
\begin{aligned}
\hat{\Lambda} &= (\hat{\pi}_1, \hat{\pi}_2, \ldots, \hat{\pi}_N)', \text{ where } \hat{\pi}_i, i = 1, 2, \ldots, N, \text{ are the estimated factor loadings} \\
\hat{Q}_{\hat{\Lambda}} &= I_N - \hat{\Lambda}(\hat{\Lambda}'\hat{\Lambda})^{-1}\hat{\Lambda}' \\
y_{i,-1} &= (y_{i,0}, y_{i,1}, \ldots, y_{i,T-1})' \\
y_i &= (y_{i,1}, \ldots, y_{i,T})' \\
Y &= (y_1, y_2, \ldots, y_N)
\end{aligned}
$$

$$
\begin{aligned}
Y_{-1} &= (y_{1,-1}, y_{2,-1}, \ldots, y_{N,-1}) \\
\hat{u}_i &= (\hat{u}_{i,1}, \ldots, \hat{u}_{i,T})' \\
\hat{u} &= (\hat{u}_1, \hat{u}_2, \ldots, \hat{u}_N) \\
\hat{e} &= \hat{u}\hat{Q}_{\hat{\Lambda}} \\
\omega_{e,i}^2 &= \left(\sum_{j=0}^{\infty} d_{i,j} \right)^2 \\
\lambda_{e,i} &= \sum_{l=1}^{\infty} \sum_{j=0}^{\infty} d_{i,j} d_{i,j+l} \\
\omega_e^2 &= \frac{1}{N} \sum_{i=1}^{N} \omega_{e,i}^2 \\
\phi_e^4 &= \frac{1}{N} \sum_{i=1}^{N} \omega_{e,i}^4 \\
\lambda_e^N &= \frac{1}{N} \sum_{i=1}^{N} \lambda_{e,i}.
\end{aligned}
$$

Consistent estimators of ω_e^2, ϕ_e^4 and λ_e^N are provided by constructing kernel estimators based on sample covariances provided by $\frac{1}{T}\sum_t \hat{e}_{i,t}\hat{e}_{i,t+j}$, where $\hat{e}_{i,t}$ is the (i,t)th element of $\hat{e}$ defined above and $1 \leq t, t+j \leq T$. These are denoted by $\hat{\omega}_e^2$, $\hat{\phi}_e^4$ and $\hat{\lambda}_e^N$, respectively.

Two test statistics, denoted MP_a and MP_b, follow, defined as:

$$
\begin{aligned}
MP_a &= \frac{\sqrt{N}T(\varphi^*_{Pooled} - 1)}{\sqrt{\frac{2\hat{\phi}_e^4}{\hat{\omega}_e^4}}} \\
MP_b &= \frac{\sqrt{N}T(\varphi^*_{Pooled} - 1)}{\hat{\phi}_e^2} \sqrt{\frac{1}{NT^2} tr(Y_{-1}\hat{Q}_{\hat{\Lambda}} Y'_{-1})}\hat{\omega}_e, \\
\text{where } \varphi^*_{Pooled} &= \frac{tr(Y_{-1}\hat{Q}_{\hat{\Lambda}} Y') - NT\hat{\lambda}_e^N}{tr(Y_{-1}\hat{Q}_{\hat{\Lambda}} Y'_{-1})}.
\end{aligned}
$$

Under the null hypothesis $H_0 : \varphi_i = 1 \; \forall i$, Moon and Perron (2004) show that:

$$
MP_a, MP_b \Rightarrow N(0,1), \text{ as } N, T \to \infty \text{ with } N/T \to 0.^{19}
$$

No inference concerning the unit root behavior is conducted on the estimated factors, since these are taken to be stationary *a priori*. However, under the null hypothesis it is the accumulated factors that enter the data y.

Choi (2006a)

The final specialization discussed here, due to Choi (2006a), is based on a two-way error component model. Consider the model given by:

$$\begin{aligned} y_{i,t} &= \beta_0 + x_{i,t} \\ x_{i,t} &= \mu_i + \lambda_t + u_{i,t} \\ u_{i,t} &= \sum_{j=1}^{p_i} \alpha_{ij} u_{i,t-j} + \varepsilon_{i,t}. \end{aligned}$$

The μ_i, λ_t and $\varepsilon_{i,t}$ processes (which are uncorrelated with each other) are assumed to have the following structures:

$$E(\mu_i) = 0 \ \forall i, E(\mu_i^2) = \sigma_\mu^2 < \infty \ \forall i, E(\mu_i \mu_j) = 0 \ \forall i \neq j$$

$$E(\lambda_t) = 0 \ \forall t, E(\lambda_t \lambda_s) = \sigma_\lambda(|t-s|) < \infty$$

$$\varepsilon_{i,t} \sim \text{i.i.d. } (0, \sigma_\varepsilon^2), \quad \varepsilon_{i,t} \text{ is independent of } \varepsilon_{j,s} \ \forall i \neq j, s \neq t.$$

The test therefore consists of purging the $x_{i,t}$ process of its "common" time effects, given by λ_t, its individual specific effects, given by μ_i, and testing for a unit root in $\hat{u}_{i,t}$. The null and alternative hypotheses have the form:

$$H_0 : \sum_{j=1}^{p_i} \alpha_{ij} = 1 \ \forall i; \quad H_A : \sum_{j=1}^{p_i} \alpha_{ij} < 1 \text{ for } 0 < N_1 < N \text{ units.}$$

As earlier, the fraction of the units with no unit roots is required to fulfill the following property under the alternative:

$$\lim_{N \to \infty} \frac{N_1}{N} = k > 0.$$

Consider testing the demeaned and detrended residuals $\hat{u}_{i,t}$, for each unit i, using ADF tests (and critical values) and suppose the corresponding p-value of the test for each unit is given by p_i.

Choi (2006a) proposes the use of three different group mean tests based on the Fisher principle (generalizing his earlier work on Fisher tests for cross-sectionally independent panels):

$$\begin{aligned} C_P &= -\frac{1}{\sqrt{N}} \sum_{i=1}^{N} (\log(p_i) + 1) \\ C_Z &= \frac{1}{\sqrt{N}} \sum_{i=1}^{N} (\Phi^{-1}(p_i)) \\ C_{L*} &= \frac{1}{\sqrt{\pi^2 \frac{N}{3}}} \log\left(\frac{p_i}{1-p_i}\right). \end{aligned}$$

Here Φ denotes the distribution function of the standard normal distribution. Under the null, all three statistics tend to $N(0,1)$, $T, N \to \infty$. Under the alternative, $C_Z \to \infty$ while the remaining two statistics, $C_P, C_Z \to -\infty$, $T, N \to \infty$. This framework can, of course, be generalized to incorporate a trend in the model.

13.2.2.4 Nonlinear instrumental variables unit root test – Chang (2002)

Chang (2002) allows for cross-sectional dependence through correlation in the noise processes. Thus, the starting point is correlation between the series $u_{i,t}$ in $y_{i,t} = \rho_i y_{i,t-1} + u_{i,t}$, abstaining here from deterministic components for simplicity. Chang assumes that all $u_{i,t}$ series are stationary autoregressive processes of some orders p_i generated by some innovations $\varepsilon_{i,t}$. In particular, Chang (2002, Assumption 2.2, p. 264) assumes that $\varepsilon_t = \left(\varepsilon_{1,t}, \ldots, \varepsilon_{N,t}\right)'$ is an i.i.d. sequence with (non-diagonal) positive definite covariance matrix, which precludes cross-unit cointegration. The unit root test itself is based on instrumental variable estimation with the instrument given by integrable functions of the lagged levels of $y_{i,t}$. The test statistic, labeled NL, for the null hypothesis $H_0 : \rho_i = 1$ for $i = 1, \ldots, N$ against the heterogeneous alternative, is given by an appropriately weighted sum of the individual t-statistics. Chang (2002, p. 277) proposes the following instrument generating function $F(y_{i,t-1}) = y_{i,t-1} e^{-c_i |y_{i,t-1}|}$, where c_i is related to the sample standard error of $\Delta y_{i,t}$. Im and Pesaran (2003) show that the asymptotic behavior established in Chang (2002) holds only when $N \ln T / \sqrt{T} \to 0$, which suggests that N has to be quite small compared to T in practice.

13.2.2.5 Summary of section 13.2.2

We have described above a broad class of methods developed to deal with cross-sectional dependence. These are largely dependent on using factor models of varying degrees of generality to model dependence across the units. It is thus of interest to investigate the size and power of these methods within the context of a simulation study, and to apply these methods to real-world datasets (although a direct comparison of the results cannot be made since the tests operate under different assumptions).

Some general principles can be identified. First, cross-sectional dependence is mainly modeled by resorting to factor models, which allows us to model both short- and long-run dependence, albeit with some restrictions. Second, for certain special configurations – as, for example, the one considered by O'Connell (1998) – short-run correlation can be relatively easily accounted for in simple testing approaches by resorting to some corrections; for example, feasible GLS. Third, under appropriate assumptions, many of the test statistics are, under the null hypothesis, asymptotically standard normally distributed (after appropriate centering and re-scaling). This is most easily established for cross-sectionally independent panels and sequential limits with $T \to \infty$ followed by $N \to \infty$, but can also be established (under appropriate assumptions) in panels with cross-sectional dependencies.

We turn next to the most general formulation (13.5)–(13.7), which allows not only for cross-sectional dependence but also for the presence of structural breaks in the deterministic components of the series comprising the panel. These structural breaks are typically assumed to take the form of changes in the intercept or linear trend of the process (in a given unit or a set of units) at a potentially unknown date in-sample. As in time series unit root problems, inference about unit roots in

integrated panels needs to take account of shifts in the deterministic parts of the processes, since breaks in series may lead (as in Perron, 1989) to spurious findings of a unit root. The analysis can, in principle, also be extended to allow for breaks in the factors or in the loading coefficients on the factors, but this takes us beyond the scope of the current discussion.

13.2.3 Relaxing structural stability – Bai and Carrion-i-Silvestre (2007)

The restrictions underlying (13.5)–(13.7) above, with specification of the breaks given in (13.9), are relatively mild. This model formulation allows for a very general specification of the testing framework, which allows not only for cross-sectional dependence via common factors but also for structural instability. As in the assumptions underlying the Bai and Ng model (given in section 13.2.2.2) the factor loadings need to be identifiable; there are conditions on the short- and long-run variance of ΔF_t and the $\varepsilon_{i,t}$ processes are assumed to be weakly serially correlated but cross-sectionally independent (as given by the set of conditions (iii) for $\varepsilon_{i,t}$ in section 13.2.2.2).[20] Under certain assumptions, the machinery of feasible GLS-type corrections could be employed for cases where the errors are thought to be correlated in the short-run, but within the broader problem we wish to address in this section, this issue remains a somewhat mild technicality. Finally, some restrictions on the initial conditions are also needed.

The key part of the testing strategy of Bai and Carrion-i-Silvestre (2007) is based on constructing so-called modified Sargan–Bhargava statistics (henceforth MSB), due to Sargan and Bhargava (1983) and Stock (1999). The unit-specific MSB statistics are based on computing:

$$MSB_i = \frac{T^{-2} \sum_{t=1}^{T} \hat{e}_{i,t}^2}{\hat{\omega}_i^2}, \tag{13.13}$$

where the denominator is a measure of the long-run variance of $e_{i.t}$.

The most important aspect of the analysis is therefore to extract consistent estimates of $e_{i,t}$ (denoted $\hat{e}_{i,t}$) in the presence of common factors and structural breaks, and to test these series for the presence of unit roots. In addition to the different specifications for the breaks which may be considered (to allow for breaks only in the intercept or also to allow for changes in the trend slope), a further crucial distinction among the methods is to deal with the cases where the break date(s) are known versus cases where they need to be estimated consistently (for example, by means of the algorithms considered in Bai and Perron, 1998).[21] We touch upon all these issues in turn.

Under the assumption of cross-sectional independence of the idiosyncratic components, the final form of the test statistic proposed by Bai and Carrion-i-Silvestre takes the form of pooling the individual MSB_i statistics, using correction terms for the mean and variance so that the limiting distribution is standard normal. An alternative strategy involves pooling p-values in the spirit of Maddala and Wu

(1999). For pooling to lead to tests with power requires all the idiosyncratic processes to be integrated under the null hypothesis, while under the alternative a strictly positive fraction of these processes is stationary even as $N \to \infty$.

13.2.3.1 Break dates known

Two models are considered, given by the specification of the deterministic processes.

$$\textit{Model 1}: \quad D_{i,t} = \mu_i + \sum_{j=1}^{l_i} \theta_{i,j} DU_{i,j,t}, i = 1, 2, \ldots, N.$$

$$\textit{Model 2}: \quad D_{i,t} = \mu_i + \delta_i t + \sum_{j=1}^{l_i} \theta_{i,j} DU_{i,j,t} + \sum_{k=1}^{m_i} \gamma_{i,k} DT^*_{i,k,t}, i = 1, 2, \ldots, N.$$

Thus in Model 1 only the intercept of the process is broken, with the ith unit being characterized by l_i breaks at fractions (of the time-span of the sample) given by $\frac{T^i_{a,j}}{T} = \gamma_{i,j}$, which are fractions that remain constant as $T \to \infty$. In Model 2, by contrast, both the intercept and trend are broken (the latter at fractions given by $\frac{T^i_{b,k}}{T} = \lambda_{i,k}, k = 1, 2, \ldots, m_i$). The break dates can be positioned heterogeneously across i, the breaks can be of different magnitudes, each unit may have different numbers of breaks, and the breaks in the intercept can be located at different time periods from the breaks in trend.

To presage the results somewhat, it is simple to note that in Model 1, since the factors are extracted from a model for the differenced observations, the breaks in intercept reduce to impulse dummies which do not, in fact, have any impact on the asymptotic distribution of the MSB statistics. Thus whether or not the breaks are known or unknown does not make any difference, as long as these breaks are restricted to the intercept. By contrast, for Model 2, where the breaks in trend reduce upon differencing to changes in the intercept of the differenced process, the statistics do depend upon the nuisance parameters $\lambda_{i,k}$ and critical values need to be computed to take this into account. In addition, if the break dates are not known *a priori*, consistent estimates of the break fractions are needed.

Analysis of Model 1

Differencing Model 1 yields:

$$\Delta y_{i,t} = \pi_i' \Delta F_t + \Delta e^*_{i,t}, \tag{13.14}$$

where:

$$\Delta e^*_{i,t} = \Delta e_{i,t} + \sum_{j=1}^{l_i} \theta_{i,j} D(T^i_{a,j})_t,$$

and $D(T^i_{a,j})_t$ are the impulse dummies with $D(T^i_{a,j})_t = 1$ if $t = T^i_{a,j} + 1$ and 0 elsewhere.

As in section 13.2.2.2, let:

$$\Delta y_i = (\Delta y_{i,2}, \ldots, \Delta y_{i,T})'$$
$$\Delta e_i^* = (\Delta e_{i,2}^*, \ldots, \Delta e_{i,T}^*)'$$
$$\Delta F = (\Delta F_2, \ldots, \Delta F_T)' \quad ((T-1) \times r \text{ matrix of differenced factors for all the units})$$
$$\pi_i = (\pi_{i,1}, \ldots, \pi_{i,r})' \quad (r \times 1 \text{ vector of loadings of factors for } i\text{th unit}).$$

Then we may write the model (in vector notation) as:

$$\tilde{y}_i = f\pi_i + z_i,$$

where $\tilde{y}_i = \Delta y_i$, $f = \Delta F$ and $z_i = \Delta e_i^*$.

The estimated factors $\hat{f}$ and their loadings $\hat{\pi}_i$ are calculated as in section 13.2.2.2, and:

$$\hat{z}_i = \tilde{y}_i - \hat{f}\hat{\pi}_i; \text{ and, finally, } \hat{e}_{i,t} = \sum_{s=2}^{t} \hat{z}_{i,s}.$$

Since the MSB statistic is not affected by the impulse dummies, and hence by the break fractions γ_i, Bai and Carrion-i-Silvestre prove that under the null hypothesis of a unit root and the assumption that $\frac{T_{a,j}^i}{T} = \gamma_i$ remain constant as $T \to \infty$:

$$MSB(i) \Rightarrow \int_0^1 W_i^2(r)dr,$$

where $W_i(r)$ is a standard Brownian motion independent across i.

The pooled statistic has the form:

$$Z = \sqrt{N}\frac{\overline{MSB} - 0.5}{1\Big/\sqrt{3}},$$

and has a limiting normal distribution, as $N \to \infty$, where $\overline{MSB} = \frac{1}{N}\sum_{i=1}^{N} MSB_i$.

The mean and variance correction terms are those appropriate for the individual $MSB(i)$ statistics.

A pooled Fisher-type test can also be constructed. Denoting by p_i the p-value of the $MSB(i)$ test for the ith unit, then:

$$BC_{\chi^2} = -2\sum_{i=1}^{N} \log p_i \sim \chi_{2N}^2.$$

This is a result applicable to cases where the cross-section dimension N is finite. When N is large, we may also use the asymptotic approximation to the chi-squared statistic proposed by Choi (2001), that is,

$$BC_N = \frac{-2\sum_{i=1}^{N} \log p_i - 2N}{\sqrt{4N}} \Rightarrow N(0,1).$$

These results apply even when the break dates are unknown.[22]

Analysis of Model 2

Here things are slightly more complicated, since differencing the processes does not eliminate the dependence of the relevant test statistics on the break fractions. For Model 2 we have, upon differencing:

$$\Delta y_{i,t} = \Delta F_t' \pi_i + \delta_i + \sum_{k=1}^{m_i} \gamma_{i,k} DU_{i,k,t} + \Delta e^*_{i,t}, \tag{13.15}$$

where $DU_{i,k,t} = 1$ when $T > T^i_{b,k}$ and zero elsewhere are the step dummies which arise from differencing the trend breaks.

To follow Bai and Carrion-i-Silvestre's notation, let:

$$d_i = (\delta_i, \gamma_{i,1}, \ldots, \gamma_{i,m_i})'$$
$$a_{i,t} = (1, D_{i,1,t}, \ldots, D_{i,m_i,t})'$$
$$a_i = (a_{i,2}, \ldots, a_{i,T})'.$$

Then the first-differenced model can be rewritten (using the notation established previously) as:

$$\tilde{y}_i = f\pi_i + a_i d_i + z_i.$$

Since the break dates are assumed known the matrix a_i is completely specified. Conditional on δ_i being known, the variable $w_i = \tilde{y}_i - a_i d_i$ has a "complete" factor structure, in the sense of assumption (i), which follows (13.5)–(13.7) above. f and Π can therefore be estimated based on $w = (w_1, w_2, \ldots, w_N)$. If, on the other hand, $f\pi_i$ is known, regressing $\tilde{y}_i - f\pi_i$ on a_i leads to consistent estimates of d_i. Bai and Carrion-i-Silvestre therefore propose (conditional upon the break dates being known) an iterative procedure for estimating the model as follows:

Step 1: Estimate d_i by least squares – that is, $\tilde{d}_i = (a_i' a_i)^{-1} a_i' \tilde{y}_i$ – ignoring the presence of the factors, which are assumed to have zero mean and will thus be included in the regression errors.

Step 2: Given $\tilde{d}_i$, construct the series $\tilde{w}_i = \tilde{y}_i - a_i \tilde{d}_i$ and estimate the factors and factor loadings to give $\tilde{f}\tilde{\pi}_i$.

Step 3: Regress $\tilde{w}_i$ on a_i to obtain updated estimates of d_i and iterate until convergence.

Step 4: Denoting the final estimates by $\hat{f}$, $\hat{\pi}$ and $\hat{d}_i$, compute $\hat{z}_i = \tilde{y}_i - \hat{f}\hat{\pi}_i - \hat{a}_i \hat{d}_i$ and cumulate to obtain $\hat{e}_{i,t} = \sum_{s=2}^{t} \hat{z}_{i,s}$. Compute the *MSB* statistic for each unit.

Then, as $T \to \infty$,

$$MSB(i, \lambda_i) \Rightarrow \sum_{k=1}^{m_i+1} (\lambda_{i,k} - \lambda_{i,k-1})^2 \int_0^1 V^2_{i,k}(b) db,$$

where:

$\lambda_{i,k} = \frac{T^i_{b,k}}{T}, k = 1, \ldots, m_{i+1},$ which are fractions that remain constant as $T \to \infty$

$\lambda_i = (\lambda_{i,0}, .\lambda_{i,k}, \ldots, \lambda_{i,m_i+1})', \text{ with } \lambda_{i,0} = 0, \lambda_{i.m_i+1} = 1, i = 1, 2, \ldots, N,$

and:

$$V^b_{i,k} = W_{i,k}(b) - bW_{i,k}(1),$$

are Brownian bridges independent across i and k.

Note the dependence of the statistics on the break fractions. Thus, denoting $\lambda = (\lambda_1, \ldots, \lambda_N)'$, we have:

$$Z = \sqrt{N}\frac{\overline{MSB} - \overline{\xi}}{\overline{\zeta}} \Rightarrow N(0,1)$$

$$\overline{MSB} = \frac{1}{N}\sum_{i=1}^{N} MSB(i, \lambda_i)$$

$$\xi_i = \frac{1}{6}\sum_{k=1}^{m_i+1} (\lambda_{i,k} - \lambda_{i,k-1})^2$$

$$\zeta_i^2 = \frac{1}{45}\sum_{k=1}^{m_i+1} (\lambda_{i,k} - \lambda_{i,k-1})^4$$

$$\overline{\xi} = \frac{1}{N}\sum_{i=1}^{N} \xi_i$$

$$\overline{\zeta}^2 = \frac{1}{N}\sum_{i=1}^{N} \zeta_i^2.$$

The Fisher or p-value versions of these tests *à la* Choi (2006a), referred to as BC_N, and *à la* Maddala and Wu (1999), referred to as BC_{χ^2}, can similarly be constructed, as long as the break fractions are known. This is because the p-values for the individual tests will depend on the break fractions in the presence of breaks in trend.

13.2.3.2 Break dates unknown

The results and methods discussed above go through as before for Model 2 (note that for Model 1 knowledge of the break fractions is not a relevant consideration) provided consistent estimates of the break fractions can be obtained. From (13.15), defining the composite error $n_{i,t} = \Delta F_t' \pi_i + \Delta e^*_{i,t}$, and assuming without loss of generality that ΔF has zero mean, we can write the model as:

$$\Delta y_{i,t} = \delta_i + \sum_{k=1}^{m_i} \gamma_{i,k} DU_{i,k,t} + n_{i,t}.$$

Then (13.15) can be thought of as a model with intercept breaks, where the number and timing of the breaks can be calculated (unit by unit) using the Bai–Perron dynamic programming algorithm. Thus, due to the fast convergence of the estimated break points to their "true" values, the a_i matrix can be assumed to be known upon substituting a_i by $\hat{a}_i$. Asymptotically, given consistency, the theoretical results are unaffected by replacing the true break dates with their estimated values. The accuracy of the estimation of the break dates and its impact on the properties of the testing for unit roots using the MSB statistic may well be a pragmatic issue in cases where T is relatively small. This can again be addressed within the framework of simulation studies, an example of which is contained in Bai and Carrion-i-Silvestre's paper but for which further work is clearly justifiable.

13.2.4 Two empirical examples

In this section, we illustrate the arguments and tests developed above by means of two examples, analyzing in particular the effect of incorporating cross-sectional dependence (via factors) and structural breaks into the testing procedures. The two examples are based on Wagner (2008a) and Wagner (2008b) respectively.

13.2.4.1 Purchasing power parity

The empirical analysis of (weak) purchasing power parity (PPP), in an $I(1)$ modeling framework, typically formulated as stationarity of the real exchange rate (RER), is a prime application of both time series and panel unit root (respectively cointegration) testing. We have already referred to the influential paper by O'Connell (1998) when discussing the consequences of overlooking the impact of cross-sectional dependence.

In logarithms, the RER for country i is given by:

$$q_{i,t} = e_{i,t} + p_{i,t} - p_t^*, \tag{13.16}$$

where $q_{i,t}$ is the RER, $e_{i,t}$ is the nominal exchange rate, $p_{i,t}$ is the price level in country i and p_t^* is the price level of the base country (all in logarithms). In our application below the base country is the United States, the nominal exchange rates are thus vis-à-vis the US dollar (per unit of local currency) and the prices are given by the consumer price indices, which implies that, like almost all of the literature, we do not study real exchange rates but real exchange rate indices.

Early panel studies of PPP, including Coakley and Fuertes (1997), Frankel and Rose (1996), Lothian (1997) and Wu (1996), have used first-generation panel unit root tests to test stationarity (respectively unit root behavior) of RER panels. Panel methods have been used to overcome the deficiencies of time series unit root tests, as highlighted in the PPP context by Engel (2000) and as discussed in the introductory sections to this chapter.

Such studies have often "found support for PPP," that is, rejections of the unit root null hypothesis, although it is presumably well understood that rejection of the null hypothesis (that is, a unit root in RER) is not acceptance of the alternative. Much more seriously, the use of first-generation tests designed for cross-sectionally independent panels appears to be troublesome in the PPP context.

Looking at (13.16), it becomes clear that there are several potential sources of cross-sectional dependence in RER panels. First, all nominal exchange rates are coupled to each other by no arbitrage restrictions which appear to hold quite well in liquid foreign exchange markets. Given that nominal exchange rates, if not fixed to the base country currency, typically fluctuate more than prices, this dependence will not be wiped out by price level movements across countries. Second, all RERs contain the same (non-stationary) base country price index p_t^*. Since the goods contained in the consumer baskets generally differ across countries, it is realistic to assume that the permanent components in $(e_{i,t} + p_{i,t})$ and p_t^* do not exactly coincide. If they do not perfectly coincide, then in general the $q_{i,t}$ series contain a common permanent component related to p_t^*. Third, the no arbitrage (in the goods markets) arguments underlying the law of one price and PPP rely upon economic interaction of one form or the other. The world economy becomes ever more integrated and thus shocks can also be expected to be transmitted more strongly across countries. The type of short-run dependence considered by O'Connell (1998) and discussed above may not be sufficient since, as we have just argued, RER panels may be prone to the presence of common non-stationary components.

Lyhagen (2000) studies a special case of this situation with one common stochastic trend and shows that several first-generation tests, including those of Levin, Lin and Chu (2002) and Im, Pesaran and Shin (2003), are severely affected in this case. In particular, Lyhagen shows that, in the presence of one common stochastic trend, the size of the tests tends to one with increasing cross-sectional dimension.

To assess the impact of cross-sectional dependence when testing for PPP, Wagner (2008a) applies a battery of first- and second-generation panel unit root tests to four monthly RER panels. The sample periods, as well as the cross-section and time dimensions of the panels, are contained in Table 13.1. Details are given in Appendix A.

The euro-area dataset (the data are taken from the IMF IFS, OECD MEI and ECB databases) consists of 11 of the 12 countries that were starting members of the euro-area in January 1999, with Ireland missing due to constraints on data availability. The Central and Eastern European countries (CEEC) dataset consists of 11 transition

Table 13.1 Time periods and panel dimensions of the four monthly datasets considered

	Start	*End*	*T*	*N*
Euro-area	1980/1	1998/12	228	11
CEEC	1993/1	2004/6	138	11
Industrial	1980/1	1998/12	228	29
Worldwide	1981/1	2004/4	280	57

Note: The number of observations over time is denoted by T while N denotes the cross-sectional dimension.

Table 13.2 Results of first-generation panel unit root and stationarity tests

	LLC	*Breitung*	IPS_t	*MW*	*Hadri*
Euro-area	*−1.31*	*−1.37*	*−1.34*	24.65	*12.79*
CEEC	**–8.87**	−0.58	**–4.17**	**98.69**	**14.52**
Industrial	−1.04	**–2.49**	**–1.73**	66.10	**22.68**

Breitung: Breitung modification of LLC test in section 13.2.1.1.
IPS_t: t-test proposed by Im, Pesaran and Shin in section 13.2.1.2.
MW: Maddala and Wu's p-value test in section 13.2.1.3.
Hadri: Test with stationarity as null in section 13.2.1.4.

economies with the sample ranging from January 1993 to June 2004. The start date is chosen to exclude the high inflation period of the early 1990s. Two other datasets containing a larger number of countries are also considered. One of these is an industrial countries dataset consisting of 29 countries, including the countries of the euro-area dataset, for which the sample period coincides with the sample period for the euro-area. The other, labeled Worldwide, contains 57 non-euro-area countries for which monthly data are available back to January 1981.

The detailed discussion in Wagner (2008a) shows clearly that all four panel datasets exhibit cross-sectional dependence, investigated by computing the long-run covariance matrix of $\Delta q_t = \left[\Delta q_{1,t}, \ldots, \Delta q_{N,t}\right]'$ (respectively sub-vectors thereof), by inspecting the cross-correlation functions and by cointegration analysis. In particular there appears to be evidence for the presence of common non-stationary components, in line with the discussion above.

The results obtained when applying a battery of first-generation panel unit root tests are reported in Table 13.2.

Depending upon the panel considered, two or three of the four reported panel unit root tests lead to a rejection of the unit root null hypothesis. For the euro-area dataset the three rejections only occur at the 10% level. The quite substantial number of rejections, and hence the strong evidence "in favor" of PPP, is a typical finding in this literature and is in line with the results discussed in Lyhagen (2000).

When the null is taken to be stationarity of the $q_{i,t}$ series, however, the reported results for the Hadri test show rejections of the null hypothesis of stationarity for all the panels. This is consistent with the evidence concerning non-stationarity in the RER panels, as documented in detail in Wagner (2008a), and runs counter to the evidence from the unit root tests. However, as illustrated by Hlouskova and Wagner (2006), the poor performance of the Hadri test, with rejections occurring far too often whenever the data exhibit sizeable serial correlation, severely limits the usefulness of this test, even if the panels were cross-sectionally independent.

Table 13.3 Results of Bai and Ng (2004) analysis

	Factors	BN_N	$BN_{\chi 2}$	$MQ_c(m)$	$MQ_f(m)$
Euro-area	6	0.17	23.14	6	6
CEEC	5	1.24	30.25	5	5
Industrial	4	**1.93**	**78.76**	4	4
Worldwide	4	0.25	117.78	3	3

Notes: Bold entries indicate rejection of the unit root null hypothesis at the 5% critical level; BN_N and $BN_{\chi 2}$ denote the Bai and Ng tests on the estimated idiosyncratic components described in section 13.2.2.2; and $MQ_c(m)$ and $MQ_f(m)$ are the Bai and Ng tests for common trends in section 13.2.2.2.

Further evidence concerning the cross-sectional dependence structure in the RER panels is collected by applying the Bai and Ng (2004) methodology for computing common factors and the results are reported in Table 13.3. The second column contains the estimated number of common factors chosen according to the information criterion BIC_3 of Bai and Ng (2002), while the third and fourth columns provide the results of tests on the idiosyncratic components based on using the pooled inverted normal test and the Maddala and Wu test respectively. The fifth and sixth columns give the number of common trends amongst the common factors according to the two different tests described previously.

These results reflect a well-known weakness of the information criteria to determine the number of common factors (see the second column), which tend to favor large numbers of estimated common factors (given that the upper bound for the number of common factors is six). For the euro-area six factors are selected, five factors are selected for the CEEC panel and four for the other two datasets. Onatski (2006) reports simulations showing that correlation between the idiosyncratic components of the individual units (for which evidence is presented in Wagner, 2008a, for the RER panels at hand) leads to overestimation of the number of common factors when using the information criteria of Bai and Ng (2002). Thus, the results concerning the *number* of common factors should be interpreted with caution, given that the cross-sectional dimensions are rather small in the panels.

The second striking feature is that the number of common trends is selected to be equal to the number of common factors, with the exception of the worldwide dataset where the number of common trends in the common factors is selected to be three (that is, a lot of evidence for unit roots in the common factors). Simulations performed by the authors indicate a tendency of the tests to lead to too large a number of common trends unless, for example, the time series dimension T is very large. Hence, the results concerning the number of common trends also have to be interpreted with some caution.

The Bai and Ng (2004) panel unit root tests are designed for cross-sectionally independent data. In order to verify whether the de-factored data are cross-sectionally independent, one can again look at the cross-correlation functions or the long-run

covariance matrices of the first differences of the estimated idiosyncratic components. Doing so (for details, see again Wagner, 2008a) indicates that even the de-factored data do not appear to be uncorrelated. In this respect, note that the correlation structure between the estimated idiosyncratic components depends upon the number of factors chosen, which is intuitively clear because extracting too many factors may actually induce cross-sectional dependence. Having this potential caveat in mind, for the idiosyncratic components the unit root hypothesis is only rejected for the industrial country dataset. Thus, from the perspective of the Bai and Ng (2004) approach, there is little support for stationarity in the RER panels.

When the computations are performed with only one common factor as an additional robustness check, the unit root null hypothesis is not rejected for this common factor for the euro-area, CEEC and industrial countries datasets but is rejected for the common factor in the worldwide dataset. With one common factor, the panel unit root tests on the idiosyncratic components lead to no rejection of the unit root null hypothesis.

The second-generation test results in Table 13.4 show that, much like for the first-generation tests and for the more restrictive second-generation tests, the unit root null hypothesis is by and large rejected for our datasets, with the exception of the Chang (2002) test.

It is important to remember that these tests are designed for more restricted DGPs than the Bai and Ng (2004) framework allows for. The Pesaran (2007) and Choi (2006a) tests allow for only one common stationary serially uncorrelated factor, with identical loadings for the latter test. The Moon and Perron (2004) approach restricts the factors to be stationary under the alternative. Thus for all these approaches key assumptions necessary for the panel unit root tests are most likely violated, which is consistent with the rejections of the null hypothesis (compare also Breitung and Das, 2008, and Gengenbach, Palm and Urbain, 2006). Finally, it is unclear what drives the non-rejections of the unit root null hypothesis obtained by applying the Chang (2002) test, since this is designed for panels

Table 13.4 Results of other second-generation panel unit root tests

	MP_a	MP_b	*CIPS*	C_p	C_Z	C_{L*}	*NL*
Euro-area	**–9.67**	**–4.88**	−1.96	**5.08**	**–4.56**	**–4.43**	1.52
CEEC	**–12.44**	**–7.86**	**–2.91**	**7.34**	**–4.57**	**–5.31**	1.95
Industrial	**–15.81**	**–6.62**	−1.85	**9.87**	**–8.01**	**–8.04**	1.50
Worldwide	**–20.77**	**–9.37**	**–2.43**	**18.05**	**–12.27**	**–13.67**	−0.05

Notes: The abbreviations are as in the discussion of the tests in section 13.2.2. Bold entries indicate rejection of the unit root null hypothesis at the 5% critical level.
MP_a and MP_b: Moon and Perron tests in section 13.2.2.3.
CIPS: Pesaran test with cross-sectional demeaning in section 13.2.2.3.
C_p, C_Z and C_{L*}: Choi tests in section 13.2.2.3.
NL: Chang test in section 13.2.2.4.

Table 13.5 Results of the tests of Bai and Carrion-i-Silvestre (2007) for unit roots in non-stationary panels with common factors and structural breaks

	Euro-area	*CEEC*	*Industrial*	*Worldwide*
	Z and p-value tests			
Z	6.36	−1.61	2.36	−1.55
BC_N	−2.33	1.44	−0.24	−0.04
$BC_{\chi 2}$	6.54	31.57	55.46	113.37
	Simplified Z and p-value tests			
Z	17.51	3.03	15.96	0.51
BC_N	−2.61	0.49	−1.08	0.05
$BC_{\chi 2}$	4.69	25.25	46.40	114.81
Number of breaks	9	5	11	8

Notes: The number of factors is chosen according to the information criterion BIC_3. The test results reported allow for at most one break in both the intercept and linear trend, except for the euro-area dataset where up to two breaks are allowed for. The critical value (at the 5% nominal level) is given by –1.645 for the Z test, by 1.645 for the BC_N test and by 32.92 (N = 11), 76.78 (N = 29) and 139.92 (N = 57) for the $BC_{\chi 2}$ test. Number of breaks indicates the number of countries in which breaks have been detected. The tests are as described in section 13.2.3.

without non-stationary common components. All in all, the findings show that a careful modeling of cross-sectional dependence that leads to an appropriate choice of panel unit root test is of key importance.

Let us finally turn to the issue of structural change, neglected up to now. Table 13.5 contains the results obtained when applying the Bai and Carrion-i-Silvestre (2007) tests. Bai and Carrion-i-Silvestre also propose simplified approximate tests whose limiting distributions are independent of the break fractions. The results obtained with these tests are also included in Table 13.5.

The major observation that emerges is that the unit root null hypothesis is not rejected for any of the datasets by any of the tests. Thus, even when allowing for structural breaks and common factors, no evidence for stationarity of the RER panels emerges. In particular, contrasting the findings obtained by allowing for multiple factors (and breaks), with no evidence for stationarity of the RER, with the findings obtained with first-generation tests or more restrictive second-generation tests, where seemingly more evidence for PPP prevails, indicates that the resurrection of PPP due to the usage of panel methods may not yet have been accomplished.

13.2.4.2 The environmental Kuznets curve

The empirical example, based on Wagner (2008b), considered in this sub-section is based partly upon using the Groningen dataset mentioned in the introduction. Since the seminal work of Grossman and Krueger (1995) many econometric studies of the relationship between measures of economic development (typically per

capita GDP) and pollution (often proxied by emissions) have been conducted. Most of the papers focus on a specific conjecture, the so-called environmental Kuznets curve (EKC) hypothesis, which postulates an inverted U-shaped relationship between the level of economic development and pollution. This hypothesis therefore states that pollution first rises with increasing income up to a certain point to then fall for income increasing further. The term EKC refers by analogy to the inverted U-shaped relationship between the level of economic development and the degree of income inequality, postulated by Kuznets (1955) in his 1954 presidential address to the American Economic Association.

The theoretical underpinnings for EKCs are discussed, for example, in Andreoni and Levinson (2001), Brock and Taylor (2004, 2005), Jones and Manuelli (2001) and Stokey (1998). Brock and Taylor (2005) identify three different mechanisms that link economic activity with pollution (respectively emissions). These are the scale, composition and technique effects. For unchanging composition of output and unchanging technology, emissions rise alongside the scale of economic activity. For given scale and technique, emissions can rise or fall when the composition of output changes towards a more or less emissions-intensive composition. Finally, emissions (per unit of output, that is, emissions intensity), can decrease with improvements in technology, that is, via improved abatement technology. Depending upon the relative magnitudes of these three effects, a monotonic, a U-shaped, or an inverted U-shaped relation (among the different patterns possible) between per capita GDP and per capita emissions may emerge.

Disentangling the relative importance of the three effects requires detailed structural modeling. The empirical EKC literature is typically less ambitious and focuses on reduced form modeling to address the issue of whether the three distinct mechanisms are jointly sufficiently strong to allow for an inverted U-shaped relationship.

The basic parametric panel formulation of a homogeneous EKC is given by:

$$e_{i,t} = \alpha_i + \gamma_i t + \beta_1 y_{i,t} + \beta_2 y_{i,t}^2 + u_{i,t}, \tag{13.17}$$

where $e_{i,t}$ here denotes the logarithm of per capita emissions, $y_{i,t}$ the logarithm of per capita GDP, $u_{i,t}$ denotes the stochastic error term, $i = 1, \ldots, N$ is the country index and $t = 1, \ldots, T$ is the time index as before. The formulation also includes country specific fixed effects and country specific linear trends, to allow for income independent level and slope effects that could *inter alia* reflect country specific preferences with respect to emissions.

An EKC, that is, an inverted U-shaped relationship, occurs if $\beta_1 > 0$ and $\beta_2 < 0$, in which case the turning point with respect to income (in the homogeneous formulation identical across countries) is given by $y_{TP} = \exp\left(-\beta_1/2\beta_2\right)$. The primary task in an empirical EKC analysis is to estimate the relationship (13.17) by appropriate methods and to test the relevant hypothesis concerning the coefficients.

As discussed in the introduction and also in the convergence example at the beginning of this chapter, $y_{i,t}$ is often considered to be a unit root process. Often, due to the relatively short time series available for many countries, for both per

capita GDP and emissions, the use of a panel perspective may appear fruitful to enhance the performance of unit root and cointegration tests. In any empirical analysis of an EKC like (13.17), using panel unit root and cointegration techniques, all the complications discussed above, such as cross-sectional dependence or structural changes in the deterministic component, may arise and have consequently to be addressed. We turn to each of these problems below. Furthermore, the homogeneity restriction (that is, $\beta_{1i} = \beta_1$ and $\beta_{2i} = \beta_2$ for $i = 1, \ldots, N$) needs to be investigated, which we address in a later section in this chapter (having discussed testing for cointegration and estimation of cointegrating vectors).

There is one additional problem that arises in an equation like (13.17): log per capita GDP and its square are both present. However, at most one of the two processes can be a unit root process, with the other process necessarily being a nonlinear transformation thereof. We return to this issue and its implications later when considering estimation of (13.17).

In our empirical application we consider sulphur dioxide (SO_2) emissions using a balanced panel of 97 countries over the period 1950–2000 (described in detail in a table in Appendix A).

Let us start the discussion of the empirical results by looking at the results obtained with the Bai and Ng (2004) methodology, summarized in Table 13.6. For SO_2 two common factors are found and for GDP one common factor is found. Depending upon the test chosen, $MQ_c(m)$ or $MQ_f(m)$, one or both common factors in SO_2 are non-stationary and the ADF test on the single common factor in GDP also does not lead to a rejection of the unit root null hypothesis. The GDP common factor reflects the evolution of average worldwide GDP and also tracks the observed slowdown of the mid 1970s quite well. The SO_2 common factors are less clearly interpretable and are, furthermore, not cointegrated with the GDP common factor. This implies that there is some long-run disconnect between per capita GDP and per capita SO_2 emissions.

The idiosyncratic components for GDP (as tested by BN_N and BN_{χ^2}) appear to be stationary, since the unit root null hypothesis is rejected by both tests. This implies that the deviations of the individual countries' GDP from the common global factor are stationary and that none of the countries' GDP deviates permanently from the single global stochastic trend.

For SO_2 emissions the null hypothesis of a unit root in the idiosyncratic components is not rejected. This is consistent with large inter-country systemic and technological differences in industry and energy production as well as differences in environmental legislation.

The other, more restrictive, second-generation panel unit root tests, collected in Table 13.7, provide very mixed results. The most relevant results from this table are the Moon and Perron (2004) results, since the other results collected in this table are for tests designed for panels without long-run cross-sectional dependencies.

In the specification with only fixed effects included, the unit root null hypothesis is rejected for the idiosyncratic component for both GDP and SO_2 emissions, whereas it is not rejected when both fixed effects and linear trends are included.

Table 13.6 Results of Bai and Ng (2004) analysis

	Factors	BN_N	BN_{χ^2}	$MQ_c(m)$	$MQ_f(m)$	CF_{ADF}
SO_2	2	−0.70	180.22	1	2	–
GDP	1	**2.89**	**250.96**	–	–	−2.30

Notes: Bold entries indicate rejection of the unit root null hypothesis at the 5% critical level.
CF_{ADF}: ADF test on single common factor as in section 13.2.2.2.
Also see notes to Table 13.3.

Table 13.7 Results of second-generation tests

	MP_a	MP_b	*CIPS*	*Cp*	C_Z	C_{L*}	*NL*
Fixed effects							
SO_2	**–14.70**	**–7.56**	–1.78	**9.45**	**–5.83**	**–6.22**	4.05
GDP	**–17.72**	**–9.05**	–1.64	**1.75**	–0.56	–0.79	8.29
Fixed effects and linear trends							
SO_2	–0.81	–0.49	–2.44	**1.81**	3.89	4.91	6.69
GDP	1.38	1.41	–2.46	–3.01	6.30	7.26	5.82

Notes: Bold entries indicate rejection of the unit root null hypothesis at the 5% critical level. Also see notes to Table 13.4.

The other tests are included to show again that by a strategic choice of panel unit root test any desired conclusion can be supported.

Neglected up to now and potentially important for the case of emissions series is the issue of structural change (for example, due to technological or legal changes). In this respect the short time dimension of the panels represents a major limitation, since the panel unit root tests that allow for structural change in the deterministic component, as described in section 13.2.3, require, when the break dates are assumed to be unknown, the individual specific estimation of these break dates. Nevertheless, applying the Bai and Carrion-i-Silvestre (2007) tests, see Table 13.8, provides evidence for structural change in about a third to a half of the countries included in the panel. All the unit root test results lead to non-rejection of the unit root null hypothesis even when allowing for structural breaks. The results in the table refer to the case with at most one structural break per unit, since even when allowing for more structural breaks only one break is detected.[23]

This example is continued in section 13.3.5 where, in particular, the estimation of (13.17) is discussed.

13.2.5 Some concluding remarks

We have continued to bring together the key strands of the testing strategies within the panel integration framework. Important considerations have included:

Table 13.8 Results of the tests of Bai and Carrion-i-Silvestre (2007) for unit roots in non-stationary panels with common factors and structural breaks

	GDP	SO_2
Z and p-value tests		
Z	−1.38	5.59
BC_N	0.51	−1.01
$BC_{\chi 2}$	210.14	174.02
Simplified Z and p-value tests		
Z	0.63	9.10
BC_N	−1.12	−2.10
$BC_{\chi 2}$	177.70	152.61
Number of breaks	44	39

Notes: The number of factors is chosen according to the information criterion BIC_3. The test results reported allow for at most one break in both the intercept and linear trend. The critical value (at the 5% nominal level) is given by –1.645 for the *Z* test, by 1.645 for the BC_N test and by 227.50 for the $BC_{\chi 2}$ test. Number of breaks indicates the number of countries in which a break has been detected. Also see notes to Table 13.5.

(a) Homogeneity or heterogeneity of the roots under the null and alternative hypotheses.
(b) Deciding upon testing strategy – pooled (LLC) versus group mean methods (IPS), for example, governed largely by the form of the alternative hypothesis adopted.
(c) The need to allow for dependence; based upon the definition presented in Appendix B, we distinguish short-run and long-run dependence, with the latter being related to cross-unit cointegrating relationships and, hence, in a sense made precise in Appendix B, the prevalence of joint common trends across cross-section members. Up to now the most popular model to allow for cross-sectional dependencies is the approximate factor model of Bai and Ng (2004), whose cross-unit cointegration implications are also discussed in Appendix B. For very special cases, short-run cross-sectional dependence can be handled by resorting to relatively simple corrections such as the feasible GLS procedure of O'Connell (1998), which, however, can only be used if the time dimension of the panel exceeds the cross-section dimension.
(d) The construction of the statistics themselves, involving mean and variance corrections to center and standardize the densities of the statistics derived from the individual units.
(e) The startling features of Gaussianity in the limit for many of these statistics, based on constructing statistics that are a weighted aggregate of the individual unit-by-unit statistics. If these units are taken to be independent, under appropriate assumptions (that, for example, ensure the existence of the required

moments) relatively simple sequential central limit theory provides the asymptotic normality of these densities. As soon as the assumption of cross-sectional dependence is lifted, however, issues become much more intricate, as outlined in the highly stylized discussion in Appendix C. Note that cross-sectional dependence of the data often requires the use of joint limit theory, as, for example, in the work of Bai and Ng (2004). More generally, the joint limit theory applied in factor models, where consistent estimation of the factors requires the cross-sectional dimension to tend to infinity, has implications for all unit root and cointegration test procedures that use de-factored observations. This is an issue that we believe deserves more attention in the literature.

(f) The simple ways in which factor structures are utilized and the intuitive manner in which the tests are constructed.

(g) The natural ways in which structural breaks are incorporated.

All of these features are important to the development and use of this methodology, and further work, theoretical, simulation-based and empirical, to investigate the efficacy of the various testing strategies proposed is still largely necessary.

Many of (a)–(g) carry over when it is not a unit root hypothesis that we are interested in testing, but a hypothesis of cointegration among variables of interest, and it is to a consideration of these methods to which we now turn. We could think, for example, of PPP, where we might be interested in seeing co-movement between foreign and domestic prices expressed in the same currency; or exchange rate pass-through, where one could look at how changes in exchange rates are transmitted to the price of imported goods; or the Feldstein–Horioka puzzle where the apparent co-movement of savings and investments (which runs contrary to commonly held beliefs on the consequences of quasi-perfect capital markets); or, of course, the growth literature and issues of convergence discussed earlier.

13.3 Cointegration analysis in non-stationary panels

The majority of cointegration analysis in multivariate time series panels is conducted within the single equation set-up, in which the m-dimensional time series $Y_{i,t}$ are separated into $Y_{i,t} = \left[y_{i,t}, x'_{i,t}\right]'$, where subsequently $y_{i,t}$ is the dependent variable and $x_{i,t}$ are the regressors. This approach is subject to the same limitations as Engle and Granger (1987) single-equation cointegration analysis in the time series case. The most important restriction is that the analysis is limited to situations in which there is either no cointegration in $Y_{i,t}$ (under the null hypothesis of the "no cointegration" tests) or only one cointegrating relationship (under the alternative of the "no cointegration tests").[24] This assumption is in general, with $x_{i,t}$ a multivariate vector of regressor variables, not easily sustainable, except perhaps in special cases. Clearly, methods that allow for higher-dimensional cointegrating spaces are therefore also relevant in the panel cointegration context. Such methods have until now been based on panel extensions of VAR cointegration analysis and are discussed in section 13.3.2.

Single-equation methods, however, offer some advantages, since they allow us to consider – paralleling much of the developments in panel unit root analysis – both cross-sectional dependence via factor models and structural changes in the deterministic components. None of these two aspects has yet been studied in system methods for panel cointegration analysis.

This section starts with a general formulation of the single equation panel cointegration set-up and then continues with discussing tests for cointegration that abstract from cross-sectional dependence and structural change. Structural change is considered next in tests for cointegration, following which allowing for cross-sectional dependence is also added to the testing structure. In section 13.3.1.6 we discuss single equation estimators of the cointegrating vector, for the situation without cross-sectional dependence or structural change. Section 13.3.2 then discusses testing for cointegration as well as estimation of the cointegrating spaces in panel VAR models, under the assumptions of cross-sectional independence and no structural change. Empirical examples are again used throughout to illustrate the techniques.

13.3.1 Single equation analysis of cointegration

Paralleling the set-up of the DGP for studying the unit-root problem given by (13.5)–(13.7) above, we may consider describing the general set-up of testing for cointegration in panels:

$$y_{i,t} = D_{i,t} + x_{i,t}'\beta_{i,t} + u_{i,t} \tag{13.18}$$

$$u_{i,t} = \pi_i' F_t + e_{i,t} \tag{13.19}$$

$$(1-L)F_t = C(L)\eta_t \tag{13.20}$$

$$\left(1-\varphi_i L\right) e_{i,t} = H_i(L)\varepsilon_{i,t} \tag{13.21}$$

$$(1-L)x_{i,t} = v_{i,t}, \tag{13.22}$$

where the major difference to the set-up considered in (13.5)–(13.7) is the presence of additional regressors $x_{i,t}$ in (13.22) that are potentially related to the dependent variable $y_{i,t}$ via a cointegrating relationship. Note that in general one can consider, as in (13.18), the cointegrating relationship to be both individual specific and time varying.

It is important to note that cointegration in the usual sense occurs if the error process $u_{i,t}$ in (13.18) is stationary. However, this is not the only possible form of relationship in which one could be interested. One could, for example, also consider cointegration after taking out the common factors,[25] and this is the additional aspect that the cross-sectional dimension and the modeling of cross-sectional dependence brings into play.

Short-run dependence across the units may, under appropriate circumstances and assumptions, be dealt with as before by considering the variance–covariance structure of the error processes.

As in the unit root discussion, before dealing with the general problem, let us consider a set of simplifications that help to illustrate many of the issues involved. Suppose we start, as in section 13.2, by switching off the factor dependence structure and assuming that both the deterministic processes and the cointegrating vector are unbroken. Then a very simple version of the system reduces to:

$$y_{i,t} = D_{i,t,m} + x'_{i,t}\beta_i + u_{i,t}, \quad m = 1, 2, 3 \tag{13.18′}$$

$$(1 - L)x_{i,t} = v_{i,t}, \tag{13.22′}$$

where the index m again describes the usual specifications of the deterministic component. $D_{i,t,m}$ can either be empty (that is, contain no deterministic terms), $m = 1$, or have a constant, $m = 2$, or a constant and a linear trend, $m = 3$.

Let us further assume that the vectors $x_{i,t}$, and therefore β_i and $v_{i,t}$, are l-dimensional and that, if $y_{i,t}$ and $x_{i,t}$ are cointegrated, the *unique* cointegrating vector is given by $(1, -\beta'_i)'$. Assume further that, when cointegration prevails, the processes $e_{i,t} = (u_{i,t}, v'_{i,t})'$ are cross-sectionally *independent* stationary autoregressive moving average (ARMA) processes. The ARMA assumption is stronger than we need but serves well for the purposes of illustration. In particular we are able to appeal, under this ARMA assumption, to the existence of a finite long-run covariance matrix for $e_{i,t}$, given by:

$$\Omega_i = \begin{bmatrix} \omega^2_{u,i} & \Omega_{uv,i} \\ \Omega'_{uv,i} & \Omega_{v,i} \end{bmatrix}.$$

$\Omega_{v,i}$ is taken to be of full rank, which excludes cointegration amongst the variables $x_{i,t}$. We also need to define the conditional long-run variance as:

$$\omega^2_{u.v,i} = \omega^2_{u,i} - \Omega_{uv,i}\Omega^{-1}_{v,i}\Omega'_{uv,i},$$

and the matrix:

$$\Lambda_i = \sum_{j=0}^{\infty} E(e_{i,t}e'_{i,t-j}),$$

partitioned conformably with Ω_i. Finally, let us take $\beta_i = \beta \ \forall i$ if cointegration exists. This is an assumption that can be generalized easily, as discussed by Pedroni (2004).

If there is no cointegration, equation (13.18′) is a spurious relationship with $y_{i,t}$ being an $I(1)$ process not cointegrated with $x_{i,t}$. In this case we can assume, analogously to the ARMA assumption above, that $\Delta y_{i,t} = u^{sp}_{i,t}$ and that $e^{sp}_{i,t} = \left(u^{sp}_{i,t}, v'_{i,t}\right)'$ are cross-sectionally independent stationary ARMA processes with full rank long-run covariance matrices. Of course, this includes the case of independence of $y_{i,t}$ and $x_{i,t}$. The superscript "sp" here is chosen to indicate the spurious regression nature of the relationship in the case of no cointegration.

13.3.1.1 Testing for the null hypothesis of no cointegration – Pedroni (1999, 2004)

Write:

$$\Delta u_{i,t} = \rho_i u_{i,t-1} + \upsilon_{i,t}, \tag{13.23}$$

where $\upsilon_{i,t}$ is a stationary ARMA process for all the units. As in the tests for unit roots, two combinations of the null and alternative hypotheses may be considered – the first applying to pooled tests, the second to group mean tests. Under the former, the null hypothesis is given by $H_0 : \rho_i = 0 \; \forall \; i = 1, 2, \ldots, N$ against the homogeneous alternative hypothesis $H_A : \rho_i = \rho < 0 \; \forall \; i = 1, 2, \ldots, N$, where we again restrict attention to stationarity under the alternative. The group mean tests are based on $H_A^1 : \rho_i < 0$ for $i = 1, 2, \ldots, N_1$ and $\rho_i = 0$ for $i = N_1 + 1, \ldots, N$, where $\lim_{N\to\infty} \frac{N_1}{N} = k > 0$. The analogy with the unit-root testing framework is obvious and many of the same estimation and testing principles apply. If $u_{i,t}$ were known the procedures would be exactly the same – in practice, since we must estimate $u_{i,t}$, the analogy is not exact and the tests must be based on estimating equations of the form (13.18′) instead.

Let us denote by $\hat{u}_{i,t}$ the regression residuals from (13.18′) estimated by OLS. Two adjustments to the OLS coefficient are needed, first to account for the endogeneity of the regressors and second to account for the ARMA structure in $\upsilon_{i,t}$.

The first adjustment requires an estimate of $\omega^2_{u.\upsilon,i}$, denoted $\hat{\omega}^2_{u.\upsilon,i}$. This may be done by first estimating the OLS regression of $\Delta y_{i,t}$ on the deterministic components and $\Delta x_{i,t}$, extracting the residuals $\hat{\upsilon}_{i,t}$ and fitting an ARMA or AR model to this derived process (and computing its long-run variance.) Alternatively, a nonparametric estimator of the form prescribed by Newey and West (1987) may also be used.

The correction for serial correlation can also be dealt with either parametrically, by means of ADF regressions on the residuals $\hat{u}_{i,t}$, or nonparametrically from the nonaugmented regressions given by (13.23), with $\hat{u}_{i,t}$ replacing $u_{i,t}$.

In order to compute the nonparametric correction for serial correlation, denote the estimated variance of the residuals in (13.23) by $\hat{\sigma}^2_{\upsilon,i}$ and the corresponding long-run variances by $\hat{\omega}^2_{\upsilon,i}$. The serial correlation correction factors are $\psi_i = \frac{1}{2}\left(\hat{\omega}^2_{\upsilon,i} - \hat{\sigma}^2_{\upsilon,i}\right)$ and let $\hat{\omega}^2_{N,T} = \frac{1}{N}\sum_{i=1}^{N} \frac{\hat{\omega}^2_{\upsilon,i}}{\hat{\omega}^2_{u.\upsilon,i}}$. The following test statistics for "no cointegration" can now be defined, laid out in four different categories. Each of the statistics requires re-scaling and centering in order for the asymptotic distributions to hold.

(i) Pooled tests (nonparametric corrections)

$$\textit{variance ratio}: \qquad N^{1/2}\left(N^{-1}\sum_{i=1}^{N}\hat{\omega}^{-2}_{u.\upsilon,i}\left(T^{-2}\sum_{t=2}^{T}\hat{u}^2_{i,t-1}\right)\right)^{-1}$$

$$\textit{pooled } \rho\textit{-test}: \quad N^{1/2}\frac{N^{-1}\sum_{i=1}^{N}\hat{\omega}_{u.v,i}^{-2}\left(T^{-1}\sum_{t=2}^{T}\hat{u}_{i,t-1}\Delta\hat{u}_{i,t}-\psi_i\right)}{N^{-1}\sum_{i=1}^{N}\hat{\omega}_{u.v,i}^{-2}\left(T^{-2}\sum_{t=2}^{T}\hat{u}_{i,t-1}^{2}\right)}$$

$$\textit{pooled } t\textit{-test}: \quad N^{1/2}\frac{N^{-1}\sum_{i=1}^{N}\hat{\omega}_{u.v,i}^{-2}\left(T^{-1}\sum_{t=2}^{T}\hat{u}_{i,t-1}\Delta\hat{u}_{i,t}-\psi_i\right)}{\hat{\omega}_{N,T}\left(N^{-1}\sum_{i=1}^{N}\hat{\omega}_{u.v,i}^{-2}\left(T^{-2}\sum_{t=2}^{T}\hat{u}_{i,t-1}^{2}\right)\right)^{1/2}}.$$

(ii) Pooled tests (parametric corrections)
In order to compute the parametrically corrected versions of the t-test, a similar device to that discussed previously in the construction of the LLC test is used. Two auxiliary regressions are estimated:

$$\Delta\hat{u}_{i,t}=\sum_{k=1}^{K_i}\gamma_{1,ik}\Delta\hat{u}_{i,t-k}+\zeta_{1,i,t}$$

$$\hat{u}_{i,t-1}=\sum_{k=1}^{K_i}\gamma_{2,ik}\Delta\hat{u}_{i,t-k}+\zeta_{2,i,t},$$

where the lag-length selection (of K_i) may be undertaken using automatic selection criteria such as AIC. Next, $\hat{\zeta}_{1,i,t}$ is regressed on $\hat{\zeta}_{2,i,t}$:

$$\hat{\zeta}_{1,i,t}=\rho_i\hat{\zeta}_{2,i,t}+\theta_{i,t},$$

and $\hat{\sigma}_{NT}^{2}=\frac{1}{NT}\sum_{i=1}^{N}\sum_{t=K_i+2}^{T}\hat{\theta}_{i,t}^{2}$ is computed. The variance of the estimated residuals $\hat{\theta}_{i,t}$, denoted $\hat{\sigma}_{\theta_i}^{2}$, needed for the computation of the group mean tests is also computed. The parametrically corrected pooled t-test is then:

pooled t-test – parametrically corrected:

$$N^{1/2}\frac{N^{-1}\sum_{i=1}^{N}\hat{\omega}_{u.v,i}^{-2}\left(T^{-1}\sum_{t=K_i+2}^{T}\hat{\zeta}_{1,i,t}\hat{\zeta}_{2,i,t}\right)}{\hat{\sigma}_{N,T}\left(N^{-1}\sum_{i=1}^{N}\hat{\omega}_{u.v,i}^{-2}\left(T^{-2}\sum_{t=K_i+2}^{T}\hat{\zeta}_{2,i,t}^{2}\right)\right)^{1/2}}.$$

The group mean tests are defined as follows:

(iii) Group mean tests (nonparametric corrections)

$$\textit{group mean } \rho\textit{-test}: N^{-1/2} \sum_{i=1}^{N} \frac{\left(T^{-1} \sum_{t=2}^{T} \hat{u}_{i,t-1} \Delta \hat{u}_{i,t} - \psi_i \right)}{\left(T^{-2} \sum_{t=2}^{T} \hat{u}_{i,t-1}^2 \right)}$$

$$\textit{group mean } t\textit{-test}: N^{-1/2} \sum_{i=1}^{N} \frac{\left(T^{-1} \sum_{t=2}^{T} \hat{u}_{i,t-1} \Delta \hat{u}_{i,t} - \psi_i \right)}{\hat{\omega}_{\upsilon,i} \left(T^{-2} \sum_{t=2}^{T} \hat{u}_{i,t-1}^2 \right)^{1/2}}$$

(iv) Group mean tests (parametric corrections)

$$\textit{group mean } t\textit{-test – parametrically corrected}: N^{-1/2} \sum_{i=1}^{N} \frac{\left(T^{-1} \sum_{t=K_i+2}^{T} \hat{\zeta}_{1,i,t} \hat{\zeta}_{2,i,t} \right)}{\hat{\sigma}_{\theta,i} \left(T^{-2} \sum_{t=K_i+2}^{T} \hat{\zeta}_{2,i,t}^2 \right)^{1/2}}.$$

The mean and variance correction terms (for large N and T) for each of these seven tests depend upon the deterministic specification considered, as well as upon the dimension of the $x_{i,t}$ vector. Once recentered and scaled by the appropriate mean and variance corrections, the standardized statistics tend in the limit to the $N(0, 1)$ density (under sequential convergence, $T \to \infty, N \to \infty$). Hlouskova and Wagner (2008) contains a large set of finite sample and asymptotic correction factors for up to 12 regressors.

13.3.1.2 Some general remarks

It is worth re-emphasizing that the testing principles derived earlier for unit root tests in panels carry over in direct ways to the testing for cointegration, with the obvious (but by no means trivial) embellishments of endogeneity correction, and the need for methods that estimate the cointegrating vector efficiently and consistently when required. A class of tests due to Kao (1999) is constructed under the same general framework as described above for the Pedroni tests, while Westerlund (2005) develops two simple nonparametric tests, one against a homogeneous alternative whilst the other is a group mean test against a heterogeneous stationary alternative.

Wagner and Hlouskova (2007), in a companion study to Hlouskova and Wagner (2006), report the results of an extensive simulation exercise, one part of which is devoted to looking at the behavior of the Pedroni and Westerlund tests. The study explores the size and power properties of the tests under the baseline case where cross-sectional independence is imposed in the DGP, but also reports results when cross-sectional independence is violated both via a correlation structure, as described in section 13.2.2.1 (or a slight modification, where the correlation matrix

has geometrically declining weights – that is, the (i, j)th element of the matrix Ω is given by $\omega^{|i-j|}$) and where there is also cross-unit cointegration.

They report that, among the seven Pedroni single-equation tests for the null hypothesis of no cointegration, the two parametric tests (based on estimating ADF regressions) are the ones that have the best size properties. The remaining five are severely undersized and also have low power, especially for small values of T. The authors conjecture that this may be due to the use of asymptotic correction terms (used to standardize the test statistics) when finite sample correction terms or bootstrapped values may be more beneficial.

However, the conservative properties of the parametric tests also imply that these are the ones least affected by the presence of short-run cross-sectional correlation or cross-unit cointegration of the form considered by Wagner and Hlouskova (2007). Systems tests for cointegration, discussed in section 13.3.2, are in fact outperformed by Pedroni-type tests (although the latter are not applicable in the presence of multiple cointegrating vectors). There is a tendency to overestimate the rank of the cointegrating space (that is, the number of cointegrating vectors), and size and power distortions occur not only when T is relatively small but also when the N-dimension is large (because of the difficulty with dealing with high-dimensional systems alluded to earlier.) The use of finite sample corrections or bootstrapped values is found to be efficacious here, as also reported in earlier work by Banerjee, Marcellino and Osbat (2004).

Banerjee and Carrion-i-Silvestre (2007) consider extensions of the Pedroni tests to allow for structural breaks, discussed in the following sub-section, and for structural breaks and cross-sectional dependence, discussed in section 13.3.1.4 thereafter. Structural breaks are allowed to occur in both the deterministic components and the cointegrating vector.

13.3.1.3 Allowing for structural breaks in the Pedroni tests

As mentioned, the considered structural changes may take the form of breaks in the deterministic processes and/or in the slopes of the cointegrating coefficients β. In the next sub-section, we also allow for cross-sectional dependence via a factor structure.

In this sub-section, we focus on the consequences of relaxing the assumption that the deterministic processes are not broken. Referring back to (13.18), under the null hypothesis $y_{i,t}$ and $x_{i,t}$ are not cointegrated, that is, $u_{i,t}$ is an $I(1)$ process. Under the alternative hypothesis, $u_{i,t}$ is stationary but either the deterministic terms or the cointegrating vectors are time-variant (defined more precisely below), so that, while cointegration exists under the alternative, it does so in the presence of instabilities.

That such a situation is not of pure academic interest becomes evident both from considering the simulation results in Banerjee and Carrion-i-Silvestre (2007), and from the empirical example presented below, where the presence of structural breaks is crucial for establishing the presence of cointegration. The presence of structural breaks severely undermines the size and power properties of the tests for cointegration, especially when the break occurs in the deterministic trend of the processes.

We focus here on the parametric version of the pooled t-test corrected parametrically (given the good properties of this test identified by Wagner and Hlouskova, 2007), but the theoretical and simulation analysis can be repeated for any of the tests developed by Pedroni discussed above or in the related literature.

Let us begin, as in the previous section, with the following flexible representation of the model:

$$y_{i,t} = D_{i,t} + x'_{i,t}\beta_{i,t} + u_{i,t} \tag{13.18''}$$

$$(1-L)x_{i,t} = v_{i,t}, \tag{13.22''}$$

where the further generalization at this stage is to allow for the $D_{i,t}$ and $\beta_{i,t}$ terms to be broken, although for the moment the factor structure remains switched off. For simplicity, the restriction (in relation to the Bai and Carrion-i-Silvestre, 2007, paper) imposed here is that there is only one break allowed for, and that the breaks in intercept and/or trend and/or cointegrating coefficients (under the alternative) all occur at the same, possibly unknown, time period. It is important to note, however, that the timing of these breaks is allowed to vary across the units. These breaks are specified in six ways, constituting six different sub-models nested within (13.18$''$).

Start with the general functional form for the deterministic term $D_{i,t}$:

$$D_{i,t} = \mu_i + \delta_i t + \theta_i DU_{i,t} + \gamma_i DT^*_{i,t},$$

where:

$$\begin{aligned} DU_{i,t} &= 0 \ \forall t \leq T_{b,i} \\ &= 1 \ \forall t > T_{b,i}, \end{aligned}$$

and:

$$\begin{aligned} DT^*_{i,t} &= 0 \ \forall t \leq T_{b,i} \\ &= (t - T_{b,i}) \ \forall t > T_{b,i}. \end{aligned}$$

Note that $T_{b,i}$ denotes the time of the break for the ith unit and $\lambda_i = \frac{T_{b,i}}{T}$, which is the fraction of the sample at which the break occurs in the ith unit, remains constant as $T \to \infty$ and belongs to a closed sub-set of (0,1). The time-varying cointegrating vector is specified as a function of time so that:

$$\beta_{i,t} = \beta_i + b_i \cdot DU_{i,t},$$

where $DU_{i,t}$ is as defined above.

With the allowed breaks, at least six different model specifications may be considered and we list these below. The list is not exhaustive, but probably includes the most relevant specifications, especially for the empirical applications that we would have in mind.

Model 1: Constant term with a change in intercept but stable cointegrating vector:

$$y_{i,t} = \mu_i + \theta_i DU_{i,t} + x'_{i,t}\beta_i + u_{i,t}. \tag{13.24}$$

Model 2: Time trend with a change in intercept but stable cointegrating vector:

$$y_{i,t} = \mu_i + \delta_i t + \theta_i DU_{i,t} + x'_{i,t}\beta_i + u_{i,t}. \tag{13.25}$$

Model 3: Time trend with change in both intercept and trend but stable cointegrating vector:

$$y_{i,t} = \mu_i + \delta_i t + \theta_i DU_{i,t} + \gamma_i DT^*_{i,t} + x'_{i,t}\beta_i + u_{i,t}. \tag{13.26}$$

Model 4: Constant term with change in both intercept and changing cointegrating vector:

$$y_{i,t} = \mu_i + \delta_i t + \theta_i DU_{i,t} + x'_{i,t}\beta_{i,t} + u_{i,t}. \tag{13.27}$$

Model 5: Time trend with change in intercept and changing cointegrating vector (the slope of the trend does not change):

$$y_{i,t} = \mu_i + \delta_i t + \theta_i DU_{i,t} + x'_{i,t}\beta_i + u_{i,t}. \tag{13.28}$$

Model 6: The intercept, the trend slope and the cointegrating vector all change:

$$y_{i,t} = \mu_i + \delta_i t + \theta_i DU_{i,t} + \gamma_i DT^*_{i,t} + x'_{i,t}\beta_{i,t} + u_{i,t}. \tag{13.29}$$

Under any of these specifications, Banerjee and Carrion-i-Silvestre (2007) propose methods for testing the null hypothesis of no cointegration against the alternative hypothesis of cointegration, with corresponding breaks.

The Banerjee and Carrion-i-Silvestre (2007) proposal is conceptually extremely simple. The analysis may be specialized to the case where the λ_i (break fractions) are assumed to be known but, since this is perhaps not a likely scenario, we present the more general analysis where the break dates are assumed to be unknown. The tests for cointegration in panels with structural breaks are based on time series cointegration tests developed by Gregory and Hansen (1996) and the panel cointegration tests of Pedroni (1999, 2004) discussed above. Testing entails several steps. First, one of the models (depending upon the precise empirical motivation) given in (13.24)–(13.29) above is estimated by OLS for each unit *i* of the panel. Since this requires us to specify the break fraction λ_i, and we assume here that that break dates are unknown, the models must be estimated for each unit for every possible choice of break fraction within a bounded interval, taken here to be the interval $\Lambda = [0.15,\ 0.85]$. This gives rise to a set of ADF regressions, derived from the particular choice of λ_i.

Next, for a given choice of λ_i, and for a particular choice of model, residuals $\hat{u}_{i,t}(\lambda_i)$ are extracted for each unit *i*. These residuals are then used to estimate the augmented Dickey–Fuller-type regression given by:

$$\Delta\hat{u}_{i,t}(\lambda_i) = \rho_i \hat{u}_{i,t-1}(\lambda_i) + \sum_{j=1}^{k} \phi_{i,j} \Delta\hat{u}_{i,t-j}(\lambda_i) + \varepsilon_{i,t}.$$

Since under the null hypothesis $\rho_i = 0\ \forall\ i$, the next step is to compute $t_{\rho_i=0}(\lambda_i)$ for each of these ADF regressions and to take as the estimate of the break-point/fraction

for the ith unit the fraction which minimizes the sequence of the individual t-statistics. That is, for unit i,

$$\hat{T}_{b,i} = \underset{\lambda_i \in [0.15,0.85]}{\arg\min}\ t_{\hat{\rho}_i}(\lambda_i).$$

The limiting distribution of $\inf_{\lambda_i \in [0.15,0.85]} t_{\hat{\rho}_i}(\lambda_i)$ is shown by Gregory and Hansen (1996) not to depend on the break fraction parameters and it is for this reason that the minimization is undertaken over the sequence of break fractions in unit i. The procedure is repeated for all units i, leading to a sequence of "estimated" break fractions for the N units, denoted in vector notation as $\hat{\lambda} = (\hat{\lambda}_1, \hat{\lambda}_2, \ldots, \hat{\lambda}_N)'$.

Finally, the pooled test (in the spirit of Pedroni, 1999, 2004), which allows for breaks under the alternative hypothesis, is given by:

$$N^{-1/2} Z_{\hat{t}_{N,T}}(\hat{\lambda}) = N^{-1/2} \sum_{i=1}^{N} t_{\hat{\rho}_i}(\hat{\lambda}_i).$$

The asymptotic distribution of $N^{-1/2} Z_{\hat{t}_{N,T}}(\hat{\lambda})$ is given by the theorem below. It is important to note that in this framework (apart from the restriction to cross-sectional independence, which is lifted in the following sub-section) a high degree of heterogeneity is allowed across the units, since the cointegrating vector, the short-run dynamics and the break date are all allowed to differ among units. In the spirit of much of this literature, and in particular of Pedroni (1999, 2004), the panel test statistics are shown to converge to standard normal distributions once they have been properly standardized. The correction terms, of course, differ from those tabulated by Pedroni (2004) since the models are considerably more complicated due to the presence of breaks at unknown points of time across the units, but the principles involved remain the same. The following result may now be shown:

Theorem (Banerjee and Carrion-i-Silvestre, 2007, Theorem 1): Let Θ *and* Ψ *denote the mean and variance for the vector Brownian motion functional*:

$$\Upsilon' = \left(\inf_{\lambda_i \in \Lambda} \int_0^1 Q(\lambda_i, s) dQ_i(\lambda_i, s) \left[\int_0^1 Q(\lambda_i, s)^2 ds \right]^{-1}, \inf_{\lambda_i \in \Lambda} \int_0^1 Q(\lambda_i, s) dQ_i(\lambda_i, s) \times \right.$$
$$\left. \left[\int_0^1 Q(\lambda_i, s)^2 ds \cdot (1 + \rho(\lambda_i)' D(\lambda_i) \rho(\lambda_i)) \right]^{-1/2} \right).$$

$Q(\lambda_i, s)$ *and* $\rho(\lambda_i)$ *are functions of vector Brownian motions and the deterministic components and* $D(\lambda_i)$ *depends on the model chosen (see Gregory and Hansen, 1996, for details). Then, as* $T \to \infty, N \to \infty$ *in sequence, under the null hypothesis of no cointegration the asymptotic distribution of the statistic* $Z_{\hat{t}_{N,T}}(\hat{\lambda})$ *is given by* $N^{-1/2} Z_{\hat{t}_{N,T}}(\hat{\lambda}) - \Theta_2 \sqrt{N} \Rightarrow N(0, \Psi_2)$.

Several remarks are appropriate in connection with this theorem. First, we may derive similar theorems for the remaining statistics proposed by Pedroni (1999,

2004) and would reach very similar characterizations of the limiting densities (with different correction terms in each case).

Second, the asymptotic moments of the form Θ_2 and Ψ_2 can be approximated by Monte Carlo simulation for all the different models (for all the different tests.) Banerjee and Carrion-i-Silvestre compute these moments for up to seven stochastic regressors and $T = 1,000$.

Third, since the large sample correction terms (or moments) may perform poorly in finite samples, the moments of the test statistics for different values of T, specifically $T = \{30, 40, 50, 60, 70, 80, 90, 100, 150, 200, 250, 300, 400, 500\}$ are calculated. To generalize the applicability of these techniques yet further, some response surfaces are also computed to approximate the critical values for different values of T.

13.3.1.4 Allowing for cross-sectional dependence

In some sense it is worth thinking of (13.18)–(13.22) above as the most general formulation (within the framework adopted by this chapter) of the elements necessary for testing unit roots and cointegration in a panel, and we propose this structure as one that encompasses almost all of the issues involved. There are difficulties which are not addressed in sufficient detail, for example to do with multiple cointegrating vectors, but in terms of the three key elements of (i) testing for unit roots or cointegration, (ii) cross-sectional dependence, and (iii) instability in the deterministic or stochastic processes, (13.18)–(13.22) offers all the generality that is needed.

One can regard the problem as a series of switches which, when on, introduce the technology relevant to the investigator. For example, the switch from a cointegration to a unit root framework is more or less immediate by abstracting from the $x_{i,t}$ vector, formally setting its dimension equal to zero. The switch for structural breaks in the process is given by the vectors (or scalars in the case of a single break of parameters) $(\theta_i', \gamma_i', b_i')'$, which if set to zero (together or in part) removes structural instability from the relevant parts of the process.[26] Finally, the π_i vectors multiplying the common factors F_t introduce cross-sectional dependence. Cross-sectional dependence can also be introduced via correlation in the idiosyncratic components.

This sub-section deals with testing for cointegration when all the remaining switches (governing dependence and breaks) are, in principle, also on. Thus, in addition to structural breaks, we reintroduce cross-sectional dependence through the factors. We still work within the frameworks of Models 1–6 above, but with the additional element of cross-sectional dependence.

The assumptions governing the $u_{i,t}$ processes in (13.18′) and (13.22′) are as given in section 13.2.2.2 (as they apply to (13.5)–(13.7)). The factor structure (that is, equation (13.19)) is now switched on. An important restriction (applying also to the simpler Pedroni tests described in section 13.3.1.2) should be considered explicitly concerning the relationship between the $e_{i,t}$ process in (13.19) and $v_{i,t}$ in (13.22″).[27] If $E(e_{i,t}|v_{i,t}) = 0$, the regressors are said to be (strictly) exogenous and

the limiting distributions of the statistics do not depend on the stochastic regressors as given in Theorem 2 of Banerjee and Carrion-i-Silvestre (2007). However, if, for example, $E(e_{i,t}|v_{i,t}) = \Delta x_{i,t}' A_i(L) + \xi_{i,t}$, with $A_i(L)$ being a vector of lag and lead polynomials and $\xi_{i,t} \sim$ i.i.d. $(0, \Sigma_\xi)$, the regressors are no longer strictly exogenous and modifications must be introduced to account for the endogenous regressors. The two theorems given below are for the case of exogenous regressors but a simple modification of the testing procedure is suggested to allow for endogeneity.

Consider the case where the break dates are known, so that for the deterministic components only the corresponding parameters need to be estimated.

Compute the first difference of (13.18) to give:

$$\Delta y_{i,t} = \Delta D_{i,t} + \Delta x_{i,t}' \delta_{i,t} + \Delta F_t' \pi_i + \Delta e_{i,t}.$$

Note that, depending on the specification of the deterministic breaks, the differenced deterministic component $\Delta D_{i,t}$ is a mixture of step functions (in the case of a break in trend) and impulse dummies (when there is a break in intercept).

$\Delta y_i = (\Delta y_{i,2}, \ldots, \Delta y_{i,T})'$

$\Delta e_i = (\Delta e_{i,2}, \ldots, \Delta e_{i,T})'$

$\Delta F = (\Delta F_2, \ldots, \Delta F_T)'((T-1) \times r)$ matrix of differenced factors for all the units)

$\pi_i = (\pi_{i,1}, \ldots, \pi_{i,r})'$ ($r \times 1$ vector of loadings of factors for ith unit)

$\Delta x_i = (\Delta x_{i,2}, \ldots, \Delta x_{i,T})'$.

Defining the projection matrix $M_i = (I_{T-1} - \Delta x_i^D (\Delta x_i^{D\prime} \Delta x_i^D)^{-1} \Delta x_i^{D\prime})$, with $\Delta x_{i,t}^D = (1, \Delta D_{i,t}, \Delta x_{i,t}')'$ and $\Delta x_i^D = (\Delta x_{i,2}^D, \ldots \Delta x_{i,T}^D)'$, we have:

$$\begin{aligned} M_i \Delta y_i &= M_i \Delta F \pi_i + M_i \Delta e_i \\ &= f \pi_i + z_i, \end{aligned}$$

where $f = M_i \Delta F$ and $z_i = M_i \Delta e_i$. The projection matrix M_i is sensitive to the specification of the deterministic terms, as indicated by the index D in the definition of this matrix; yet $M_i \Delta F$ cannot be sensitive to i if the common factor representation is to be valid. This is a restriction of the framework used to model dependence, and can be satisfied in two different ways – (a) either the deterministic components do not matter, as in the case where differencing leads to impulse dummies, or (b) where the timing of the breaks in the deterministic terms is the same across the units. This is relevant in the case of trend breaks, where differencing leads to shifts in intercept which are relevant for the derivation of the asymptotic distributions of the statistics, that is, for Models 3 and 6.

Pre-multiplication by this projection matrix serves to isolate the factor components, so that we can now proceed to extract the factors. The estimated factors, denoted $\tilde{f} = (\tilde{f}_2, \ldots, \tilde{f}_T)$ are given by $\sqrt{T-1}$ times the r eigenvectors corresponding to the r largest eigenvalues of the matrix $y^* y^{*\prime}$, where $y^* = (y_1^*, \ldots, y_N^*)'$ and

$y_i^* = M_i \Delta y_i$. Normalizing, $\frac{\tilde{f}'\tilde{f}}{T-1} = I$, we have the estimate of the loading matrix:

$$\tilde{\Pi} = (\tilde{\pi}_1, \ldots, \tilde{\pi}_N)' = \frac{y^{*\prime}\tilde{f}}{T-1},$$

and:

$$\tilde{z}_{i,t} = y_{i,t}^* - \tilde{f}_t' \tilde{\pi}_i.$$

Finally:

$$\tilde{e}_{i,t} = \sum_{s=2}^{t} \tilde{z}_{i,s},$$

which can now be tested for a unit root, via ADF regressions. This is, in effect, the test for the null of no cointegration, once the common factor structure and the structurally unstable deterministic processes have been accounted for.

Thus, for each unit i, we estimate the regressions:

$$\Delta \tilde{e}_{i,t}^m(\lambda_i) = \alpha_{i,0} \tilde{e}_{i,t-1}^m(\lambda_i) + \sum_{j=1}^{k} \alpha_{i,j} \Delta \tilde{e}_{i,t-j}^m(\lambda_i) + \varepsilon_{i,t},\ m = c, \tau, \gamma,$$

and test the null hypothesis $H_0 : \alpha_{i,0} = 0$ either unit by unit or by constructing a pooled panel test similar in spirit to LLC.

Three sub-cases, $m = c, \tau, \gamma$, are considered by Banerjee and Carrion-i-Silvestre (2007), which index the t-tests $t_{\alpha_{i,0}}^m(\lambda_i)$. $m = c$ denotes models which do not include a time trend and the structural change affects either the intercept and/or the cointegrating vector, $m = \tau$ stands for models with a trend where, as before, the break affects the intercept and/or the cointegrating vector, and $m = \gamma$ stands for models where a change in trend is allowed.

The dependence on the break dates (which had been suppressed earlier) is made clear here. No added estimations are needed at this stage because the breaks are assumed known. In the more general case, however, the tests will have to be based on estimates of the break dates for each of these units, as discussed for the generalization of the Pedroni tests above, but with the further complication of accounting for cross-sectional dependence. For the models considered, the following result has been derived.

Theorem (Banerjee and Carrion-i-Silvestre, 2007, Theorem 2): Under the null hypothesis that $\rho_i = \varphi_i - 1 = 0$:

(a) $t_{\alpha_{i,0}}^c(\lambda_i) \Rightarrow \frac{\frac{1}{2}(W_i(1)^2 - 1)}{\left(\int_0^1 W_i(s)^2 ds\right)^{1/2}}$

(b) $t_{\alpha_{i,0}}^\tau(\lambda_i) \Rightarrow -\frac{1}{2}\left(\int_0^1 V_i(s)^2 ds\right)^{-1/2}$
where $V_i(s) = W_i(s) - sW_i(1)$

(c) $t_{\alpha_{i,0}}^\gamma(\lambda_i) \Rightarrow -\frac{1}{2}\left(\lambda^2 \int_0^1 V_i(b_1)^2 db_1 + \left(1 - \lambda^2\right)\right) \int_0^1 V_i(b_2)^2 db_2$
where $V_i(b_j) = W_i(b_j) - b_j W_i(1)$, $j = 1, 2$ are two independent detrended Brownian motion processes.

Moreover, if we assume for the moment that there is only one factor, then the estimated factor $\tilde{F}_t$ can also be tested for a unit root using an ADF regression of the form:

$$\Delta\tilde{F}_t^m(\lambda_i) = \delta_0\tilde{F}_{t-1}^m(\lambda_i) + \sum_{j=1}^{k}\delta_j\Delta\tilde{F}_{t-j}^m(\lambda_i) + u_t.$$

Then, for cases where there is no break in trend:

(d) $$t_{\delta_0} \Rightarrow \frac{\int_0^1 W^d(s)dW^d(s)}{\left(\int_0^1 W^d(s)^2ds\right)^{1/2}}$$

where $W^d(s)$ denotes a detrended Brownian motion. However, allowing for a change in trend leads to dependence on the break fraction, such that:

(e) $$t_{\delta_0}(\lambda) \Rightarrow \frac{\int_0^1 W^d(s,\lambda)dW^d(s,\lambda)}{\left(\int_0^1 W^d(s,\lambda)^2ds\right)^{1/2}}.$$

It is key to note the following features of the results:

(i) The densities derived above show no dependence on the stochastic regressors (that is, the $x_{i,t}$ processes). This follows from assuming orthogonality of the stochastic regressors to the factors and exogeneity with respect to the idiosyncratic errors. It may be shown that this implies that the above results also hold in cases where breaks in the cointegrating vector occur.

(ii) The limiting distributions, as long as a change in trend is not involved, do not depend on the break dates. This implies that, in principle, multiple changes in constants and slopes of the cointegrating vectors are allowed to occur. Heterogeneous break dates are allowed, and the issue of break dates being known or unknown is no longer relevant.

(iii) The situation changes substantially when a break in trend is allowed. The break fraction is important and thus must be estimated if not known. Moreover, recalling the discussion above, for the factor structure to be preserved, we need the breaks to occur at the same time across the units, so that the projection matrix M is not indexed by i. Thus trend breaks, if they occur, must have the same λ in all the units

(iv) Finally, for the case of several common factors, that is, $r > 1$, variations of the MQ tests proposed by Bai and Ng (2004) can be used and are subject to the same remarks as above. Models that do not allow for changes in trend show no dependence either on the stochastic regressors or, more importantly, on the timing of the breaks. Models that allow for a change in trend lead to statistics that depend upon the common break date.

The pooled test statistics are given by:

$$N^{-1/2}Z_{t_{NT}}^c, N^{-1/2}Z_{t_{NT}}^\tau \text{ and } N^{-1/2}Z_{t_{NT}}^\gamma,$$

where:

$$Z^{m}_{t_{NT}} = \sum_{i=1}^{N} t^{m}_{\alpha_{i,0}}; \quad m = c, \tau$$
$$Z^{\gamma}_{t_{NT}}(\lambda) = \sum_{i=1}^{N} t^{\gamma}_{\alpha_{i,0}}(\lambda),$$

and, as $T \to \infty, N \to \infty$ in sequence,

$$N^{-1/2} Z^{m}_{t_{NT}} - \sqrt{N}\Theta^{m}_{2} \Rightarrow N(0, \Psi^{m}_{2}), m = c, \tau$$
$$N^{-1/2} Z^{\gamma}_{t_{NT}}(\lambda) - \sqrt{N}\Theta^{m}_{2}(\lambda) \Rightarrow N\left(0, \Psi^{m}_{2}(\lambda)\right).$$

The moments for the pooled tests when $m = c, \tau$ are the same as those derived by Bai and Ng (2004), while for $m = \gamma$, the moments (which depend on the break fractions) are presented by Banerjee and Carrion-i-Silvestre (2007).

The analysis described above generalizes both the results of Bai and Carrion-i-Silvestre (2007) and Bai and Ng (2004) and also of Pedroni (1999, 2004). We have proposed here an encompassing framework that allows investigators to study dependence and breaks within the context of testing for cointegration and unit roots in macro-panels.

Two further extensions may be considered to allow exogenous regressors and for unknown break dates. The former is relatively straightforward and uses dynamic OLS (D-OLS) regressions to extract the residuals to be tested for integration. The methods are as rehearsed in section 13.3.2, albeit for the case of systems estimators without breaks, but no conceptual novelties are involved. It is shown by Banerjee and Carrion-i-Silvestre (2007) that using D-OLS leads to the asymptotic distributions being the same as those given above, even in the presence of endogeneity of regressors.

The case of unknown break dates is somewhat more complicated but relies on consistent estimation of the break fractions, so that wherever knowledge of the break date is necessary (as in the case where there are changes in trend) the true break date can be replaced by a consistent estimate. Since the estimation algorithms must allow for the breaks to occur at every point in time (within the closed interval), the densities depend on computing the infimum of the standardized t-statistics and are therefore non-standard. The critical values for this case are also given by Banerjee and Carrion-i-Silvestre (2007).

13.3.1.5 Empirical illustration with exchange rate pass-through in the euro-area

This sub-section is based on material from Banerjee and Carrion-i-Silvestre (2007) and de Bandt, Banerjee and Kozluk (2008) and provides an illustration of single-equation panel cointegration techniques when both cross-sectional dependence and structural breaks are allowed to be present.

Prominent in the exchange rate pass-through literature are the papers by Campa and González-Minguez (2006) (henceforth CM), Campa, Goldberg and González-Minguez (2005) (henceforth CGM), and Frankel, Parsley and Wei (2005), *inter alia*, who have investigated the issue of exchange rate pass-through (ERPT) of foreign to domestic prices – that is, how changes in prices of imported goods are transmitted

to the domestic market in the face of exchange rate fluctuations (say, relative to the dollar if foreign prices are denominated in dollars) and pricing strategies of the exporters in the foreign countries. Studies of ERPT have been conducted both for the United States and for countries of the euro-area to study the importance of institutional arrangements (such as the inauguration of the euro-area) in generating responses to exchange rate institutions and changes.

An important feature missing from the discussion is a connection between the theoretical arguments surrounding the key determinants of pass-through, and the inappropriate techniques used to estimate equations measuring import or export exchange rate pass-through. For example, while almost all the theories contain a long-run or steady-state relationship in the levels of a measure of import unit values (in domestic currency), the exchange rate (relating the domestic to the numeraire currency) and a measure of foreign prices (unit values in the numeraire currency, typically US dollars), this long-run relationship is routinely disregarded in most of the empirical implementations.

Since there is substantial consensus in the literature that the time series being studied are integrated variables, one way of defining the long run is in the sense of Engle and Granger (1987) (henceforth EG), where it is given by the cointegrating relationship. A reason often given for ignoring this long-run relationship, and substituting it by an *ad hoc* measure, is a failure to find evidence for cointegration in the data. We argue that a more satisfactory approach is to look for the long-run relationship using more appropriate and powerful methods, such as those which allow for changes in the long-run or use more powerful panel data methods. In doing so, it is also important to allow for breaks in the long-run theoretical relationship so as to take due account of potential changes in pass-through rates in response to changes in financial regimes, such as the introduction of the euro in January 1999.

Exchange rate pass-through into import prices

By definition, import prices for any country i and type of good j, $MP_t^{i,j}$, are a transformation of the export prices of a country's trading partners, $XP_t^{i,j}$, using the bilateral exchange rate ER_t (say with respect to the dollar, if prices are denominated in dollars). Thus dropping superscripts i, j for clarity:

$$MP_t = ER_t \times XP_t.$$

In logarithms (depicted in lower case):

$$mp_t = er_t + xp_t.$$

If the export price consists of the exporters marginal cost and a mark-up:

$$XP_t = FMC_t \times FMKUP_t,$$

we have, in logarithms, by substituting for xp_t:

$$mp_t = er_t + fmc_t + fmkup_t.$$

The industrial organization literature offers explanations for why the effect of the change in er_t on mp_t may differ from one (with typically less than full pass-through, where the latter is defined as pass-through equal to one), using determinants of the mark-up such as competitive conditions among exporters in the destination markets. Mark-up responsiveness depends on the market share of domestic producers relative to foreign producers, the form of competition that takes place in the market for the industry, and the extent of price discrimination. Other factors affecting pass-through are the currency denomination of exports and the structure and importance of intermediate goods markets.

For example, the empirical set-up of CGM is based on assuming unity translation of exchange rate movements. If pass-through is complete (for example, in the case of producer currency pricing), and the mark-ups of producers do not fluctuate in response to fluctuations of the exchange rates, this leads to a pure currency translation. At the other extreme, the exporter can decide not to vary the prices in the destination country currency (local currency pricing) and absorb the fluctuations within the mark-up. Thus, mark-ups in an industry are assumed to consist of a component specific to the type of good, independent of the exchange rate, and a reaction to exchange rate movements:

$$fmkup_t = a + \Phi er_t.$$

It is also important to consider effects working through the marginal cost. These are a function of demand conditions in the importing country, denoted y_t; marginal costs of production in the exporting country (labor wages in domestic currency), denoted fw_t; and commodity prices denominated in foreign currency, fcp_t:

$$fmc_t = c_o y_t + c_1 fw_t + c_2 er_t + c_3 fcp_t.$$

We therefore have:

$$mp_t = a + (1 + \Phi + c_2) er_t + c_0 y_t + c_1 fw_t + c_3 fcp_t + \varepsilon_t$$

where the coefficient $b \equiv (1 + \Phi + c_2)$ on the exchange rate er_t is the pass-through elasticity and ε_t is a stochastic error term. In the CGM "integrated world market" specification, $c_0 y_t + c_1 fw_t + c_3 fcp_t$ is independent of the exchange rate. It is called the opportunity cost of allocating those same goods to other customers and is reflected in the world price of the product fp_t in the world currency (here taken to be the US dollar). Thus the final pass-through equation can be rewritten as follows:

$$mp_t = a + ber_t + cfp_t + \varepsilon_t,$$

which gives the long-run relation between the import price, exchange rate and a measure of foreign price.

Testing for ERPT

Both economic theory and relevant tests lead us to think of each of the series (import price, exchange rate and world price) as being characterized by a unit root.

However, despite the underlying levels equation described as the pass-through equation above, CM are not able to reject the null hypothesis of the non-existence of a cointegrating relationship among the three series. This implies that no evidence can be found in favor of an Engle–Granger long-run relationship among the three series, and thus of an estimate of ERPT in this sense. Hence, they proceed by estimating the long-run equation above *in first differences* (with some dynamic augmentation):

$$\Delta mp_t = a + \sum_{k=0}^{4} b_k \Delta er_{t-k} + \sum_{k=0}^{4} c_k \Delta fp_{t-k} + \varepsilon_t,$$

for industrial sector i in country j, where superscripts have been omitted for clarity. Since CM do not find evidence of a long-run relationship in the EG sense, they propose their own working definition of the long run. They define the coefficient b_k and the sum of coefficients $\sum_{k=0}^{4} b_k$ as the short-run and long-run ERPT respectively.

An alternative route, based on retaining use of the original EG formulation whilst not losing power to look at the long run, is to use the panel cointegration technology developed in this chapter, where for each (i, j) pair there are roughly 110–20 observations. Given that we have ten countries and nine industrial sectors, a panel-based test could use up to approximately $9 \times 10 \times 110$ observations).

The number of observations in the panel is dependent on our need to use a balanced panel. In order to obtain the longest *time* dimension (that is, from 1995), three countries, Austria, Finland and Portugal, need to be deleted from the whole sample since we do not have observations before 1996 for these countries. In order to maximize the *cross-section dimension*, however, so that no country is dropped, our sample needs to start in 1996:1 and end in 2004:12. The estimation results reported below are for this choice of the sample since fewer observations are lost under this configuration and, by allowing for heterogeneity, we should in principle obtain a far clearer idea of the common trends underlying the series and hence of the long run. In the spirit of the discussion above, any such estimation procedure in panels would of course need to allow for structural change. We look at these issues in turn after a brief consideration of the data.

Data

An unbalanced sample of 1995–2005 from Eurostat is available. The construction of the variables follows CM, and is described in Appendix A. The indicator we use for import prices, the index of import unit values (IUV), has a series of caveats associated with their use but we are constrained in our investigations by the quality of the publicly available data.

It is also important to support our claim that there are a number of reasons why we expect there may be a change in the long-run ERPT within our sample. First, on January 1, 1999, 11 European countries fixed their exchange rates by adopting the euro. Greece failed to fulfill the Maastricht Treaty criteria, and therefore joined two years later, effective January 1, 2001. This constituted a change in monetary

policy, especially for countries that previously had less credible policy regimes. Especially in countries with previously rather less successful monetary policy, the perceived stabilization of monetary policy may well have induced the producers to change their pricing strategies and would thus be expected to have an influence on the long-run ERPT. Moreover, the adoption of a common currency has changed competitive conditions by increasing the share of goods denominated in the (new) domestic currency. Finally, virtually all the currencies were depreciating against the US dollar in the period 1995–2000, and especially since 1996. Thereafter, following a short period of a stable euro–dollar exchange rate, the euro started appreciating till the end of our sample. This asymmetry of exchange rate developments may have different implications for ERPT.

Panel cointegration tests

There would essentially be three ways of proceeding in order to construct panels from the datasets – (1) creating country panels of industry cross-sections, (2) industry panels with country cross-sections, and (3) a pooled panel in which every country and industry combination constitutes a separate unit. In search of the existence of a cointegrating relationship in the series we try to maximize the dimensions of our panel, and thus will focus on (3). Results for (1) and (2) are available from us upon request.

In Table 13.9 we present the results of the modified Pedroni tests due to Banerjee and Carrion-i-Silvestre (2007), allowing for structural breaks (as described in section 13.3.1.3) and allowing for both structural change and cross-sectional dependence (as described in section 13.3.1.4). As noted earlier, results are presented for the longest available panel which includes all countries. Throughout the analysis it is assumed that in each cross-section member at most one break occurs, with, depending upon the model, this break occurring at the same time in all breaking components (intercept, trend, cointegrating vector).

The panel headed "Cross-sectionally independent" reports the results from the modified Pedroni (pooled panel t-) tests on the idiosyncratic components under the assumption that these are cross-sectionally independent. The results for all six model specifications concerning the deterministic components as outlined in section 13.3.1.3 – for all of which heterogeneous break dates are permitted – are reported in this panel.

The panel headed "Cross-sectionally dependent" provides the results for the tests of Banerjee and Carrion-i-Silvestre (2007), where cross-sectional dependence is also allowed. The test results are again reported for the idiosyncratic components and we display the results for both cross-sectionally homogeneous and heterogeneous break dates. For Models 3 and 6, we are restricted to imposing a cross-sectionally homogeneous (but unknown) break point. The remaining models allow for both heterogeneous and homogeneous breaks. The maximum number of factors allowed is six, the column labeled $\hat{r}$ provides estimates of the number of common factors, and under the heading $\hat{r}_1$ the number of integrated common trends detected from the MQ statistic is also reported. The break dates detected by the cross-sectionally dependent test, when homogeneous breaks are imposed, are also given.

Table 13.9 Banerjee and Carrion-i-Silvestre (2007) cointegration test results

Model	*Cross-sectionally independent*	*Cross-sectionally dependent*						
		Homogeneous break dates				*Heterogeneous break dates*		
	Panel test t-ratio	*Idiosyn.*	*Break date*	$\hat{r}$	$\hat{r}_1$	*Idiosyn.*	$\hat{r}$	$\hat{r}_1$
1	−22.596	−5.009	1999.02	6	1	−2.744	6	2
2	−26.500	−6.409	2002.11	6	1	−2.933	6	1
3	−25.018	−5.816	2002.03	6	1			
4	−22.523	−5.201	2000.03	6	1	−3.060	6	3
5	−24.677	−6.189	2002.08	6	1	−2.239	6	2
6	−23.498	−6.353	2002.10	6	1			

It is clear that in each case the tests overwhelmingly reject the null hypothesis of no cointegration. The reported breaks all occur in the neighborhood of the introduction of the euro in 1999 or the beginning of its strong appreciation in 2002. A refinement of our tests to allow for multiple breaks would perhaps allow us to detect both these "regime" changes, although it may be argued that the time dimension of the panel will not permit such detailed discrimination. Finally, if one were to think of Model 4 as the most plausible choice, there is very clear evidence, under every configuration, for a long-run relationship with a structural break in 2000.

There are a number of further issues that may be considered, including the magnitude of the pass-through coefficient and its change in response to the new monetary arrangements (or exchange rate movements). On the whole, allowing for a structural break in the relationship, we find that ERPT generally increases in the vicinity of the introduction of the euro. This may be the effect of stabilization in the monetary regime, leading to less noisy exchange rate behavior. Thus actual changes in the exchange rate may be perceived as more permanent and based on macro-fundamentals and exporters may therefore be more willing to pass these on to prices. An alternative explanation relates to the effect of the appreciation of the euro. In a world with a depreciating euro, exporters to the euro-area would be expected to hold back from passing through exchange rate changes to the price (since this would lead to their becoming more uncompetitive relative to the local producers in the euro-area). An appreciating currency means, however, that dollar prices become cheaper in the intra-euro market, leading producers to shift away from local currency pricing. Passing through more of their dollar price, to maintain their revenue in dollars, would still not erode their ability to keep an edge on the market and compete with local products. This asymmetrical response to currency appreciation versus its depreciation could explain the higher pass-through following the likely changes in regime identified above. All these results are tabulated in great detail in de Bandt, Banerjee and Kozluk (2008) and are also available from us on request.

Having studied testing for cointegration in some detail, we move next to a consideration of methods of estimating cointegrating vectors, both in single equations and in systems.

13.3.1.6 Single equation estimation of the cointegrating vector

In this sub-section we consider estimation of the cointegrating vector β for data given by (13.18′) and (13.22′), that is, when abstracting from the presence of cross-sectional dependence via factors and without structural breaks in the deterministic component. This is a topic of further research, as is the study of systems estimators of cointegrating vectors in a similar set-up (see section 13.3.2).

Note that in this case (that is, without cross-sectional dependence or breaks) we have already imposed the assumption that the cointegrating vectors are cross-sectionally identical, that is, $\beta_i = \beta$ for all $i = 1, \ldots, N$. This restriction appears reasonable (although it may be generalized) since in order to gain by resorting to panel methods some of the coefficients should be considered identical for all cross-section members. Given that cointegration is the prime focus, it appears natural to assume identical cointegrating relationships and to allow for heterogeneity in the other characteristics of the DGP.

It has to be noted, however, that, as distinct from the pure time series case, the pooled OLS estimator of β in (13.18′) also converges to a well-defined limit when the cointegrating vectors are not cross-sectionally identical and, more interestingly, converges to a well-defined limit even in the spurious regression case. This limit is given by the so called *average long-run regression coefficient* (for a detailed discussion and the precise assumptions, see Theorems 4 and 5 of Phillips and Moon, 1999). As in the time series case, the limiting distribution of the OLS estimator depends upon so called second-order bias terms, which necessitates the use of modified estimation methods to result in mean zero mixed normal limiting distributions, which are required, for example, to perform valid inference. The literature has, similar to the time series case, proposed two modifications of the OLS estimator to take account of second-order bias. These are given by fully modified OLS (FM-OLS) estimation, as proposed by Phillips and Hansen (1990), and D-OLS estimation, introduced in Saikkonen (1991) (to which we have already referred in section 13.3.1.4). Furthermore, similar to the cointegration tests, estimation can be performed in a pooled or group mean fashion.

For simplicity, we focus in the description of the estimation procedures on the case $m = 2$, that is, the case including only fixed effects and note that the other two cases for m – no deterministic components or both fixed effects and individual specific linear trends – can be handled analogously. If $m = 1$ the original observations are used as inputs in the procedure and if $m = 3$ the variables are individually demeaned and detrended first. Let $\bar{y}_i = \frac{1}{N}\sum_{t=1}^{T} y_{i,t}, \bar{x}_i = \frac{1}{N}\sum_{t=1}^{T} x_{i,t}$ and denote the cross-sectionally demeaned variables by $\tilde{y}_{i,t} = y_{i,t} - \bar{y}_i$ and $\tilde{x}_{i,t} = x_{i,t} - \bar{x}_i$.[28]

Fully Modified OLS

Estimation of the cointegrating vector in the panel context by using FM-OLS estimation is discussed in Phillips and Moon (1999), Kao and Chiang (2000) and Pedroni (2000). In a first step obtain estimators $\hat{\Omega}_{uv,i}, \hat{\Omega}_{v,i}$ and $\hat{\Lambda}_{v,i}$ from the residuals $(\hat{u}_{i,t}, v'_{i,t})'$. The residuals can be obtained by either individual specific OLS estimation or by using the least squares dummy variable (LSDV) estimator

in (13.18′), which puts the homogeneity restriction on the cointegrating relationship in place. Next, defining the endogeneity corrected variable $\tilde{y}^{+}_{i,t} = \tilde{y}_{i,t} - \hat{\Omega}_{uv,i}\hat{\Omega}^{-1}_{v,i}\Delta\tilde{x}_{i,t}$ leads to the following pooled FM-OLS estimator:

$$\hat{\beta}_{FM} = \left(\sum_{i=1}^{N}\sum_{t=1}^{T}\tilde{x}_{i,t}\tilde{x}'_{i,t}\right)^{-1}\left(\sum_{i=1}^{N}\sum_{t=1}^{T}\left(\tilde{x}_{i,t}\tilde{y}^{+}_{i,t} - \left(\hat{\Lambda}^{+}_{uv,i}\right)'\right)\right),$$

where $\Lambda^{+}_{uv,i} = \hat{\Lambda}_{uv,i} - \hat{\Omega}_{uv,i}\hat{\Omega}^{-1}_{v,i}\hat{\Lambda}_{v,i}$. Phillips and Moon (1999) use in their formulation of the FM-OLS estimator averaged correction factors, for example, $\hat{\Omega}_{v} = \frac{1}{N}\sum_{i=1}^{N}\hat{\Omega}_{v,i}$ and similarly for the other required matrices. The limiting distribution of the FM-OLS estimator (see, for example, Theorem 9 of Phillips and Moon, 1999) is given by:

$$N^{1/2}T\left(\hat{\beta}_{FM} - \beta\right) \Rightarrow N\left(0, 6\omega^{2}_{u.v}\Omega^{-1}_{v}\right),$$

with $\omega^{2}_{u.v} = \lim_{N\to\infty}\frac{1}{N}\sum_{i=1}^{N}\omega^{2}_{u.v,i}$ and $\Omega_{v} = \lim_{N\to\infty}\frac{1}{N}\sum_{i=1}^{N}\Omega_{v,i}$, with these limits (in most papers implicitly) assumed to exist.[29] For the case $m = 0$ (without deterministic components), the multiplicative factor 6 in the variance term of the limiting distribution has to be replaced by 2. Also note that the limiting covariance matrix is composed of cross-sectional averages.

Standard, up to the factor 2 or 6 depending upon the deterministic specification considered, normally distributed pooled FM-OLS estimators are also easily constructed. These are popular due to their implementation in freely available software. Define the following:

$$\begin{aligned}
\tilde{y}^{0}_{i,t} &= \hat{\omega}^{-1}_{u.v,i}\tilde{y}^{+}_{i,t} - \left[\left(\hat{\omega}^{-1}_{u.v,i}I_{\dim(x)} - \hat{\Omega}^{-1/2}_{v,i}\right)\tilde{x}_{i,t}\right]'\hat{\beta}\\
\tilde{x}^{0}_{i,t} &= \hat{\Omega}^{-1/2}_{v,i}\tilde{x}_{i,t}\\
\hat{\Lambda}^{0}_{uv,i} &= \hat{\omega}^{-1}_{u.v,i}\hat{\Lambda}^{+}_{uv,i}\hat{\Omega}^{-1/2}_{v,i},
\end{aligned}$$

where $I_{\dim(x)}$ denotes the identity matrix with dimensional equal to the number of regressors $x_{i,t}$. and $\hat{\beta}$ denotes the LSDV estimator. Then, the normalized FM-OLS estimator is given by:

$$\hat{\beta}^{0}_{FM} = \left(\sum_{i=1}^{N}\sum_{t=1}^{T}\tilde{x}^{0}_{i,t}\tilde{x}^{0\prime}_{i,t}\right)^{-1}\left(\sum_{i=1}^{N}\sum_{t=1}^{T}\left(\tilde{x}^{0}_{i,t}\tilde{y}^{0}_{i,t} - \left(\hat{\Lambda}^{0}_{uv,i}\right)'\right)\right),$$

for which it holds that $N^{1/2}T\left(\hat{\beta}^{0}_{FM} - \beta\right) \Rightarrow N\left(0, 6I_{\dim(x)}\right)$, where again the factor 6 has to be replaced by the factor 2 in the case of no deterministic components.

Furthermore, group mean FM-OLS estimation is considered in Pedroni (2000), with the estimator in its un-normalized form simply being given by the cross-sectional average of the individual FM-OLS estimators:

$$\hat{\beta}_{FM}^{G} = \frac{1}{N}\sum_{i=1}^{N}\left(\left(\sum_{t=1}^{T}\tilde{x}_{i,t}\tilde{x'}_{i,t}\right)^{-1}\left(\sum_{t=1}^{T}\tilde{x}_{i,t}\tilde{y}_{i,t} - \left(\hat{\Lambda}_{uv,i}^{+}\right)'\right)\right).$$

Dynamic OLS

We now turn to dynamic OLS estimation of the cointegrating relationship as discussed in Kao and Chiang (2000) and Mark and Sul (2003). The idea of D-OLS estimation is to correct for the correlation between $v_{i,t}$ and $u_{i,t}$ (see equations (13.18′)–(13.22′)) by including leads and lags of $\Delta x_{i,t}$ as additional regressors in the cointegrating regression. As in the time series case (in general), the number of leads and lags has to be increased with the (time dimension of the) sample size at a suitable rate to induce the noise process in the lead and lag augmented regression and $v_{i,t}$ to be uncorrelated asymptotically. Thus, considering again the case $m = 2$, let the augmented cointegrating regression be given by:

$$\begin{aligned}\tilde{y}_{i,t} &= \tilde{x}_{i,t}^{'}\beta + \sum_{j=-p_i}^{p_i}\Delta\tilde{x}_{i,t-j}^{'}\gamma_{i,j} + u_{it}^{*}\\ &= \tilde{x}_{i,t}^{'}\beta + \tilde{Z}_{i,t}^{'}\gamma_i + u_{it}^{*},\end{aligned}$$

where the last equation defines $\tilde{Z}_{i,t}$ and γ_i. The pooled D-OLS estimator for β is then obtained from OLS estimation of the above equations. Let $\tilde{Q}_{i,t} = \left[\tilde{x}_{i,t}^{'}, 0^{'}, \ldots, 0^{'}, \tilde{Z}_{i,t}^{'}, 0^{'}, \ldots, 0^{'}\right] \in R^{2\dim(x)\left(1+\sum_{i=1}^{N}p_i\right)}$, where the variables $\tilde{Z}_{i,t}$ are at the ith position in the second block of the regressors. Using this notation we arrive at:

$$\begin{bmatrix}\hat{\beta}_D\\ \hat{\gamma}_1\\ \vdots\\ \hat{\gamma}_N\end{bmatrix} = \left(\sum_{i=1}^{N}\sum_{t=1}^{T}\tilde{Q}_{i,t}\tilde{Q}_{i,t}^{'}\right)^{-1}\left(\sum_{i=1}^{N}\sum_{t=1}^{T}\tilde{Q}_{i,t}\tilde{y}_{i,t}\right).$$

Mark and Sul (2003) obtain the asymptotic distribution of $\hat{\beta}_D$, which has a sandwich type limit covariance matrix. Denote this as $\overline{V} = \lim_{N\to\infty}\frac{1}{N}\sum_{i=1}^{N}\omega_{u.v,i}^{2}\Omega_{v,i}$ (again assumed to exist), then it holds that:

$$N^{1/2}T\left(\hat{\beta}_D - \beta\right) \Rightarrow N\left(0, 6\Omega_v^{-1}\bar{V}\Omega_v^{-1}\right).$$

Kao and Chiang (2000) discuss a normalized version of the D-OLS estimator that corresponds to $\hat{\beta}_{FM}^{0}$. This estimator, $\hat{\beta}_D^0$ say, is obtained when, in the above discussion of the D-OLS estimator, $\tilde{y}_{i,t}$ and $\tilde{x}_{i,t}$ are replaced by $\tilde{y}_{i,t}^{0}$ and $\tilde{x}_{i,t}^{0}$. These changes

lead to an estimator with a limiting covariance matrix proportional to the identity matrix.

Pedroni (2001) considers a group mean D-OLS estimator. Denote $\tilde{R}_{i,t} = \left[\tilde{x}_{i,t}^{'}, \tilde{Z}_{i,t}^{'}\right]^{'}$ and estimate, for each $i = 1, \ldots, N$,

$$\begin{bmatrix} \hat{\beta}_{D,i} \\ \hat{\gamma}_i \end{bmatrix} = \left(\sum_{i=1}^{N} \sum_{t=1}^{T} \tilde{R}_{i,t} \tilde{R}_{i,t}^{'} \right)^{-1} \left(\sum_{i=1}^{N} \sum_{t=1}^{T} \tilde{R}_{i,t} \tilde{y}_{i,t} \right).$$

Then the group mean D-OLS estimator is given by $\hat{\beta}_D^G = \frac{1}{N} \sum_{i=1}^{N} \hat{\beta}_{D,i}$. The group mean D-OLS estimator can also be computed in a normalized fashion.

13.3.2 Testing for cointegration and estimation of the cointegrating vectors in systems

The analysis of multiple cointegrating vectors in panels is still very limited. The analysis is plagued by problems of arriving at a proper, yet statistically tractable, formulation of multiple cointegration (since one needs not only to consider the cointegration possibilities within the units of a panel, but also to identify those that link across the units of the panel). Estimation and inference are thus hampered by theoretical difficulties, as well as dimensionality issues, even when the panel dimensions are large.

Breitung (2005), Groen and Kleibergen (2003) and Larsson, Lyhagen and Löthgren (2001) have attempted analysis of this framework under restrictive assumptions such as a homogeneous cointegrating space (for the units of the panel) and, more unrealistically, cross-sectional independence of the units of the panel. Some of these methods are described in detail below.

If cross-unit cointegration is allowed then, as shown by Banerjee, Marcellino and Osbat (2004), tests for cointegration in panels (in the presence of multiple cointegrating vectors) suffer from size distortions and loss of power. Inference on the full cointegration structure in such situations remains an extremely difficult exercise and much further work is needed to understand the theoretical properties of feasible estimators and their performance in finite and large samples. For a detailed simulation study of some of the issues involved, see Wagner and Hlouskova (2007).

The established system methods are panel extensions of vector autoregressive (VAR) cointegration analysis (see Johansen, 1995). Compared to the single-equation methods several differences are worth mentioning. First, the systems approach allows us to test for and model multiple cointegrating relationships. Second, the cointegrated VAR approach allows for the incorporation of a richer specification concerning (restricted) deterministic components which are considered relevant in the applied cointegration literature. Third, specifying a parametric model incorporates the modeling of the short-run dynamics of the data, which are treated as nuisance parameters in the single-equation methods.

Given that the system methods are based on VAR estimates, substantial biases arise with short time series. Thus, for practical applications the time series dimension has to be sufficiently large, which is also required since the specification of a

dynamic model necessitates the estimation of a substantial number of parameters. Clearly, it has to be mentioned that accurate estimation of the long-run variances for the nonparametric methods requires sufficiently long time series.

Open issues are allowing for a factor structure in the error processes of the VAR models to allow for cross-sectional dependencies, and considering structural change in the deterministic components.

Without imposing any cross-sectional homogeneity assumption, the cross-sectionally independent panel VAR DGP considered is given in *error correction form* by:

$$\Delta Y_{i,t} = C_{1i} + C_{2i}t + \alpha_i \beta_i^{'} Y_{i,t-1} + \sum_{j=1}^{p_i} \Gamma_{ij} \Delta Y_{i,t-j} + w_{i,t}, \tag{13.30}$$

with $Y_{i,t} = (y_{i,t}, x_{i,t})^{'} \in R^m, m = l + 1, C_{1i}, C_{2i} \in R^m, \alpha_i, \beta_i \in R^{m \times k_i}$ with full rank $k_i, \Gamma_{ij} \in R^{m \times m}$ and w_{it} are cross-sectionally independent m-dimensional white-noise processes with covariance matrices $\Sigma_i > 0$.[30] To ensure that all the processes described by (13.30) are (up to the deterministic components) $I(1)$ processes, the matrices $\alpha_{i\perp}^{'} \Gamma_i \beta_{i\perp}$ have to be invertible, where $\alpha_{i\perp} \in R^{m \times (m-k_i)}, \beta_{i\perp} \in R^{m \times (m-k_i)}$ are full rank matrices such that $\alpha_{i\perp}^{'} \alpha_i = 0, \beta_{i\perp}^{'} \beta_i = 0$ and $\Gamma_i = I_m - \sum_{j=i}^{p_i - 1} \Gamma_{ij}$. One possible choice is given by $\alpha_{i\perp} = I_m - \alpha_i (\alpha_i^{'} \alpha_i)^{-1} \alpha_i^{'}$ and similarly for β_i. Under these assumptions the column space of the matrix β_i is the k_i-dimensional cointegrating space of unit i.

In the VAR cointegration literature the following five specifications of the deterministic components are usually discussed. Case 1 is without any deterministic components. In case 2 restricted intercepts of the form $C_{1i} = \alpha_i \tau_i$ are contained in the cointegrating space whereas in case 3 unrestricted intercepts C_{1i} that induce linear time trends in $Y_{i,t}$ are included. In case 4 unrestricted intercepts and restricted trend coefficients $C_{2i} = \alpha_i \kappa_i$ are included, which allows for linear trends in both the data and the cointegrating relationships. Finally, in case 5 unrestricted intercepts and trend coefficients are included, which leads to quadratic deterministic trends in $Y_{i,t}$. For a detailed discussion of these specifications concerning the deterministic variables see Johansen (1995, sec. 5.7). This monograph also includes a very detailed discussion of the statistical analysis, that is, parameter estimation via reduced rank regression, testing for the cointegrating rank as well as hypothesis testing. Therefore we do not include a description of this widely-used method here.

In the following two sub-sections we discuss two approaches, due to Larsson, Lyhagen and Löthgren (2001) and Breitung (2005), to test for cointegration in panel VAR models. In common with the single-equation approaches described above, both these methods put *at least* the restriction of a cross-sectionally homogeneous cointegrating space, that is, $\beta_i = \beta$, in place. Again the argument in favor of such a restriction is that in order to apply panel methods fruitfully, some of the coefficients have to be considered cross-sectionally identical. Since in cointegration analysis the main focus is on the cointegrating relationships, it is natural to assume identical cointegrating spaces and allow for individual specific short-run dynamics. This is

very similar to the analysis relating to single-equation estimators. In panel VAR cointegration analysis, however, the testing for cointegration and the estimation steps are much more intertwined than in the single-equation tests discussed above, for most of which the null hypothesis is that of no cointegration. The two tests to be discussed differ in this respect, since the test of Larsson, Lyhagen and Löthgren (2001) does not impose cross-sectional homogeneity in the construction of the test statistic (but needs this assumption for the derivation of the asymptotic distribution of the test statistic) whereas the test of Breitung (2005) incorporates this restriction.

13.3.3 Larsson, Lyhagen and Löthgren (2001)

Larsson, Lyhagen and Löthgren (2001) (henceforth LLL) consider testing for cointegration in the above framework under the assumption that $\Pi_i = \alpha_i \beta_i^{'} = \alpha\beta^{'} = \Pi$ for all $i = 1, \ldots, N$. For some further technical assumptions we refer the reader to their paper. Note here that their test is based simply on the cross-sectional average of the Johansen (1995) trace statistic, where the cross-sectional homogeneity assumption just mentioned is not put in place anywhere in the construction of their test. However, the asymptotic distribution (under the null hypothesis) of their test statistic is established only under this assumption (see Assumption 3 and Theorem 1 of LLL). The null hypothesis of their test is $H_0 : rk(\Pi) = k$ and the test is consistent against the alternative hypothesis $H_1 : rk(\Pi_i) > k$ for a non-vanishing fraction of the cross-section members.

The construction of the test statistic is similar to that of IPS and it is given by a suitably centered and scaled cross-sectional average of the individual trace statistics. Thus, denote by $LR_i^s(k, m)$ the trace statistic for the null hypothesis of a k-dimensional cointegrating space for cross-section unit i, where the superscript $s = 1, \ldots, 5$ indicates the specification of the deterministic components. Further, denote by $\mu_{LR}^s(k, m)$ and $\sigma_{LR}^{2,s}(k, m)$ the expected value and variance of $LR_i^s(k, m)$. In this respect LLL is a most notable but unfortunately underrated exception in the panel unit root and cointegration literature, insofar as the authors derive, admittedly only for the model without deterministic components and with normally distributed innovations, the existence of the necessary moments as well as uniform integrability and Lindeberg-type conditions. These are needed to derive formally the asymptotic normality of the test statistic.[31] Using a sequential limit with first $T \to \infty$ followed by $N \to \infty$, it holds that:

$$LLL^s(k, m) = N^{-1/2} \sum_{i=1}^{N} \frac{LR_i^s(k, m) - \mu_{LR}^s(k, m)}{(\sigma_{LR}^{2,s}(k, m))^{1/2}} \Rightarrow N(0, 1). \tag{13.31}$$

Finite-sample correction factors for the LLL test statistic are given in Hlouskova and Wagner (2008) for all five mentioned specifications of the deterministic components, where we note again that the theoretical result is only derived for the case without deterministic components and with normally distributed innovations.

LLL do not explicitly consider estimation of the cointegrating space. Given that their test is based on the assumption of a cross-sectionally identical cointegrating space, one possibility to obtain an estimate of the cointegrating space is given by the cross-sectional average of identically normalized individual specific cointegrating

spaces, for example, normalized as $\hat{\beta}_i = \left[I_k, \hat{\beta}_{i,2}^{'}\right]^{'}$, which are in any case computed in the derivation of the test statistic.

13.3.4 Breitung (2005)

Breitung (2005) proposes a two-step estimation and test procedure that extends the Ahn and Reinsel (1990) and Engle and Yoo (1991) approach from the time series to the panel case.

Breitung considers the homogeneous cointegration case where, however, only the cointegrating spaces are assumed to be identical for all cross-section members. In the first step of his procedure the parameters are estimated individual specifically (applying the method outlined in Johansen, 1995). This includes the first-step estimates of β_i. In the second step the common cointegrating space β is estimated in a pooled fashion.

For simplicity we describe the method here for the VAR(1) model excluding any deterministic component. In the general case lagged differences as well as potentially restricted deterministic components are treated in the usual way by being concentrated out at the beginning of the procedure. Thus, consider the following:

$$\Delta Y_{i,t} = \alpha_i \beta^{'} Y_{i,t-1} + w_{i,t}. \tag{13.32}$$

Next, define $T_i = \left(\alpha_i^{'} \Sigma_i^{-1} \alpha_i\right)^{-1} \alpha_i^{'} \Sigma_i^{-1}$ and pre-multiply (13.32) with this quantity to obtain:

$$\begin{aligned}
\left(\alpha_i^{'} \Sigma_i^{-1} \alpha_i\right)^{-1} \alpha_i^{'} \Sigma_i^{-1} \Delta Y_{i,t} &= \beta^{'} Y_{i,t-1} + \left(\alpha_i^{'} \Sigma_i^{-1} \alpha_i\right)^{-1} \alpha_i^{'} \Sigma_i^{-1} w_{i,t} \\
T_i \Delta Y_{i,t} &= \beta^{'} Y_{i,t-1} + T_i w_{i,t} \\
\Delta Y_{i,t}^{+} &= \beta^{'} Y_{i,t-1} + w_{i,t}^{+},
\end{aligned} \tag{13.33}$$

where the last equation defines the variables with superscript +. Note also that $E[w_{i,t}^{+}(w_{i,t}^{+})^{'}] = \left(\alpha_i^{'} \Sigma_i^{-1} \alpha_i\right)^{-1}$. Next use the normalization $\beta = \left[I_k, \beta_2^{'}\right]^{'}$ and partition $Y_{it} = \left[(Y_{i,t}^1)^{'}, (Y_{i,t}^2)^{'}\right]^{'}$ with $Y_{i,t}^1 \in R^k$ and $Y_{i,t}^2 \in R^{m-k}$. Using this notation the above equation (13.33) can be rewritten as:

$$\Delta Y_{i,t}^{+} - Y_{i,t-1}^1 = \beta_2^{'} Y_{i,t-1}^2 + w_{i,t}^{+}. \tag{13.34}$$

Breitung suggests estimating (13.34) by pooled OLS using the estimates $\hat{T}_i = \left(\hat{\alpha}_i^{'} \hat{\Sigma}_i^{-1} \hat{\alpha}_i\right)^{-1} \hat{\alpha}_i^{'} \hat{\Sigma}_i^{-1}$ based on the individual specific Johansen estimates. Note that, given that the covariance structure of the errors in (13.34) is known and an estimate is readily available, pooled feasible GLS estimation of (13.34) can also be performed.

Breitung's estimation procedure stops here. However, an iterative estimator based on the above procedure is easily conceived. With the estimated $\hat{\beta}_2$, all individual-specific parameters in (13.32) can be re-estimated. Since we have chosen the VAR(1)

set-up without deterministic components for illustration, these parameters are contained in the matrices α_i and Σ_i. Based on the new estimates of α_i and Σ_i, equation (13.34) can be re-estimated. This can be repeated until convergence, according to some numerical criterion, occurs.

Such an iterative procedure corresponds by and large to the iterative estimator proposed in Larsson and Lyhagen (1999), with the only difference being that Larsson and Lyhagen propose using $\hat{\beta}_2 = \frac{1}{N}\sum_{i=1}^{N}\hat{\beta}_{i,2}$ as the initial estimator. $\hat{\beta}_{i,2}$ denotes as before the (not-normalized coordinates of the) individual specific Johansen (1995) estimates. Let us note as a side remark that the set-up of Larsson and Lyhagen (1999) is more general, since these authors consider, in the VAR(1) case without deterministic components, the specification:

$$\begin{bmatrix} \Delta Y_{1,t} \\ \vdots \\ \Delta Y_{N,t} \end{bmatrix} = \begin{bmatrix} \alpha_{11} & \cdots & \alpha_{1N} \\ \vdots & \ddots & \vdots \\ \alpha_{N1} & \cdots & \alpha_{NN} \end{bmatrix} \begin{bmatrix} \beta' & & \\ & \ddots & \\ & & \beta' \end{bmatrix} \begin{bmatrix} Y_{1,t-1} \\ \vdots \\ Y_{N,t-1} \end{bmatrix} + \begin{bmatrix} w_{1,t} \\ \vdots \\ w_{N.t} \end{bmatrix},$$

with a full covariance matrix of the stacked noise process and all necessary assumptions such that the joint process is an $I(1)$ process. Thus, Larsson and Lyhagen (1999) consider a VAR model for the stacked vector of variables, where only the cointegrating space is restricted to be cross-sectionally identical and where no cross-unit cointegration occurs (meaning, in the notation of Appendix B, that the B matrix that collects all cointegrating relationships is block-diagonal).

It is not clear whether such an almost unrestricted VAR model for the stacked process should really be interpreted as a panel model or as a time series model for a high-dimensional process with some cross-equation restrictions. Pragmatically, the loose parameterization implies that the time dimension of the panel has to be very large compared to the cross-sectional dimension. Similar comments apply to the work of Groen and Kleibergen (2003), who also consider a very general (panel) VAR model and consequently present simulation evidence for a bivariate example for $N = 1, 3$ and 5 and $T = 1{,}000$.

Breitung (2005) shows that his two-step estimator, $\tilde{\beta}_2$ say, is asymptotically normally distributed in the sequential limit with first $T \to \infty$ followed by $N \to \infty$:

$$N^{1/2}Tvec(\tilde{\beta}_2 - \beta_2) \Rightarrow N(0, \Omega_2^{-1} \otimes \Sigma_\alpha),$$

where $\otimes$ denotes the Kronecker product,

$$\Omega_2 = \lim_{N\to\infty}\lim_{T\to\infty} E[\frac{1}{NT^2}\sum_{i=1}^{N}\sum_{t=1}^{T} Y_{i,t-1}^2 (Y_{i,t-1}^2)'],$$

and $\Sigma_\alpha = \lim_{N\to\infty}\frac{1}{N}\sum_{i=1}^{N}\left(\alpha_i'\Sigma_i^{-1}\alpha_i\right)^{-1}$, with these limits, in case of Ω_2 non-singular, implicitly assumed to exist by Breitung (2005).

Let us now turn to the test for cointegration that Breitung considers, which is based on Saikkonen (1999). The main difference to the test of LLL discussed above is

that Breitung incorporates the homogeneity restriction on the cointegrating spaces in the construction of the test statistics. We continue the discussion for the VAR(1) model without deterministic components. Denote with $\gamma_i \in R^{m\times(m-k)}$ full column rank matrices and consider:

$$\Delta Y_{i,t} = \alpha_i \beta^{'} Y_{i,t-1} + \gamma_i \beta_{\perp}^{'} Y_{i,t-1} + w_{i,t}. \tag{13.35}$$

Under the null hypothesis of a k-dimensional cointegrating space it holds that $\gamma_i = 0$ for $i = 1, \ldots, N$ and, under the alternative of an m-dimensional cointegrating space, γ_i is unrestricted to allow for $\Pi_i = \alpha_i \beta^{'} + \gamma_i \beta_{\perp}^{'}$ of full rank. For test consistency the alternative has to comprise a non-vanishing fraction of cross-section members. Pre-multiply (13.35) with $\alpha_{i,\perp}^{'}$ to obtain:

$$\begin{aligned} \alpha_{i,\perp}^{'} \Delta Y_{i,t} &= \alpha_{i,\perp}^{'} \gamma_i \beta_{\perp}^{'} Y_{i,t-1} + \alpha_{i,\perp}^{'} w_{i,t} \\ \alpha_{i,\perp}^{'} \Delta Y_{i,t} &= \phi_i (\beta_{\perp}^{'} Y_{i,t-1}) + \tilde{w}_{i,t}, \end{aligned} \tag{13.36}$$

where the last equation defines the coefficient matrices and variables. Replacing $\alpha_{i,\perp}^{'}$ and $\beta_{\perp}$ by estimates allows us to estimate equations (13.36) separately for each cross-section unit by OLS and to construct test statistics for the hypothesis $H_0 : \phi_i = 0, \ i = 1, \ldots, N$.

Any of the classical testing principles, that is, the likelihood ratio, Wald or Lagrange multiplier principle, can be used. Breitung discusses the Lagrange multiplier test statistic, which has the advantage that it only requires estimation under the null hypothesis. Denoting by $\hat{f}_{i,t} = \hat{\alpha}_{i,\perp}^{'} \Delta Y_{i,t}$ and with $\hat{g}_{i,t} = \hat{\beta}_{\perp}^{'} Y_{i,t}$, the Lagrange multiplier test statistic for unit i is given by:

$$LM_i(k,m) = Ttr\left[\sum_{t=2}^{T} \hat{f}_{i,t}\hat{g}_{i,t-1}^{'} \left(\sum_{t=2}^{T} \hat{g}_{i,t-1}\hat{g}_{i,t-1}^{'}\right)^{-1} \sum_{t=2}^{T} \hat{g}_{i,t-1}\hat{f}_{i,t}^{'} \left(\sum_{t=2}^{T} \hat{f}_{i,t}\hat{f}_{i,t}^{'}\right)^{-1}\right],$$

which is sequentially computed for the different values of $k = 0, \ldots, m$.

The panel test statistic is then, as usual, given by the corresponding centered and scaled cross-sectional average, where we now use again the superscript s to indicate the dependence upon deterministic components. Under the null hypothesis we hence arrive at:

$$B^s(k,m) = N^{-1/2} \sum_{i=1}^{N} \frac{LM_i^s(k,m) - \mu_{LM}^s(k,m)}{(\sigma_{LM}^{2,s}(k,m))^{1/2}} \Rightarrow N(0,1). \tag{13.37}$$

The correction factors $\mu_{LM}^s(k,m)$ and $\sigma_{LM}^{2,s}(k,m)$ coincide exactly with those of LLL above. The method also shares with LLL the limitations concerning the availability of proper asymptotic theory. Clearly, instead of basing the panel tests upon the trace statistic, the max statistic of Johansen (1995) could be used as the underlying time series test statistic in both the LLL and Breitung tests.

The final substantive section of our chapter is to apply some of the estimation methods described in this section to the EKC analysis, building on our findings in section 13.2.4.2.

13.3.5 The environmental Kuznets curve analysis continued

As indicated above, estimation of an equation of the form (13.17) using usual cointegration methods is troublesome given the presence of nonlinear transformations of integrated regressors (GDP and its square). Regressions involving nonlinear transformations of integrated regressors behave differently from the regressors usually considered and have been studied for the time series case in Chang, Park and Phillips (2001) and Park and Phillips (1999, 2001). Hong and Wagner (2008a) develop an FM-OLS estimator for nonlinear cointegrating relationships including integer powers of integrated regressors as well as specification and cointegration tests for this set-up. Hong and Wagner (2008b) derive first results for a simple panel setting by considering a seemingly unrelated nonlinear cointegrating regressions framework.

Ignoring the problems caused by nonlinear transformations, cross-sectional dependencies and structural change, and applying the seven tests of Pedroni (1999, 2004) leads to seemingly overwhelming support for cointegration (with the detailed results available upon request). Again these findings are in line with the Lyhagen result that in the presence of common non-stationary components the unit root null hypothesis is over-rejected, which leads to seemingly strong support for cointegration. Note that these findings are obtained both when using the quadratic formulation (13.17) as well as the specification when only GDP is included in the regression, with the latter specification being subject only to the cross-sectional dependence and structural change problems.

Given the seemingly "strong evidence for cointegration," the final step in panel cointegration analysis is the estimation of relationship (13.17). In Table 13.10 we present the results for sulphur dioxide emissions when applying the fully modified OLS estimator discussed in detail in Phillips and Moon (1999), the dynamic OLS estimator of Mark and Sul (2003) and the two-step estimator of Breitung (2005). With the exception of the D-OLS estimator, seemingly strong evidence for the prevalence of an EKC for sulphur dioxide appears, even with plausible turning points with respect to income. Especially when applying fully modified estimation the turning points are well within the sample. However, these findings should be treated with some caution, given that the properties of the estimation methods in the presence of cross-sectional dependence and, in particular, of nonlinear transformations of integrated regressors are far from fully worked out.

The finding of stationary de-factored GDP allows us to use standard econometric methods to estimate equation (13.17) with de-factored observations. Table 13.11 shows the results from a variety of specifications, for example, one-way and two-way fixed effects estimation and equations including the extracted factors as additional regressors. For none of these specifications is there evidence for an inverted U-shaped relationship, since the coefficients to income and squared income are significantly positive.

Table 13.10 Panel cointegration estimation results for SO_2

	FM-OLS	*D-OLS*	*Two-step*
	Fixed effects		
$\ln y_{it}$	**5.26**	**1.35**	**4.80**
	(35.65)	(6.93)	(13.34)
$(\ln y_{it})^2$	**–0.26**	−0.01	−0.22
	(-28.22)	(−0.60)	(−10.18)
TP (in $)	24,720	–	54,671
	Fixed effects and linear trends		
$\ln y_{it}$	**4.82**	**−12.63**	**4.12**
	(34.45)	(-68.80)	(11.74)
$(\ln y_{it})^2$	**−0.23**	**0.86**	**-0.18**
	(−26.35)	(16.12)	(−8.34)
TP (in $)	35,534	–	93,381

Notes: Estimation results obtained with the panel cointegration estimation methods described in sections 13.3.1–4. The upper panel contains the results with only fixed effects included in the regression and the lower panel reports the results with both fixed effects and linear trends included. Bold indicates significance of the estimated coefficients at the 5% level and the numbers in brackets are the *t*-values. TP denotes the implied turning point.

Table 13.11 Estimation results with de-factored observations

	DF-1			*DF-2*		
	One-way	*Two-way*	*Incl.* F_t	*One-way*	*Two-way*	*Incl.* F_t
$\ln y_{it}$	**0.86**	**0.79**	**0.78**	**0.92**	**0.66**	**0.69**
	(14.75)	(13.90)	(13.47)	(14.86)	(10.80)	(11.30)
$(\ln y_{it})^2$	**0.48**	**0.44**	**0.38**	**0.55**	0.10	**0.22**
	(12.24)	(11.30)	(9.60)	(6.34)	(1.09)	(2.52)

Notes: One-way refers to equations including fixed individual effects, Two-way refers to equations including fixed individual and time effects and Incl. F_t refers to equations including fixed individual effects and the estimated common factors of both SO_2 emissions and GDP. *DF*-1 indicates that the common factors are obtained from the model without linear trends and *DF*-2 indicates that the common factors are obtained from the model with linear trends. Bold indicates significance of the estimated coefficients at the 5% level and the numbers in brackets are the *t*-values.

The estimation results just mentioned are robust in a number of ways. First, they are qualitatively unchanged if the de-factorization method allows for structural breaks, as found when using the Bai and Carrion-i-Silvestre (2007) methodology. The results are also robust to using smaller sets of countries or shorter time periods to rule out the potential structural changes. Also, when allowing for parameter

heterogeneity across countries, only very limited evidence for an EKC arises, with the main observation being that for several countries very implausible parameter estimates occur.

The scarcity of evidence for an EKC for sulphur dioxide in the panel at hand is in line with the observation that the common factors driving GDP and SO_2 appear not to be cointegrated. This long-run disconnect between these two variables potentially shows the limitation of reduced form EKC modeling and it may be necessary to resort to more structural modeling approaches to shed further light on the EKC hypothesis, from either a time series or a panel perspective.

13.4 Conclusions

We have sought in this chapter to provide an up-to-date analysis of the methods involved for estimation and inference in non-stationary panels. Our overriding objective has been not only to provide information on the tools but also to interpret the literature and to highlight the considerable challenges that remain. Starting with the motivating example and concluding with the appendices, this chapter has sought to emphasize the difficulties involved in formulating hypotheses within a panel framework, estimating them and conducting inference coherently.

Features of the data that the methods need to incorporate include (in addition to non-stationarity) cross-sectional dependence and structural instability. For example, we have argued that assuming cross-sectional independence of the units leads to relatively simple sequential central limit theory that provides the asymptotic normality of many of the test statistics. As soon as this assumption is relaxed, matters become much more complicated and in ways which are still not fully understood in the literature.

Modeling dependence via factors is a popular device but is only one of the many ways of formulating the problem. Account must be taken of short-run versus long-run dependence, which must be dealt with appropriately. The link between cointegration and factor models in panels needs to be adequately explored (see Appendix B).

More generally, the asymptotic theory must be put on a surer footing to deal not only with many of the joint limiting arguments that arise in the consideration of any form of dependence in the panel but also to deal with cases where there is potential structural instability in the data. In this chapter we have demonstrated some preliminary (and fairly crude) ways of modeling structural instability but a closer look is clearly warranted. The extension of systems methods to panels – to allow for multiple cointegrating vectors – in the possible presence of cross-sectional dependence and structural breaks is an important task but one of considerable complexity. Dealing with these problems should constitute fruitful areas of research in the years ahead.

Cuba	Italy	Poland	USSR
Denmark	Jamaica	Portugal	Venezuela
Djibouti	Japan	Qatar	Yugoslavia
Dominican Republic	Jordan	Reunion	Zaire
Ecuador	Kenya	Romania	
Egypt	Lebanon	Sierra Leone	
El Salvador	Liberia	South Africa	

Notes: The data for CSSR, USSR and Yugoslavia are constructed by taking the values for all the countries that previously constituted these countries before the separations in the early 1990s. The GDP series are taken from the Groningen Growth and Development Center dataset already mentioned in the introduction, and the SO_2 emissions series are from Stern (2006).

All variables are used in logarithms in the econometric analysis

SITC code – Industry
0 – Food and live animals chiefly for food
1 – Beverages and tobacco
2 – Crude materials, inedible, except fuels
3 – Mineral fuels, lubricants and related materials
4 – Animal and vegetable oils, fats and waxes
5 – Chemicals and related products
6 – Manufactured goods classified chiefly by materials
7 – Machines, transport equipment
8 – Manufactured goods

CM dataset 1989–2001 – series for 1989:1–2001:3 for Belgium + Luxembourg, France, Germany, Greece, Ireland, Italy, Netherlands, Portugal and Spain.

Series for 1996:1–2001:3 for Austria and Finland.

Our "new" dataset 1995–2005 – 1995:1–2005:3 for ten out of eleven countries of the CM dataset (Belgium + Luxembourg excluded, Austria and Finland start 1996:1, Portugal and Austria stop 2004:12)

Full panel – reduced version of 1995–2005 dataset: trimmed in order to obtain a balanced panel. Covers 1996:1–2004:12 for all ten countries.

13.6 Appendix B: Cross-sectional dependence

Allowing for cross-sectional dependence complicates matters substantially compared to the case of cross-sectionally independent panels. In the early literature on non-stationary panels, cross-sectional dependence had been modeled by allowing for common fixed (respectively random) effects. It was, however, quickly realized that in a non-stationary time series panel context the modeling of cross-sectional dependence needed to allow for richer types of dependencies that allow us, in particular, to model both transitory (short-run) and permanent (long-run) cross-sectional dynamic dependencies.

During the course of the chapter, in modeling cross-sectional dependence, we have typically followed the route prescribed by Bai and Ng (2004), *inter alia*, in using approximate factor models. Dependence can also be introduced, as in Banerjee *et al*. (2004), by considering cointegrating relationships across the variables in the cross-sectional units. In this brief appendix, we attempt to provide an exploration of these issues, including a discussion of the restrictions on the cointegrating space (of the full panel) implied by factor models and of the links between these alternative formulations of cross-sectional dependence.

In order to clarify the concepts, consider the case of a panel of *univariate* time series, neglecting for simplicity deterministic components, and denote the stacked joint vector (for given N) as $y_t = (y_{1,t}, \ldots, y_{N,t})'$.

The first assumption that is usually, unfortunately typically only implicitly, made is that the joint vector process is a vector $I(1)$ process, or, in the case of all series being stationary, a multivariate stationary process. Clearly, this is an assumption that has to be put in place over and above the assumption that all the *individual* series are $I(1)$ or stationary. This stems from the fact that stacking stationary processes does not in general lead to a jointly stationary vector process. Stationarity of the stacked process occurs if and only if all the processes are *stationary correlated*, that is, if all cross-correlation functions between the individual processes are stationary. For cross-sectionally independent processes this latter condition is fulfilled by construction. Since stacked stationary processes are not necessarily stationary it is clear also that stacked $I(1)$ processes are not necessarily $I(1)$ processes.

Given that we consider panels of non-stationary time series, dependence concepts well-established in the time series literature are also of prime importance in this context. In particular we will distinguish between short-run and long-run dependence. To be precise, in these definitions we will focus on the dependence

structure of the second moments, that is, the covariance, respectively correlation, structure. Obviously, this focus stems from the fact that when using the $I(1)$ framework we are dealing with cumulated weakly stationary processes which are characterized by their second moment structure. Focusing on the second moment structure is enough for studying the structure of dependencies although, in general, it will not be enough for the statistical analysis, since, for example, the cross-section members might be uncorrelated but not independent. However, for our discussion here we use dependence synonymously with correlation.

Considering the non-stationary panel (for any given cross-sectional dimension N) as a high-dimensional time series, we will first define cross-unit cointegration (following Wagner and Hlouskova, 2007), which will then be used to define short-run and long-run dependence.

Let us start our discussion with panels of univariate time series, noting here that the concept of cross-unit cointegration becomes more interesting for panels of multivariate time series. Take without loss of generality in the panel of time series the first N_1 series to be (jointly) stationary and the remaining $N - N_1$ series to be $I(1)$. With the first N_1 series stationary, a set of *trivial* cointegrating relationships emerges for y_t, with a basis given by $[I_{N_1}, 0]'$. Cross-unit cointegration is present if, over and above these, cointegrating relationships that are not contained in the above trivial cointegrating space are present.

This concept can be formalized by denoting as B (a basis of) the cointegrating space of the vector y_t. Then, we define the *cross-unit cointegrating space* as the projection of B on the orthogonal-complement of the trivial cointegrating space (that is, $[I_{N_1}, 0]'$,) given by $B^{CU} = \begin{bmatrix} 0 & 0 \\ 0 & I_{N-N_1} \end{bmatrix} B$, which in our currently simple framework of panels of univariate series amounts to nothing but the cointegrating space of the $N - N_1$ integrated series contained in the panel, assumed to be ordered last in the discussion. The dimension of this space is called the cross-unit cointegrating rank.

Let us now turn to panels of multivariate time series and consider a panel comprised of Nm-dimensional vectors of time series that are assumed to be jointly $I(1)$, respectively stationary, that is, $Y_t = (Y_{1,t}', \ldots, Y_{N,t}')' \in R^{Nm}$.[32] Next denote with $\beta_i \in R^{m \times k_i}$ the k_i-dimensional cointegrating space of $Y_{i,t}$. As before we denote the cointegrating space of the stacked process as $B \in R^{Nm \times \sum_i k_i}$. We stack the individual specific cointegrating spaces in:

$$\beta\!\!\!/ = \begin{bmatrix} \beta_1 & 0 & \cdots & 0 \\ 0 & \beta_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & 0 \\ 0 & \cdots & 0 & \beta_N \end{bmatrix} \in R^{Nm \times \sum_i k_i}.$$

By definition it holds that $sp\{B\} \supseteq sp\{\beta\!\!\!/\}$. The cross-unit cointegrating space is defined as the projection of B on the orthogonal-complement of $\beta\!\!\!/$, that is, it is

given by:

$$B^{CU} = (I_{Nm} - \not{\beta}(\not{\beta}'\not{\beta})^{-1}\not{\beta}')B. \tag{B.1}$$

The dimension of the space (spanned by) B^{CU} is defined as the cross-unit cointegrating rank. The definition merely formalizes the notion that, considering here the simplest example, cointegrating relationships of the form $[\beta_1^{'}, \beta_2^{'}, 0, \ldots, 0]^{'}$ that involve variables from different cross-sections but lead to a stationary transformed process $\beta_1^{'}Y_{1,t} + \beta_2^{'}Y_{2,t}$ merely via combining already stationary processes from different cross-section units (in the example $\beta_1^{'}Y_{1,t}$ and $\beta_2^{'}Y_{2,t}$) should not be considered as *genuine* cross-unit cointegrating relationships. The above definition of the space B^{CU} as the projection of B on the ortho-complement of $\not{\beta}$ delivers all cointegrating relationships that are not given by linear combinations of individual specific cointegrating relationships, that is, $B = B^{CU} \oplus \not{\beta}$, with $\oplus$ denoting the direct sum. We say that the panel exhibits long-run cross-sectional dependence if the cross-unit cointegrating rank is larger than 0. In case the cross-sectional units are correlated, but there is no cross-unit cointegration, we speak of (*pure*) short-run cross-sectional dependence.

Note for completeness that the previous sentence implies that panels comprised of independent random walks are short-run dependent – since independent random walks are asymptotically correlated, this is the famous spurious correlation (for example, Phillips, 1986). Therefore, if one were to be keen on excluding spurious asymptotic correlations, the above definition of short-run dependence can simply be reformulated and stated in terms of cross-sectional correlation once all variables have been transformed to stationarity, that is, by first-order differencing all integrated variables in the panel. In other words, the definition might be based on the innovations of the individual series to avoid the necessity to explicitly discuss spurious correlations.

Given that we consider processes that have a representation as a solution to autonomous stochastic difference equations, both forms of dependence, short-run and long-run, originate in the dependence structure of the error processes driving the individual series in the respective difference equations. Consider, for example, the DGP considered for testing for cointegration by single equation methods in (13.18)–(13.22), abstracting here from deterministic components. In this system the stochastic behavior is governed by the three random processes $\eta_t, \varepsilon_{i,t}$ and $\nu_{i,t}$. The *raison d'être* of the common factors is to induce cross-sectional dependencies via the common factors, but short- and long-run dependence can also arise via the other two components as soon as the assumption that they are cross-sectionally independent is relaxed. To illustrate the issue consider (13.21), that is, $(1-\varphi_i L)e_{i,t} = H_i(L)\varepsilon_{i,t}$, with the $\varepsilon_{i,t}$ being white-noise processes. Noting that the fact that the $\varepsilon_{i,t}$ are individually white-noise processes does not imply that the stacked vector $\varepsilon_t = \left(\varepsilon_{1,t}, \ldots, \varepsilon_{N,t}\right)^{'}$ is a vector white-noise process, it becomes immediately clear

that even via $\varepsilon_{i,t}$ both short- and long-run dependence can be introduced into the panel. The same applies for the vector $u_t = \left(u_{1,t}, \ldots, u_{N,t}\right)'$.

In a way, short-run dependence can, in several respects be potentially less problematic than long-run dependence. If we think of, for example, unit root testing, then short-run cross-sectional correlation will lead to distorted inference, of which account can be taken. Compare the discussion of O'Connell (1998) or the set-up of Chang (2002). Long-run dependence typically is found to have more detrimental effects, see Lyhagen (2000), that cannot be remedied easily, for example, by simple feasible GLS-type corrections.

There is one further issue with respect to long-run dependence or cross-unit cointegration. Our discussion up to here has been for the case of fixed cross-sectional dimension. In general, the dimension of the cross-unit cointegrating space is itself dependent upon N since, due to the inclusion of additional panel members, additional cross-unit cointegrating relationships may emerge. Consequently, a thorough analysis of cross-unit dependence and its effects needs to consider the dependence behavior when $N \to \infty$. Part of the literature takes short-cuts in this respect; for example, Evans and Karras (1996) and Lyhagen (2000) consider a panel set-up with exactly one common trend and with all pair-wise differences of the series being stationary for all values of N. In this way they avoid a proper consideration of the dependence of the cointegration structure on the cross-sectional dimension.

Considering all series together as a high-, or in the limit infinitely-, dimensional time series is useful for understanding the algebraic structure of cointegration, cross-unit cointegration and short-run cross-sectional dependence. However, from a panel modeling perspective, restrictions on the joint DGP have to be put in place in order to materialize gains from pooling in one way or another.

Looking at factor models, consider the joint process $u_t = \left(u_{1,t}, \ldots, u_{N,t}\right)'$, where for simplicity we ignore deterministic components:

$$u_t = \Pi' F_t + e_t,$$

with $\Pi = \left[\pi_1', \ldots, \pi_N'\right]' \in R^{r \times N}$, the r common factors $F_t \in R^r$, and the idiosyncratic components $e_t = \left(e_{1,t}, \ldots, e_{N,t}\right)'$.

Since we focus here on the cointegration implications of the factor model, we assume for simplicity that the factor loadings matrix Π is non-stochastic and that the idiosyncratic components are cross-sectionally independent. As noted previously, the fact that Bai and Ng (2004) also allow the factor loadings Π to be stochastic is mainly a mathematical achievement but does not really change any of the properties of the time series panel since all observations are generated from *one single realization* of the factor loadings. Bai and Ng (2004) allow for a certain form of correlation between the components of e_t (described in section 13.2.2.2) which is why they dub their model an approximate factor model. The corresponding assumption (see Bai and Ng, 2004, p. 1130, Assumption C) is, however, of mainly a technical character and simply allows for bounded correlation between the

innovation sequences. Under some further simplifying assumptions, the long-run covariance matrix of Δu_t, Ω_Δ say, is given by:

$$\Omega_\Delta = \Pi' \Omega_{\Delta F} \Pi + diag\left(\omega_{\Delta i}\right),$$

with $\Omega_{\Delta F} \in R^{r \times r}$ denoting the long-run covariance matrix of the first difference of the factors and $diag(\omega_{\Delta i})$ collecting the long-run variances of Δe_{it} for $i = 1, \ldots, N$. As is well known, cointegration prevails when the long-run covariance matrix has reduced rank. Starting with the idiosyncratic components, we know that the long-run variance of $\Delta e_{i,t}$ is equal to 0 when $e_{i,t}$ is itself already stationary. The first part of Ω_Δ has at most rank r. A cointegrating relationship has to be contained in the left kernel of both terms above. These observations allow us to immediately study the cointegration properties of u_t.

Assume, without loss of generality, that the first $0 \leq r_1 \leq r$ factors are integrated but not cointegrated and the remaining ones are stationary. Also assume that the units are ordered in such a way that the first $0 \leq N_1 \leq N$ coordinates of e_t are stationary and the remaining ones integrated. With this set-up, cointegration prevails if, in $\beta' u_t$, the first r_1 factors and the lower $N - N_1$ coordinates of e_t are annihilated. Partition the factors as $F_t = \left[(F_t^1)', (F_t^2)'\right]'$, with $F_t^1 \in R^{r_1}, F_t^2 \in R^{r-r_1}$ and $\Pi = \left[\Pi_1', \Pi_2'\right]'$ accordingly. Then the cointegrating space is given by the intersection of the orthogonal-complement of Π_1' and $\left[I_{N_1}, 0'_{(N-N_1)\times N_1}\right]'$ to wipe out the two non-stationary contributions to the vector u_t. Without further assumptions on the various spaces the cointegrating rank cannot be determined.

Note in addition that the identification of the factors for $N \to \infty$ rests upon the assumption that $\lim_{N\to\infty} \frac{1}{N} \sum_{i=1}^{N} \pi_i \pi_i' = \Sigma_\Pi > 0$, which does not, determine the ranks of the loading matrices for finite cross-sectional dimension and hence does not, in particular, determine the number of linearly independent integrated common factors for finite N.

However, some simple observations can be made. First, cointegration can only occur if some of the idiosyncratic components are stationary, since it can only occur between series with stationary idiosyncratic components.

Second, if all common factors are stationary, the dimension of the cross-unit cointegrating space is zero.

Third, to allow for a bit more detailed analysis of the cointegrating space assume now that, for the given cross-sectional dimension N, it holds that $rk\left(\Pi_1\right) = r_1$. We already know from the first observation that we only need to consider the first N_1 series $\left(u_{1,t}, \ldots, u_{N_1,t}\right)'$ corresponding to the stationary idiosyncratic components to analyze cointegration. Amongst these series the cointegrating space is given by the left kernel of:

$$\begin{bmatrix} \left(\pi_1^1\right)' \\ \vdots \\ \left(\pi_{N_1}^1\right)' \end{bmatrix} \in R^{N_1 \times r_1}. \tag{B.2}$$

The assumption of full rank of Π_1 does not imply that the above sub-matrix composed of the first N_1 columns of Π_1 also has rank equal to r_1. Clearly, it necessarily has rank smaller than r_1 if $N_1 < r_1$, but can also have reduced rank otherwise. A reduced rank, s_1 say, of the matrix in (B.2) implies that only this smaller number s_1 of common trends is distinguishable within the first N_1 coordinates of u_t. The cointegrating space is given by the orthogonal-complement in R^{N_1} of the space spanned by the matrix (B.2), which is of dimension $N_1 - s_1$ in our discussion. The cross-unit cointegrating space can be determined as in the definition above, again by projecting on the orthogonal-complement of the stacked individual specific cointegrating spaces (β in the notation introduced above). In our univariate context individual specific cointegration means that a series $u_{i,t}$, for some $i = 1, \ldots, N_1$, is stationary, which happens when the corresponding $\lambda_i^1 = 0$. In this case the corresponding entry in β is set equal to 1. Note that, due to possible rank reduction in (B.2), for this to happen it is not necessary for the condition $\pi_i^1 = 0$ to hold, although it is of course sufficient. The above analysis also applies when all idiosyncratic components are stationary, in which case $N_1 = N$.

Altogether the discussion highlights the price that has to be paid, in terms of very restricted structures of the cointegrating spaces, when reducing model complexity (to be precise the modeling of cross-sectional dependence) by resorting to (approximate) factor models.

Clearly, the limitations discussed above are also present when using factor models in a multivariate panel context, either by using factor DGPs as error processes in single equation cointegration analysis (as in section 13.3.1.4) or when considering systems inference procedures with a factor structure in the stochastic component.

13.7 Appendix C: Limiting concepts for integrated panels

One major difference to classical microeconometric panels is that for time series panel applications the assumption of cross-sectional independence is often untenable. For many applications from the realms of international macroeconomics or finance, dependence of the variables across countries appears to be the norm rather than the exception.

The first generation of the literature, by which we label all methods (that is, tests and estimation procedures) that are based on the assumption of cross-sectional independence, has made this strong assumption of cross-sectional independence not because of its empirical validity but because of methodological simplicity. The assumption of cross-sectional independence facilitates many parts of the theoretical analysis considerably.

To illustrate the relative simplicity that the cross-sectional independence assumption – in conjunction with sequential limit theory where $N \to \infty$ after $T \to \infty$ – consider the following simple example. Assume that for each cross-section member the data are generated according to $\Delta y_{it} = \rho_i y_{it-1} + \varepsilon_{it}$, that is, by an autoregression of order 1 without any deterministic components and with ε_{it} a white-noise

process with variance σ_i^2. The OLS estimates and corresponding t-statistics of ρ_i are given by:

$$\hat{\rho}_i = \frac{\sum y_{it-1} \Delta y_{it}}{\sum y_{it-1}^2} \tag{C.1}$$

$$t_{\rho_i} = \frac{\sum y_{it-1} \Delta y_{it}}{\hat{\sigma}_i \left(\sum y_{it-1}^2 \right)^{1/2}}, \tag{C.2}$$

with $\hat{\sigma}_i^2 = \frac{1}{T} \sum \left(\Delta y_{it} - \hat{\rho}_i y_{it-1} \right)^2$. Under the null hypothesis that $\rho_i = 0$, it holds under rather general assumptions on ε_{it} for $T \to \infty$ that:

$$T\hat{\rho}_i \to \frac{\int W(r) dW(r)}{\int W^2(r) dr} \tag{C.3}$$

$$t_{\rho_i} \to \frac{\int W(r) dW(r)}{\left(\int W^2(r) dr \right)^{1/2}}. \tag{C.4}$$

For example, Nabeya (1999) shows the existence of moments up to order six for the above two limiting quantities (C.3) and (C.4) under the assumption that the innovation ε_{it} is an i.i.d. sequence. Denote the expected value, respectively the variance, of the limit in (C.4) by μ_{t_ρ} and $\sigma_{t_\rho}^2$. Now, if we assume that the individual series are cross-sectionally independent and that it holds for all cross-section members that $\rho_i = 0$, then it immediately follows for $N \to \infty$ after $T \to \infty$ that:

$$\bar{t}_\rho = \frac{1}{N} \sum_{i=1}^{N} \frac{t_{\rho_i} - \mu_{t_\rho}}{\sigma_{t_\rho}} \Rightarrow N(0, 1).$$

This result also holds true in the sequential limit if one allows for heterogeneity in the individual series, for example, by allowing for different autoregressive orders and performing corresponding ADF regressions since, as is well known, the same time series limit (C.4) prevails also in this case.

If one wants to consider a joint limit where N and T tend to infinity together, matters become more complicated even if we stick to the assumption of cross-sectional independence. Two properties need to be established to allow for the applicability of joint central limit theorems, which we illustrate again for the t-test. First, the existence of the necessary moments of the finite T quantities (C.2) has to be established. Such results have been derived only under relatively strong assumptions, mainly relying upon normality of the innovations ε_{it} and often only for simple DGPs (see, for example, Evans and Savin, 1981, or Larsson 1997). In this respect it is also important to note that the finite sample distributions of, for example, the t-values depend, in the case of higher-order autoregressive processes, upon all autoregressive coefficients, since the dependence upon these nuisance parameters vanishes only in the limit for $T \to \infty$. This dependence upon characteristics of the DGPs of the cross-section members is often the reason for joint limits being

only established with certain *rate restrictions*, for example, of the form $\frac{\sqrt{N}}{T} \to 0$ or $\frac{N}{T} \to 0$. Phillips and Moon (1999) contains an insightful discussion in this respect.

To return to our example, as long as T is finite, the individual specific t-statistics will in general not be identically distributed. One way of overcoming this problem is to assume cross-sectionally identically distributed series $y_{i,t}$, which is, however, far too strong an assumption to be of any practical relevance. Therefore, since identical distributions for finite T samples are usually out of the question, other conditions that allow the use of joint central limit theorems for independent but not identically distributed random variables have to be established. A prime candidate in this respect is to establish a Lindeberg-type condition, or some special cases formulated in terms of uniform integrability conditions, in the joint limit. On a detailed discussion and an example of this approach see Phillips and Moon (1999).

The major problem for the panel unit root and cointegration literature is to establish the required conditions for finite values of T, which are partly not even derived for the time series limits of the building blocks of the panel statistics. One underrated but good exception in this respect is the work of Larsson, Lyhagen and Löthgren (2001), discussed in section 13.3.2.1, who work out the proofs in detail for a panel version of the Johansen (1995) trace test for VAR models without deterministic components and with normally distributed errors. However, substantial parts of the current literature need theoretical strengthening. It is clearly a major task for the literature to work out the correctness of necessary intermediate results for the numerous test statistics and estimators. Until this task has been accomplished, the panel unit root and cointegration literature urgently needs to make further significant progress in terms of establishing mathematical rigor.

Clearly, relaxing the assumption of cross-sectional independence complicates matters even further, since now limit theory for dependent doubly indexed random sequences has to be invoked to establish results. It is clear that without modeling the extent and form of cross-sectional dependence carefully it will not, in general, be possible to establish any well-defined limiting behavior. Up to now no general modeling strategies for cross-sectionally dependent unit root non-stationary panels have been devised and only certain special modeling approaches are in use to date. Two approaches appear to be prominent. One is actually to treat the N dimension as finite and fixed, which means that essentially high-dimensional time series problems are considered (see, for example, Pedroni *et al.*, 2008). The other approach is given by modeling cross-sectional dependence by resorting to factor models, as we have discussed in the main body of the chapter.

Note as a final remark that the usage of panel techniques with both the time series and the cross-sectional dimension tending to infinity allows us to solve some problems that cannot be addressed in a pure time series setting. These include, for example, the consistent estimation of the non-centrality parameter in a local-to-unity framework or of distant initial conditions (see Moon and Phillips, 2000).

Acknowledgments

We are very grateful to our students, colleagues and co-authors, whose insights and results we share in the results reported in this chapter. Particular thanks go to Josep Carrion-i-Silvestre, Jaroslava Hlouskova, Massimiliano Marcellino and Chiara Osbat for participating in research projects on panel unit roots and cointegration with us over several years. AB also wishes to thank Victor Bystrov for valuable research assistance and the Department of Economics of the European University Institute for funding his research projects over the past eight years. MW thanks the Jubiläumsfonds of the Oesterreichische Nationalbank for partially funding his research over the last years. The help of Kerry Patterson and an anonymous referee is also gratefully acknowledged. Responsibility for any errors that remain rests with us.

Notes

1. Later in our chapter we illustrate the methods described by some other examples. These include the frequently studied topic of purchasing power parity, but we also look at less common examples such as the analysis of environmental Kuznets curves and exchange rate pass-through. Further applications for which non-stationary panel methods have been used include business-cycle synchronization, house price convergence, regional migration and household income dynamics.
2. The discussion in this subsection draws on Wagner (2008c) who considers the precise econometric implications of several economic convergence definitions.
3. Throughout our chapter, when referring to $I(1)$ processes we refer to processes whose stochastic component is integrated of order 1 and allow also for deterministic components.
4. Clearly, this definition leaves lots of possibilities, for example, multiple convergence clubs, entirely unexplored. See Wagner (2008c) for a discussion of these issues.
5. Remember that in the Granger representation r indicates the number of linearly independent common stochastic trends, which in our case is 1 in the case of convergence. Clearly, algebraically this single stochastic trend can be split into r components in infinitely many ways, that is, the constituent parts are not identified. An alternative way of formulating the same thing is to simply remember the fact that for $I(1)$ processes the sum of the dimension of the cointegrating space and the number of common trends equals the dimension of the process.
6. The discussion in EK at pp. 254–5 shows that the authors focus in their considerations on potential correlation in the processes $u_{i,t}$ but ignore the potential of both the presence of deterministic components as well as stochastic trends in the panel of series $y_{i,t} - \overline{y}_t$. The authors make the assumption that as the cross-sectional dimension tends to infinity the series $u_{i,t}$ become uncorrelated. This assumption, coupled with assuming that the Dickey–Fuller regression also describes the DGP, with the series $u_{i,t}$ being indeed white-noise processes, then implies that there is no cointegration between the series $y_{i,t} - \overline{y}_t$ under the null hypothesis of divergence.
7. See Appendix B for further details.
8. This formulation is similar to Bai and Carrion-i-Silvestre (2007), see also Bai and Ng (2004).
9. Breaks may of course coexist with cross-sectional independence. We merely look here at the simplest cases first – that is, without dependence and without breaks – and introduce some of the complications in later sub-sections.
10. For both the unit root and cointegration tests consistency of the tests is established for the case that the process is stationary under the alternative. This implies restrictions on the coefficients φ_{ik} and ρ_i to ensure $I(1)$ behavior under the null hypothesis and stationarity under the alternative, which is the common framework in unit root and cointegration analysis.

11. The efficacy of information criteria such as AIC and BIC in dealing with serial correlation is an issue of some debate. Simulation evidence suggests that, due to the choice of very low lag lengths, especially with BIC, serial correlation remains.
12. Phillips and Moon (1999) contains an excellent discussion concerning sequential (that is, first T to infinity followed by N to infinity) versus joint (that is, T and N tend to infinity simultaneously, potentially with some restrictions on the divergence rates), as well as the relationships between the different asymptotic concepts. Appendix C of our chapter discusses some of these issues.
13. Hlouskova and Wagner (2006) discuss the consequences of assuming, instead of constant covariance, a Toeplitz structure for the covariance matrix which corresponds to a geometrically declining correlation with distance. This same idea is pursued in more detail in Baltagi, Bresson and Pirotte (2007). For simplicity, since it serves to make the substantive point, in our illustration this geometrical decline is absent.
14. Hlouskova and Wagner (2006) present a larger experimental design and also consider more tests.
15. This is a simplifying assumption adopted here, and is stronger than is needed for the Bai and Ng (2004) results to hold. Bai and Ng allow for weak cross-correlation in the errors, "weak in the sense that the column sum of the error covariance matrix remains bounded" (Bai and Ng, 2004, p. 1131). This leads to what is termed an approximate factor model.
16. Considering the factor loadings to be stochastic appears to be more of mathematical rather than practical value, given that for each loading it is only one realization that generates the data.
17. If the number of factors r is unknown, it must be estimated consistently using, for example, the Bai and Ng information criteria. The factors themselves are estimated via principal components, as described above in the discussion of the Bai and Ng (2004) method.
18. The model discussed here does not allow for a linear trend. Section 3 of Moon and Perron (2007) extends the analysis to allow for linear trends.
19. Moon and Perron (2004) derive results for the distribution of the estimator under local-to-unity alternatives for the root. They also need a further restriction on the rate of convergence of N and T to infinity in order to obtain consistent estimates $\hat{\omega}_e^2$,$\hat{\phi}_e^4$ and $\hat{\lambda}_e^N$. Assumption 10 (p. 91) of their paper gives this as $a = \liminf_{(N,T\to\infty)} \log T / \log N > 1$. The parameter a is related to the speed of N/T tending to zero.
20. As noted in note 15, cross-sectional independence of the $e_{i,t}$ processes, via the cross-sectional independence of the $\varepsilon_{i,t}$ processes, is not needed for estimation and inference concerning the factors. We assume it here (and earlier) for simplicity – since this allows for the construction of pooled panel tests for the idiosyncratic terms.
21. The problem is formulated in terms of obtaining consistent estimates of the *break fractions* (as discussed below.) This allows the derivations to deal with $T \to \infty$ in order to provide large-sample results. If instead the break date were fixed, the problem would become degenerate in cases where T was large.
22. The Bai and Carrion-i-Silvestre result presented above, as well as those discussed below, rely upon limiting arguments not fully discussed either by these authors or in the seminal Bai and Ng (2004) paper. A major problem is posed by the fact that, for finite N, the de-factored observations and, consequently, the test statistics based upon these, are not cross-sectionally independent, since only the product of the estimated loadings and the estimated factors are subtracted. Cross-sectional independence requires both N and T to go to infinity to have consistent factors (and loadings). Therefore, one cannot simply appeal to sequential limit theory to derive the asymptotic distribution for $MSB(i)$ above by letting T tend to infinity first (to derive the p-values) and then derive the asymptotic distribution of BC_N by letting N "tend to infinity again." A similar issue arises with the derivation of the Z statistic above. In fact, similar problems plague all of the rapidly growing panel unit root literature based on de-factored observations that fails to take into account that joint limit theory for (in finite samples) cross-sectionally dependent

quantities has to be employed. Such limit theory is, to the best of the authors' knowledge, very sparse at best.

23. For completeness we have also performed the computations including only those countries where no structural breaks are detected or with a shorter panel that excludes the structural breaks. The latter experiment, however, suffers from the poor performance of panel unit root and cointegration tests for short panels, compare again Hlouskova and Wagner (2006) and Wagner and Hlouskova (2007). The potentially poor performance notwithstanding, the additionally obtained results, available upon request, are highly similar in terms of findings and conclusions to the results for the full country set and full period panel discussed in the chapter.
24. As in testing for unit roots in panels, the role of the null and alternative hypotheses can be reversed in the construction of the tests – that is, the null hypothesis can be taken to be that a cointegration vector exists while the alternative hypothesis is that of no cointegration. The limitations nevertheless remain.
25. The analogous discussion with respect to unit roots is contained in section 13.2.2.2.
26. There are other ways in which one can think of introducing instability, in particular through instability in the factors themselves or in the factor loadings π_i. We choose not to address this issue here, since the general problem is already over-detailed.
27. η_t in (13.20) may be taken to be independent of $v_{i,t}$.
28. Remember that in sections 13.2.2.2 and 13.2.3.1 we used the notation $\tilde{y}_{i,t}$ to denote first differences whereas we use this notation here to denote the deviations from the cross-sectional averages. Some overlap in notation appears to be unavoidable but we hope that this does not lead to any confusion.
29. Note that Phillips and Moon (1999) is the only paper that formulates explicitly stochastic assumptions on the underlying DGP that ensure the existence of the required cross-sectional limits by introducing so-called stochastic linear processes, in which the coefficients describing the DGP are cross-sectionally independent random variables with certain properties. This implies that one can, under appropriate assumptions, determine the required limits by laws of large numbers. Clearly the case of deterministic coefficients with corresponding assumptions is nested in this framework.
30. Again some overlap in notation occurs since the index m has been used before to indicate the three main specifications of the deterministic components in unit root and single equation and cointegrating testing whereas here and in Appendix B it denotes the dimension of the multivariate time series in the panel data.
31. The authors consider also a specific joint limit where the rate condition $\frac{N^{1/2}}{T} \to 0$ is put in place. For this specific joint limit, a Lindeberg-type condition is required since the cross-section specific building blocks of the panel test statistic are not i.i.d. for finite values of T, whereas once T has passed to infinity, the time series building blocks of the test statistics are identically distributed in the cross-section dimension.
32. Note that the restriction to the same dimension m for each panel member is not required for the discussion of the cointegration properties.

Microeconometrics: Current Methods and Some Recent Developments

A. Colin Cameron

Abstract

This chapter surveys microeconometrics methods with the emphasis being on recent developments in these methods. The survey presumes the basic theory for the standard estimation methods (LS, ML and IV). Estimation methods surveyed include GMM, empirical likelihood, simulation-based estimation, Bayesian methods, quantile regression and semiparametric estimation. Inference methods include robust inference and bootstrap methods. The chapter addresses the recent literature on estimation of marginal effects that can be given a causative interpretation, notably treatment effects. The common data complications of nonrandom sampling, missing data and mismeasured data are also discussed.

14.1 Introduction

Applied microeconometrics primarily applies regression methods to cross-section and longitudinal economics-related data. Most often the goal is to obtain estimates of one or more marginal effects. A stereotypical example is estimation of the effect on earnings of a one-year increase in education. A simple approach is ordinary least squares (OLS) estimation of a linear cross-section regression of log-earnings on years of schooling and other control variables. Potential complications include nonlinearity (with implications for estimation and statistical inference); endogeneity of the regressor schooling (that is chosen by the individual); unobserved individual heterogeneity (the marginal effect even after controlling for regressors may differ across individuals); and missing or mismeasured data.

In this chapter I survey various methods to deal with these complications. Some of these methods have already become well established and command little current theoretical research. Other methods, especially those that are currently active areas of research, may or may not ultimately become part of the toolkit. An impetus for many of these methods is increased computing power and data availability, discussed in the next chapter in this volume, by Jacho-Chávez and Trivedi.

The survey presumes the basic theory for least squares (LS), maximum likelihood (ML) and instrumental variables (IV) estimation of nonlinear cross-section models and linear panel data models, methods well established by the late 1970s. Section 14.2 presents a summary of identification that includes more recent semiparametric identification and partial identification. Section 14.3 presents estimation methods that enable the use of richer models, notably generalized methods of moments (GMM), empirical likelihood, simulation-based methods (classical and Bayesian), quantile regression, and semiparametric estimation. Even when more basic LS, ML and IV estimators are used, there have been considerable developments in statistical inference, most notably the use of robust standard errors and bootstrap methods. These are presented in section 14.4. Section 14.5 presents a wide range of methods that have been developed to obtain marginal effects that can be given a causative interpretation, even when observational data are used. A fundamental change in thinking is the use of the potential outcomes framework and quasi-experimental approaches to tease out causation. Section 14.6 discusses methods to control for unobserved heterogeneity. Section 14.7 presents adjustments to standard methods that incorporate the practical data complications of survey sampling schemes, missing data, and measurement error.

The following notation is used. The typical observation is the ith, with scalar dependent variable y_i, $k \times 1$ regressor vector $\mathbf{x}_i$, and, where relevant, $m \times 1$ instrument vector $\mathbf{z}_i$. Unless otherwise noted independence over i is assumed. At times

it is convenient to denote the ith observation by $\mathbf{w}_i = (y_i, \mathbf{x}_i)$ or $\mathbf{w}_i = (y_i, \mathbf{x}_i, \mathbf{z}_i)$. The parameter vector in general is a $q \times 1$ vector $\boldsymbol{\theta}$. In some cases this is specialized to a $k \times 1$ parameter vector $\boldsymbol{\beta}$. Combining all N observations, $\mathbf{y}$ is the $N \times 1$ vector of dependent variables, and $\mathbf{X}$ is the $N \times K$ regressor matrix. The linear regression model is written as $y_i = \mathbf{x}_i'\boldsymbol{\beta} + u_i$ or $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{u}$.

The reader should be aware that this is a methods survey, rather than a literature survey. It is not possible to cite more than a few relevant references for each topic, leading to omission of the important contributions of many authors. More complete references are given in the relevant texts by T. Amemiya (1985), Greene (2003, first edition 1990), Davidson and MacKinnon (1993), Wooldridge (2008, first edition 2002) and Cameron and Trivedi (2005), and in the lectures by Imbens and Wooldridge (2007). The most recent references given in this chapter should provide a useful start to the current literature.

14.2 Identification

Most applied econometrics studies use methods and models for which identification is not an issue, with a notable exception being the need to have sufficient instruments in linear regression with endogenous regressors. Identification does come to the forefront when more complex models are estimated, or when models are incompletely parameterized.

14.2.1 Point identification

Introductory treatments of econometrics focus on specifying a parametric model for the conditional distribution $f(y|\mathbf{x}, \boldsymbol{\theta})$, or for the conditional mean, $\mathrm{E}[y|\mathbf{x}] = g(\mathbf{x}, \boldsymbol{\beta})$. Given a specification of $f(\cdot)$ or $g(\cdot)$ and a sampling process, such as random sampling or an exogenous stratified sampling that provides no additional complication, the emphasis is on estimation of the parameters $\boldsymbol{\theta}$ or $\boldsymbol{\beta}$, and on statistical inference based on these parameter estimates. Identification, meaning unique determination of $\boldsymbol{\theta}$ or $\boldsymbol{\beta}$, is discussed briefly in the context of rank conditions to ensure identification in linear simultaneous equations models.

For nonlinear parametric models, identification can be more challenging. A standard result is that in, for example, Newey and McFadden (1994, p. 2134), who state that "the identification condition for consistency of an extremum estimator is that the limit of the objective function has a unique maximum at the truth."

For semiparametric modeling, the identification question is whether a model, or key features of that model, can be estimated assuming an infinitely large sample is available and given the relevant sampling scheme. Only after identification is secured can one move on to estimation and inference given a finite sample. An example is a censored regression model, with observed data $y_i = y_i^*$ if $y_i^* = \mathbf{x}_i'\boldsymbol{\beta} + u_i \geq 0$ and $y_i = 0$ otherwise. The goal is to (uniquely) identify $\boldsymbol{\beta}$ given assumptions on the distribution of u_i that fall short of complete parameterization of the distribution of u_i (such as assuming normality). In general there is no unified theory and identification conditions vary with the model being considered and the sampling

process. Also, not all parameters may be identified. For example, regression coefficients may be identified only up to scale or an intercept may not be identified while slope parameters are; Pagan and Ullah (1999) provide many examples.

A nonparametric nonlinear simultaneous equations model is $\mathbf{r}(\mathbf{y}_i, \mathbf{x}_i) = \mathbf{u}_i$, where $\mathbf{y}$ and $\mathbf{u}$ are $G \times 1$ vectors and $\mathbf{x}$ is $K \times 1$. The model is nonparametric identified if it is possible to recover the unknown function $\mathbf{r}(\cdot)$ and the distribution of $\mathbf{u}$ from the joint distribution of $(\mathbf{y}, \mathbf{x})$. Matzkin (2008) provides identification conditions when $\mathbf{u}$ is independent of $\mathbf{x}$.

14.2.2 Partial identification

Manski (1995, 2008) and related papers emphasize partial identification or set identification that merely provides bounds, rather than stronger point identification or complete identification. Partial identification can be possible under weaker assumptions about the data-generating process (DGP) than those needed for point identification.

For example, suppose data on y are missing for 20% of the sample, potentially due to self-selection. Then, without any further assumptions, the median is necessarily bounded by the 0.375 and 0.625 quantiles of the nonmissing data. For example, with 80 observed values of y suppose that the 20 missing values are all less than the smallest observed value. Then the median of all 100 observations is the 30th or 31st of the 80 observed values, or the $30/80 = 0.375$ quantile. Bounding $\mathrm{E}[y]$, rather than the median, is more challenging as it requires additional assumptions on the minimum and maximum value of the mean for the missing data. Qualitatively similar results exist if a fraction of the data are mismeasured rather than missing. In practice the bounds obtained can be wide, but additional information or assumptions can tighten bounds considerably.

Manski and Pepper (2000) provide an upper bound for returns to schooling, controlling for schooling level being endogenously chosen. Haile and Tamer (2003) provide bounds on the quantiles of the distribution of bidders' valuations using auction outcomes. Blundell *et al.* (2007) provide bounds on the interquartile range of wages, controlling for changing composition of the employed and unemployed. Statistical inference, using a framework of estimation based on moment inequalities, is presented in Chernozhukov, Hong and Tamer (2007).

Finally, it should be noted that while much of the literature focuses on identification of parameters, this may not be necessary. In particular, many studies in microeconometrics seek to calculate the marginal effect on the conditional mean of, say, the jth regressor, $\partial \mathrm{E}[y|\mathbf{x}]/\partial x_j\big|_{\mathbf{x}=\mathbf{x}^*}$, and this can be achieved by nonparametric or semiparametric regression. Even where a model for $\mathrm{E}[y|\mathbf{x}]$ is posited, complete identification of $\mathrm{E}[y|\mathbf{x}]$ may not be necessary. For example, consider a linear panel fixed effects model where $\mathrm{E}[y_{it}|\mathbf{x}_{it}] = \mathbf{x}_{it}'\boldsymbol{\beta}$ and $\mathbf{x}_{it}$ includes a time-invariant variable, the kth say, with $x_{ik} = x_k$. Then even if x_k is unobserved, fixed effects estimation provides consistent estimates of the components of $\boldsymbol{\beta}$ corresponding to time-varying regressors, and hence the marginal effect.

14.3 Estimation

Most applied microeconometric studies include estimation of parametric models or the conditional mean, $\mathrm{E}[y_i|\mathbf{x}_i]$, or the conditional density $f(y_i|\mathbf{x}_i)$. The specific models used vary with the type of outcome y that is being modeled. The commonly used estimation methods are ML and quasi-ML (where appropriate) for fully parameterized models, and LS and IV for linear conditional mean models.

In the simplest case y is continuous on $(-\infty, \infty)$ and the linear model $\mathrm{E}[y_i|\mathbf{x}_i] = \mathbf{x}_i'\boldsymbol{\beta}$ is used. But often the outcome is restricted in some way, leading to various nonlinear models. In the most extreme case y can take only one of two values, such as whether or not employed. Then the distribution is necessarily a Bernoulli (the binomial with one trial) and different models for the probability parameter correspond to logit and probit models. When there are only a few possible categorical outcomes a wide range of multinomial models exist, including multinomial and ordered logit and probit. For count outcome y that takes only non-negative integer values, such as number of doctor visits, the standard parametric models are Poisson and negative binomial with $\mathrm{E}[y_i|\mathbf{x}_i] = \exp(\mathbf{x}_i'\boldsymbol{\beta})$. For duration outcome y, such as length of employment spell, the standard parametric models are exponential and Weibull.

Econometrics packages for cross-section data provide estimators for these models, as well as for the standard corrections for the common complications of truncation and censoring. We do not detail these models and their standard estimators, though the appropriate statistical inference is detailed in section 14.4.

This section instead reviews more advanced estimation methods that permit estimation of more flexible parametric models, when models are fully parameterized, as well as methods that permit estimation when models are not fully parameterized. The most important of these methods is GMM, which provides a very general framework for estimation of nonlinear models that nests OLS, IV and ML estimation. Empirical likelihood is an adaptation of GMM that has different finite sample properties. Simulation methods permit classical and Bayesian methods to be applied to a much wider range of parametric models. Quantile regression and semiparametric methods place less structure on the data generating process.

Among these methods only GMM, quantile regression and nonparametric regression (with single regressor) appear in one or more standard econometrics software packages, so the methods are currently not as widely used as they might be.

14.3.1 Generalized method of moments

The starting point for GMM is the moment condition:

$$\mathrm{E}[\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta})] = \mathbf{0}, \tag{14.1}$$

where $\mathbf{h}(\cdot)$ is an $r \times 1$ vector.

The analogy principle, emphasized by Manski (1988) who attributes it to Goldberger, proposes estimation using the sample analog of the population condition (14.1). In the just-identified case this leads to a method of moments (MM) estimator $\widehat{\boldsymbol{\theta}}_{\mathrm{MM}}$ that solves $N^{-1}\sum \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}) = \mathbf{0}$. A simple example is that

$\mathrm{E}[y_i - \mu] = 0$ leads to the estimator $\widehat{\mu} = \bar{y}$. OLS, ML and just-identified IV estimators can be interpreted as examples of MM estimators.

In the overidentified case in which the dimension r of h_i is greater than q, there are more moment conditions than parameters. Hansen (1982) proposed the GMM estimator $\widehat{\boldsymbol{\theta}}_{\mathrm{GMM}}$ that minimizes the quadratic form:

$$Q(\boldsymbol{\theta}) = \left[\frac{1}{N}\sum\nolimits_i \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta})\right]' \mathbf{W}_N \left[\frac{1}{N}\sum\nolimits_i \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta})\right], \tag{14.2}$$

where $\mathbf{W}_N$ is an $r \times r$ symmetric full rank weighting matrix that is usually data-dependent. The resulting estimator sets a $q \times r$ linear combination of $\frac{1}{N}\sum_i \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta})$ equal to $\mathbf{0}$. Under appropriate assumptions, including that (14.1) holds at $\boldsymbol{\theta} = \boldsymbol{\theta}_0$, $\widehat{\boldsymbol{\theta}}_{\mathrm{GMM}}$ is asymptotically normally distributed with mean $\boldsymbol{\theta}_0$ and estimated asymptotic variance matrix of "sandwich form":

$$\widehat{\mathrm{V}}[\widehat{\boldsymbol{\theta}}_{\mathrm{GMM}}] = \frac{1}{N}\left(\widehat{\mathbf{G}}'\mathbf{W}_N\widehat{\mathbf{G}}\right)^{-1}\widehat{\mathbf{G}}'\mathbf{W}_N\widehat{\mathbf{S}}\mathbf{W}_N\widehat{\mathbf{G}}\left(\widehat{\mathbf{G}}'\mathbf{W}_N\widehat{\mathbf{G}}\right)^{-1}, \tag{14.3}$$

where $\widehat{\mathbf{G}} = N^{-1}\sum_i \partial \mathbf{h}_i/\partial \boldsymbol{\theta}'\big|_{\widehat{\boldsymbol{\theta}}}$ and $\widehat{\mathbf{S}}$ is a consistent estimate of $\mathbf{S}_0 = \mathrm{plim}\frac{1}{N}\sum_i\sum_j \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}_0)\mathbf{h}(\mathbf{w}_j, \boldsymbol{\theta}_0)'$. Given independence over i, $\widehat{\mathbf{S}}$ simplifies to $\widehat{\mathbf{S}} = \frac{1}{N}\sum_i \mathbf{h}(\mathbf{w}_i, \widehat{\boldsymbol{\theta}})\mathbf{h}(\mathbf{w}_i, \widehat{\boldsymbol{\theta}})'$, while for clustered observations adaptations similar to those given in section 14.4.1 are used.

A leading overidentified example is IV estimation. The condition that instruments $\mathbf{z}_i$ are uncorrelated with the error term $u_i = y_i - \mathbf{x}_i'\boldsymbol{\beta}$ in a linear regression model implies that $\mathrm{E}[\mathbf{z}_i(y_i - \mathbf{x}_i'\boldsymbol{\beta})] = \mathbf{0}$. In the just-identified case the MM estimator solves $\sum_i \mathbf{z}_i(y_i - \mathbf{x}_i'\boldsymbol{\beta}) = \mathbf{0}$, which yields the IV estimator. In the overidentified case the GMM estimator minimizes $\left[\sum_i \mathbf{z}_i(y_i - \mathbf{x}_i'\boldsymbol{\beta})\right]' \mathbf{W}_N \left[\sum_i \mathbf{z}_i(y_i - \mathbf{x}_i'\boldsymbol{\beta})\right] = \mathbf{0}$. The two-stage least squares (2SLS) estimator is the special case $\mathbf{W}_N = \left[N^{-1}\sum_i \mathbf{z}_i\mathbf{z}_i'\right]^{-1}$. Estimators for dynamic panel data models, such as that of Arellano and Bond (1991), are also overidentified GMM estimators that are in common use.

The GMM estimator reduces to the MM estimator, regardless of the choice of $\mathbf{W}_N$, for just-identified models. For overidentified models the most efficient GMM estimator based on the moment conditions (14.1), called the optimum GMM (OGMM) or two-step GMM estimator $\widehat{\boldsymbol{\theta}}_{\mathrm{OGMM}}$, sets $\mathbf{W}_N = \widehat{\mathbf{S}}^{-1}$, where $\widehat{\mathbf{S}}$ is a consistent estimate of $\mathbf{S}_0$. Given independence over i, $\widehat{\mathbf{S}} = \frac{1}{N}\sum_i \mathbf{h}(\mathbf{w}_i, \widetilde{\boldsymbol{\theta}})\mathbf{h}(\mathbf{w}_i, \widetilde{\boldsymbol{\theta}})'$, where $\widetilde{\boldsymbol{\theta}}$ is a first-step GMM estimator based on an initial choice of $\mathbf{W}_N$. Then the OGMM estimator has estimated asymptotic variance

$$\widehat{\mathrm{V}}[\widehat{\boldsymbol{\theta}}_{\mathrm{OGMM}}] = N^{-1}(\widehat{\mathbf{G}}'\widehat{\mathbf{S}}^{-1}\widehat{\mathbf{G}})^{-1}.$$

Chamberlain (1987) showed that the OGMM estimator is the fully efficient estimator based on condition (14.1). In practice, however, it is found that the optimal GMM estimator suffers from small sample bias (see Altonji and Segal, 1996), and other simpler choices of $\mathbf{W}_N$ may be better. This has spawned an active literature, including Windmeijer (2005) and the empirical likelihood methods given in section 14.3.2.

There are several attractions to GMM. First, it provides a unifying framework to estimation as it nests many estimation procedures, including LS, with $\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}) = y_i - \mathbf{x}_i'\boldsymbol{\beta}$, and ML, with $\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}) = \partial \ln f(y_i|\mathbf{x}_i, \boldsymbol{\theta})/\partial\boldsymbol{\theta}$, as special cases. Second, it provides a natural extension of instrumental variables methods in overidentified models from linear to nonlinear models, and can be viewed as a generalization of nonlinear 2SLS. Third, it views estimation as a sample analog to population moment conditions, the analogy principle emphasized by Manski (1988). Fourth, taking this view leads naturally to conditional moment tests (see section 14.4.2) that lead to model moment specification tests based on model moment conditions that are not exploited in estimation. Finally, it is relatively simple computationally as standard iterative methods such as Newton–Raphson can be employed, though not all econometric packages provide a general GMM command for nonlinear models.

A method closely related to GMM, though one less used, is minimum distance estimation. Suppose that the relationship between q structural parameters and $r > q$ reduced form parameters is that $\boldsymbol{\pi} = \mathbf{g}(\boldsymbol{\theta})$. Given a consistent estimate $\widehat{\boldsymbol{\pi}}$ of the reduced form parameters, an obvious estimator is $\widehat{\boldsymbol{\theta}}$ such that $\widehat{\boldsymbol{\pi}} = \mathbf{g}(\widehat{\boldsymbol{\theta}})$. But this is infeasible since $q < r$. Instead, the minimum distance (MD) estimator $\widehat{\boldsymbol{\theta}}_{\text{MD}}$ minimizes, with respect to $\boldsymbol{\theta}$, the objective function:

$$Q_N(\boldsymbol{\theta}) = (\widehat{\boldsymbol{\pi}} - \mathbf{g}(\boldsymbol{\theta}))'\mathbf{W}_N(\widehat{\boldsymbol{\pi}} - \mathbf{g}(\boldsymbol{\theta})), \tag{14.4}$$

where $\mathbf{W}_N$ is an $r \times r$ weighting matrix. The optimal MD estimator uses the weighting matrix $\mathbf{W}_N = \widehat{\mathbb{V}}[\widehat{\boldsymbol{\pi}}]^{-1}$ in (14.4). This estimator is used mainly in panel data analysis (see Chamberlain, 1982, 1984), especially in estimation of covariance structures (see Abowd and Card, 1987).

The statistics literature rarely uses the GMM framework. This may be because GMM is particularly useful for overidentified models, notably IV with surplus instruments, that are much more often used in econometrics. Instead, for nonlinear models the statistics literature emphasizes the more restrictive generalized linear models and generalized estimating equations frameworks (see McCullagh and Nelder, 1983).

14.3.2 Empirical likelihood

Empirical likelihood is based on the same moment conditions as GMM, but is a different estimation method with better second-order asymptotic properties. Empirical likelihood may be a better estimator in settings where optimum GMM is known to perform poorly in finite samples, but it is not widely used, in part due to computational difficulty.

Let $\pi_i = f(y_i|\mathbf{x}_i)$ denote the probability that the ith observation on y takes the realized value y_i. The empirical likelihood (EL) approach, introduced by Owen (1988), maximizes the empirical log-likelihood function:

$$Q_N(\pi_1, \ldots, \pi_N) = N^{-1}\sum_{i=1}^{N} \ln \pi_i, \tag{14.5}$$

subject to any model constraints.

With no model the only constraint is that probabilities sum to one. This leads to maximum EL estimates $\widehat{\pi}_i = 1/N$, so the estimated density function $\widehat{f}(y|\mathbf{x})$ has mass $1/N$ at each of the realized values y_i, $i = 1, \ldots, N$, and the resulting distribution function estimate is just the usual empirical distribution function.

With a model introduced, attention focuses on the estimates for parameters of that model. In the simplest case of estimation of a common population mean μ, the maximum EL estimate can be shown to be the sample mean. A more general example is to specify a model that imposes r moment conditions:

$$\mathrm{E}[\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta})] = \mathbf{0}, \tag{14.6}$$

the same condition as in (14.1) for MM or GMM estimation. The EL approach maximizes the empirical likelihood function $N^{-1} \sum_i \ln \pi_i$ subject to the constraint $\sum_i \pi_i = 1$, since probabilities sum to one, and the additional sample constraint based on the population moment condition (14.6) that:

$$\sum_{i=1}^{N} \pi_i \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}) = \mathbf{0}. \tag{14.7}$$

Thus maximize with respect to $\boldsymbol{\pi} = [\pi_1 \ldots \pi_N]'$, η, $\boldsymbol{\lambda}$ and $\boldsymbol{\theta}$ the Lagrangian:

$$\mathcal{L}_{\mathrm{EL}}(\boldsymbol{\pi}, \eta, \boldsymbol{\lambda}, \boldsymbol{\theta}) = \frac{1}{N} \sum_{i=1}^{N} \ln \pi_i - \eta \left(\sum_{i=1}^{N} \pi_i - 1 \right) - \boldsymbol{\lambda}' \sum_{i=1}^{N} \pi_i \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}), \tag{14.8}$$

where the Lagrangian multipliers are a scalar η and an $r \times 1$ column vector $\boldsymbol{\lambda}$.

This maximization is not straightforward. First concentrate out the N parameters $\pi_1, \ldots, \pi_N$. Differentiating $\mathcal{L}(\boldsymbol{\pi}, \eta, \boldsymbol{\lambda}, \boldsymbol{\theta})$ with respect to π_i yields $1/(N\pi_i) - \eta - \boldsymbol{\lambda}'\mathbf{h}_i = 0$. Then find $\eta = 1$ by multiplying by π_i and summing over i and using $\sum_i \pi_i \mathbf{h}_i = \mathbf{0}$. It follows that the Lagrangian multipliers $\boldsymbol{\lambda}$ solve $\pi_i(\boldsymbol{\theta}, \boldsymbol{\lambda}) = 1/[N(1 + \boldsymbol{\lambda}'\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}))]$. The problem is now reduced to a maximization problem with respect to $(r + q)$ variables $\boldsymbol{\lambda}$ and $\boldsymbol{\theta}$, the Lagrangian multipliers associated with the r moment conditions (14.7) and the q parameters $\boldsymbol{\theta}$. Solution at this stage requires numerical methods, even for just-identified models with $r = q$. After some algebra, the log-likelihood function evaluated at $\boldsymbol{\theta}$ is:

$$\mathcal{L}_{\mathrm{EL}}(\boldsymbol{\theta}) = -N^{-1} \sum_{i=1}^{N} \ln[N(1 + \boldsymbol{\lambda}(\boldsymbol{\theta})'\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}))]. \tag{14.9}$$

The maximum empirical likelihood (MEL) estimator $\widehat{\boldsymbol{\theta}}_{\mathrm{MEL}}$ maximizes this function with respect to $\boldsymbol{\theta}$.

Qin and Lawless (1994) show that the MEL estimator has the same limit distribution as the optimal GMM estimator. In finite samples, however, $\widehat{\boldsymbol{\theta}}_{\mathrm{MEL}}$ differs from $\widehat{\boldsymbol{\theta}}_{\mathrm{GMM}}$. Furthermore, inference can be based on sample estimates $\widehat{\mathbf{G}} = \sum_i \widehat{\pi}_i \partial \mathbf{h}_i / \partial \boldsymbol{\theta}' \big|_{\widehat{\boldsymbol{\theta}}}$ and $\widehat{\mathbf{S}} = \sum_i \widehat{\pi}_i \mathbf{h}_i(\widehat{\boldsymbol{\theta}}) \mathbf{h}_i(\widehat{\boldsymbol{\theta}})'$ that weight by the estimated probabilities $\widehat{\pi}_i$ rather than the proportions $1/N$. Newey and Smith (2004) show that MEL

has better second-order asymptotic properties than GMM, and it appears that using the weights $\widehat{\pi}_i$ in forming $\widehat{\mathbf{G}}$ and $\widehat{\mathbf{S}}$ leads to improved finite sample performance.

Generalized empirical likelihood estimators (GEL) use objective functions other than $N^{-1}\sum_i \ln \pi_i$. Exponential tilting uses $N^{-1}\sum_i \pi_i \ln \pi_i$, and the continuous updating GMM estimator of Hansen, Heaton and Yaron (1996) is shown by Newey and Smith (2004) to fall in the class of GEL estimators.

Computational methods for these estimators are presented in Mittelhammer, Judge and Schoenberg (2005), and in the surveys of empirical likelihood by Imbens (2002) and Kitamura (2006). The continuous updating GMM estimator has the attraction of not requiring estimation of Lagrange multipliers, but it does not always converge. More generally, the MEL and GEL estimators have an objective function that is less well-behaved than the quadratic form for regular GMM.

14.3.3 Simulation-based ML and MM estimation

Simulation-based estimation methods enable ML estimation in cases where the conditional density of y given $\mathbf{x}$ includes an integral for which a closed-form solution does not exist, so that conventional ML is not possible. The integral is approximated by Monte Carlo integration, making many draws from an appropriate distribution.

Specifically, let the conditional density of y given regressors $\mathbf{x}$ and parameters $\boldsymbol{\theta} = [\boldsymbol{\theta}_1' \ \boldsymbol{\theta}_2']'$ be an integral:

$$f(y|\mathbf{x}, \boldsymbol{\theta}) = \int f(y|\mathbf{x}, \mathbf{u}, \boldsymbol{\theta}_1) g(\mathbf{u}|\boldsymbol{\theta}_2) d\mathbf{u}, \tag{14.10}$$

where $f(y|\mathbf{x}, \mathbf{u}, \boldsymbol{\theta}_1)$, which depends in part on unobservables $\mathbf{u}$, is of closed form, but there is no closed form for the desired density $f(y|\mathbf{x}, \boldsymbol{\theta})$.

A leading example is unobserved heterogeneity. Then $\boldsymbol{\theta}_1$ denotes parameters of intrinsic interest, $\mathbf{u}$ denotes unobserved heterogeneity that may depend on unknown parameters $\boldsymbol{\theta}_2$, and the integral will not have a closed-form solution except in some special cases. A second example is the multinomial probit model. Then $\boldsymbol{\theta}_1$ denotes regression parameters, $\mathbf{u}$ denotes an error term in a latent model that may have unknown error variances and covariances $\boldsymbol{\theta}_2$, and, given m alternatives, the probability that a specific alternative is chosen is given by an $(m-1)$-dimensional integral that has no closed form solution.

If the integral is of low dimension, then numerical integration by Gaussian quadrature may provide a reasonable approximation to $f(y|\mathbf{x}, \boldsymbol{\theta})$. But these methods can work poorly in the higher dimensions often encountered in practice. For example, for multinomial probit Gaussian quadrature is felt to work poorly if there are more than four alternatives.

Instead, the maximum simulated likelihood (MSL) method makes many draws of the unobservables $\mathbf{u}$ from density $g(\mathbf{u}|\boldsymbol{\theta}_2)$. The MSL estimator maximizes the simulated log-likelihood function:

$$\widehat{L}_N(\boldsymbol{\theta}) = \sum_{i=1}^{N} \ln \widehat{f}(y_i|\mathbf{x}_i, \mathbf{u}_i^{(S)}, \boldsymbol{\theta}), \tag{14.11}$$

where $\widehat{f}(\cdot)$ is the Monte Carlo estimate or simulator:

$$\widehat{f}(y_i|\mathbf{x}_i, \mathbf{u}_i^{(S)}, \boldsymbol{\theta}) = \frac{1}{S}\sum_{s=1}^{S}\widetilde{f}(y_i|\mathbf{x}_i, \mathbf{u}_i^s, \boldsymbol{\theta}), \tag{14.12}$$

where $\mathbf{u}_i^{(S)} = (\mathbf{u}_i^1, \ldots, \mathbf{u}_i^S)$ denotes S draws with marginal density $g(\mathbf{u}_i|\boldsymbol{\theta}_2)$, and $\widetilde{f}(\cdot)$ is a subsimulator such as $f(y|\mathbf{x}, \mathbf{u}^s, \boldsymbol{\theta}_1)$. Many possible simulators may be used – the essential requirement is that $\widehat{f}_i \xrightarrow{p} f_i$ as $S \to \infty$. The MSL estimator is consistent and asymptotically equivalent to the ML estimator, provided that $S \to \infty$, in addition to the usual assumption that $N \to \infty$, with $\sqrt{N}/S \to \infty$ so that S grows at a rate slower than N.

The MSL estimator opens up the possibility of using a much wider range of parametric models, such as richer models for unobserved heterogeneity that may be more robust to model misspecification. At the same time the method can be computationally demanding. An early application of MSL was by Lerman and Manski (1981) for the multinomial probit model. Then $I \times N \times S$ draws of $\mathbf{u}_i^s$ are made if analytical derivatives are used, where I is the number of iterations, and even more draws are needed if numerical derivatives are used. A currently popular application is to the random parameters logit or mixed logit model.

For models with unobserved heterogeneity, an alternative is to treat heterogeneity as being discretely distributed. Such finite mixture or latent class models are especially popular in the duration and count (number of health services) literatures (see Meyer, 1990; Deb and Trivedi, 2002). These models do not require simulation methods, and can be more easily estimated using quasi-Newton methods or the expectation maximization algorithm. Often a heterogeneity distribution with just two or three points of support is sufficient.

The MSL can be extended to MM and GMM estimation. In that case, theory leads to a moment condition $\mathrm{E}[m(y_i|\mathbf{x}_i, \boldsymbol{\theta})] = 0$, where $m(\cdot)$ is a scalar for simplicity, but there is no closed form expression for $m(y, \mathbf{x}, \boldsymbol{\theta})$. Instead $m(y, \mathbf{x}, \boldsymbol{\theta})$ is an integral:

$$m(y_i|\mathbf{x}_i, \boldsymbol{\theta}) = \int h(y_i|\mathbf{x}_i, \mathbf{u}_i, \boldsymbol{\theta}_1)g(\mathbf{u}_i|\boldsymbol{\theta}_2)d\mathbf{u}_i, \tag{14.13}$$

for some functions $h(\cdot)$ and $g(\cdot)$, where $m(\cdot)$ has no closed form. Let $\widehat{m}_i = \widehat{m}(y_i|\mathbf{x}_i, \mathbf{u}_i^{(S)}, \boldsymbol{\theta})$ be a simulator for $m(y_i, \mathbf{x}_i, \boldsymbol{\theta})$. Then the method of simulated moments (MSM) estimator uses $\widehat{m}_i$ in place of m_i in GMM estimation. A key result, due to McFadden (1989) and Pakes and Pollard (1989), is that the MSM estimator is consistent for $\boldsymbol{\theta}$ as $N \to \infty$ even if S is very small, provided that an unbiased simulator is used, meaning $\mathrm{E}[\widehat{m}_i] = m_i$. Furthermore, small S may lead to little loss of precision. In the special case that $\widehat{m}(\cdot)$ is the frequency simulator, the MSM estimator has variance $(1 + (1/S))$ times that of the MM estimator.

There are several subtleties in the use of MSL and related estimators. Book references are Gouriéroux and Monfort (1996), who also discuss indirect inference, and Train (2003), who focuses on applications to multinomial choice. First, because the simulated likelihood is usually maximized by iterative gradient methods, the simulator $\widehat{f}_i$ should be differentiable (or smooth) in $\boldsymbol{\theta}$. For example, for limited

dependent variables models with normal errors the Geweke–Hajivassiliou–Keane (GHK) simulator is often used. Second, to enable convergence and avoid "chatter" the same underlying random numbers used to obtain $\mathbf{u}_i^S$ should be used at each iteration. Third, the draws from $g(\mathbf{u}_i|\boldsymbol{\theta}_2)$ need not be independent. For example, better approximations for given S may be obtained by using dependent quasi-random numbers, such as Halton sequences, rather than independent pseudo-random numbers, and by the use of antithetic sampling. Fourth, it may be difficult to make draws from $\mathbf{u}_i^S$ using standard methods such as inverse transformation and accept–reject methods. Newer Markov chain Monte Carlo methods, widely used in Bayesian analysis, may be then used.

14.3.4 Simulation-based Bayesian analysis

Bayesian analysis can serve two purposes. First, it can provide a quite different method of inference as it views parameters as random variables, with the goal being to combine the prior distribution on parameters and the sample distribution of the data to recover the posterior distribution of these parameters. By contrast, classical frequentist inference views parameters as taking fixed values that are unknown, with data used to make inference on those unknown values. Second, if priors are chosen to be sufficiently uninformative so that they have little effect on the posterior distribution, then it is possible to directly use the posterior distribution of parameters to perform classical frequentist inference.

Econometric applications most often use Bayesian methods for the second purpose. Recent advances in computational methods, outlined below, can make Bayesian methods especially useful in analytically intractable models with many parameters that may be very difficult to estimate using conventional ML or even simulated ML methods. Even so, Bayesian methods are used sparingly in econometrics when compared to the statistics literature. One reason is a hesitation to use fully parametric methods, though Bayesian methods do allow quite flexible parametric models to be specified.

Let $L\left(\mathbf{y}|\mathbf{X},\boldsymbol{\theta}\right) = f(\mathbf{y}|\mathbf{X},\boldsymbol{\theta})$ denote the sample joint density or likelihood, and $\pi(\boldsymbol{\theta})$ denote the prior distribution. Then by Bayes' rule the posterior density for $\boldsymbol{\theta}$ is:

$$p(\boldsymbol{\theta}|\mathbf{y},\mathbf{X}) = \frac{L(\mathbf{y}|\mathbf{X},\boldsymbol{\theta})\pi(\boldsymbol{\theta})}{f(\mathbf{y}|\mathbf{X})}, \tag{14.14}$$

where $f(\mathbf{y}|\mathbf{X}) = \int_{R(\boldsymbol{\theta})} L(\mathbf{y}|\mathbf{X},\boldsymbol{\theta})\pi(\boldsymbol{\theta})d\boldsymbol{\theta}$ and $R(\boldsymbol{\theta})$ denotes the support of $\pi(\boldsymbol{\theta})$. Because the denominator $f(\mathbf{y}|\mathbf{X})$ is free of $\boldsymbol{\theta}$, it is standard simply to write:

$$p(\boldsymbol{\theta}|\mathbf{y}) \propto L(\mathbf{y}|\boldsymbol{\theta})\pi(\boldsymbol{\theta}), \tag{14.15}$$

where the regressors $\mathbf{X}$ are suppressed for notational simplicity. The posterior density is proportional to the product of the likelihood and prior.

The heart of Bayesian analysis is the posterior $p(\boldsymbol{\theta}|\mathbf{y})$. In the simplest cases a closed form expression for this exists. For example, if $\mathbf{y}$ is normal with mean $\mathbf{X}\boldsymbol{\beta}$ and known variance and the prior for $\boldsymbol{\beta}$ is the normal with specified mean and variance, then the posterior is normal.

But for most models, especially standard nonlinear regression models, the posterior is unknown. One approach is to then obtain key moments, such as the posterior mean $\mathrm{E}[\boldsymbol{\theta}] = \int \boldsymbol{\theta} p(\boldsymbol{\theta}|\mathbf{y}) d\boldsymbol{\theta}$, using Monte Carlo integration methods that do not require draws from $p(\boldsymbol{\theta}|\mathbf{y})$. In particular, importance sampling methods can be used (see Kloek and van Dijk, 1978; Geweke, 1989).

The more modern approach is instead to obtain many draws, say $\widehat{\boldsymbol{\theta}}^1, \ldots, \widehat{\boldsymbol{\theta}}^S$, from $p(\boldsymbol{\theta}|\mathbf{y})$. The posterior mean can then be estimated by $S^{-1} \sum_{s=1}^{S} \widehat{\boldsymbol{\theta}}^s$. Furthermore, the distribution of any quantity of interest, such as the distribution of marginal effects in a nonlinear model, can be similarly computed given these draws from the posterior.

The key ingredient is the recent development of methods to obtain draws of $\boldsymbol{\theta}$ from the posterior $p(\boldsymbol{\theta}|\mathbf{y})$ even when $p(\boldsymbol{\theta}|\mathbf{y})$ is unknown (see Gelfland and Smith, 1990). The starting point is the Gibbs sampler. Let $\boldsymbol{\theta} = [\boldsymbol{\theta}_1' \ \boldsymbol{\theta}_2']'$ and suppose that it is possible to draw from the conditional posteriors $p(\boldsymbol{\theta}_1|\boldsymbol{\theta}_2, \mathbf{y})$ and $p(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1, \mathbf{y})$, even though it is not possible to draw from $p(\boldsymbol{\theta}|\mathbf{y})$. The Gibbs sampler obtains draws from $p(\boldsymbol{\theta}|\mathbf{y})$ by making alternating draws from each conditional distribution. Thus, given an initial value $\boldsymbol{\theta}_2^{(0)}$, obtain $\boldsymbol{\theta}_1^{(1)}$ by drawing from $p(\boldsymbol{\theta}_1|\boldsymbol{\theta}_2^{(0)}, \mathbf{y})$, then $\boldsymbol{\theta}_2^{(1)}$ by drawing from $p(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1^{(1)}, \mathbf{y})$, then $\boldsymbol{\theta}_1^{(2)}$ by drawing from $p(\boldsymbol{\theta}_1|\boldsymbol{\theta}_2^{(1)}, \mathbf{y})$, and so on. When repeated many times it can be shown that this process ultimately leads to draws of $\boldsymbol{\theta}$ from $p(\boldsymbol{\theta}|\mathbf{y})$, even though in general $p(\boldsymbol{\theta}|\mathbf{y}) \neq p(\boldsymbol{\theta}_1|\boldsymbol{\theta}_2, \mathbf{y}) \times p(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1, \mathbf{y})$. The sampler is an example of a Markov chain Monte Carlo (MCMC) method. The term "Markov chain" is used because the procedure sets up a Markov chain for $\boldsymbol{\theta}$ whose stationary distribution can be shown to be the desired posterior $p(\boldsymbol{\theta}|\mathbf{y})$. The method extends immediately to more partitions for $\boldsymbol{\theta}$. For example, if $\boldsymbol{\theta} = [\boldsymbol{\theta}_1' \ \boldsymbol{\theta}_2' \ \boldsymbol{\theta}_3']'$ then draws need to be made from $p(\boldsymbol{\theta}_1|\boldsymbol{\theta}_2, \boldsymbol{\theta}_3, \mathbf{y})$, and $p(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1, \boldsymbol{\theta}_3, \mathbf{y})$ and $p(\boldsymbol{\theta}_3|\boldsymbol{\theta}_1, \boldsymbol{\theta}_2, \mathbf{y})$.

In many applications some of the conditional posteriors are unknown, in which case MCMC methods other than the Gibbs sampler need to be used. A standard method is the Metropolis–Hastings (MH) algorithm, which uses a trial or jumping distribution. The Gibbs sampler can be shown to be an example of an MH algorithm, one with relatively fast convergence.

The MCMC methods in principle permit Bayesian analysis to be applied to a very wide range of models. In practice, there is an art to ensuring that the chain converges in a reasonable amount of computational time. The first B draws of $\boldsymbol{\theta}$ are discarded, where B is chosen to be large enough that the Markov chain has converged. The remaining S draws of $\boldsymbol{\theta}$ are then used. Various diagnostic methods exist to indicate convergence, although these do not guarantee convergence. MCMC methods yield correlated draws from $p(\boldsymbol{\theta}|\mathbf{y})$, rather than independent draws, but this correlation only effects the precision of posterior analysis and often the correlation is low. Many Bayesian models include both components with closed form solutions for the posterior and components that require the use of MCMC methods – the Gibbs sampler, if possible, and, failing that, the MH algorithm with hopefully a good choice of jumping distribution.

Bayesian methods are particularly attractive in models entailing latent variables, such as tobit models (see Chib, 1992, 2001), and multinomial probit models

(see McCulloch, Polson and Rossi, 2000). The data augmentation method then generates draws of unobserved values of the latent variables that can then be treated as observed values, greatly simplifying analysis. A recent application is that by Geweke, Gowrisankaran and Town (2003), who model mortality at 114 Los Angeles County hospitals allowing for the complication that better hospitals may attract more difficult cases, with difficulty depending in part on unobservables correlated with hospital mortality rates. Recent econometrics books are Koop (2003), Lancaster (2004), and Koop, Poirier and Tobias (2007).

14.3.5 Quantile regression

Quantiles, such as deciles and quartiles, are often used to summarize the distribution of variables such as income, earnings and wealth. Quantile regression is an extension to the regression case where, for example, interest may lie in the different response of earnings to education at different points of the conditional earnings distribution.

A leading example is the least absolute deviations (LAD) estimator that minimizes the sum of absolute residuals $\sum_{i=1}^{N} |y_i - \mathbf{x}_i'\boldsymbol{\beta}|$. This is a generalization of the median in the independent and identically distributed (i.i.d.) case, since with $\mathbf{x}_i'\boldsymbol{\beta} = \beta$ the resulting estimate of β is the sample median.

More generally, conditional quantiles other than the median may be estimated. The qth quantile regression estimator $\widehat{\boldsymbol{\beta}}_q$ minimizes over $\boldsymbol{\beta}_q$:

$$Q_N(\boldsymbol{\beta}_q) = \sum_{i:y_i \geq \mathbf{x}_i'\boldsymbol{\beta}}^{N} q|y_i - \mathbf{x}_i'\boldsymbol{\beta}_q| + \sum_{i:y_i < \mathbf{x}_i'\boldsymbol{\beta}}^{N} (1-q)|y_i - \mathbf{x}_i'\boldsymbol{\beta}_q|,$$

where the subscript q in $\boldsymbol{\beta}_q$ is needed as different choices of q estimate different values of $\boldsymbol{\beta}$. The special case $q = 0.5$ is the LAD estimator. The objective function is not differentiable, so linear programming methods are used rather than more familiar gradient methods. These enable relatively fast computation of $\widehat{\boldsymbol{\beta}}_q$. The quantile regression estimator is consistent and asymptotically normal. Estimation of the analytical asymptotic variance of $\widehat{\boldsymbol{\beta}}_q$ requires estimation of $f_{u_q}(0|\mathbf{x})$, the conditional density of the error term $u_q = y - \mathbf{x}'\boldsymbol{\beta}_q$ evaluated at $u_q = 0$. An easier method is to instead obtain bootstrap standard errors for $\widehat{\boldsymbol{\beta}}_q$ using a paired bootstrap.

Quantile regression was proposed by Koenker and Bassett (1978). Powell (1984, 1986) adapted the method to permit consistent estimation in censored linear regression models. With censoring the conditional median can be recovered without the strong distributional assumptions, such as normality, needed to recover the conditional mean. Buchinsky (1994) provided a much-cited application that documented recent US changes in the quantiles of the conditional wage distribution. Such analysis is now easily implemented as Stata includes a quantile regression command. Koenker and Hallock (2001) provide an early summary of applications.

Existing results specify all quantile regression functions to be linear. Angrist, Chernozhukov and Ferandez-Val (2006) provide interpretation of the quantile

regression if instead the unknown true quantile function is nonlinear, and provide the asymptotic distribution in that case. The situation is analogous to that for OLS and ML under model misspecification.

Quantile regression has recently become a very active area of research with extensions including instrumental variables estimation (see Chernozhukov and Hansen, 2005), and a richer range of models for censored data (see Honore and Hu, 2004). Koenker (2005) provides many results on quantile regression.

14.3.6 Nonparametric and semiparametric methods

Consider the regression model:

$$\mathrm{E}[y_i|\mathbf{x}_i] = m(\mathbf{x}_i), \tag{14.16}$$

where the function $m(\mathbf{x})$ is unspecified. Nonparametric regression provides a consistent estimate of $m(\mathbf{x})$. At the specific point $\mathbf{x} = \mathbf{x}_0$, $m(\mathbf{x}_0)$ can be estimated by taking a local weighted average of y_i over those observations with $\mathbf{x}_i$ in a neighborhood of $\mathbf{x}_0$. There are many variations on this approach, including kernel regression, nearest neighbors regression, local linear, local polynomial, Lowess, smoothing spline and series estimators. Less than N observations are effectively used at any point $\mathbf{x}_0$, because a local average is taken, so $\widehat{m}(\mathbf{x}_0) \xrightarrow{p} m(\mathbf{x}_0)$ at a rate less than the usual $N^{-1/2}$, although asymptotic normality still holds.

Fully nonparametric regression works best in practice when there is just a single regressor. Even then, empirical results vary greatly with the choice of bandwidth or window width that defines the size of the neighborhood. "Plug-in" estimates of the bandwidth that work well for density estimation often work poorly for regression. The standard method is to use leave-one-out cross-validation to select the bandwidth, but this method is by no means perfect.

There is no theoretical obstacle to using nonparametric regression when there are many regressors. But in practice nonparametric methods usually work poorly with more than very few regressors, due to a curse of dimensionality that arises because the local averages will be made over fewer observations. For example, if averaging is over 10 bins with one regressor then averaging may need to be over $10^2 = 100$ bins when there are two regressors. More formally, the optimal convergence rate using mean squared error as a criterion is $N^{-2/(\dim[\mathbf{x}]+4)}$, so the convergence rate decreases as $\dim[\mathbf{x}]$ increases. This problem is less severe when some regressors take only a few values, such as binary indicator variables. Racine and Li (2004) present results for kernel regression when some regressors are discrete and some are continuous.

The microeconometrics literature focuses on semiparametric methods that overcome the curse of dimensionality by partially parameterizing a model, so that there is a mix of parametric and nonparametric components. A very early example is the maximum score estimator for the binary choice model of Manski (1975).

Theoretically, a first step is to determine whether parameters are identified given only partial specification of the model. Ideally $\sqrt{N}$-consistent and asymptotically normal estimates of the parameters can be obtained. Furthermore, it is preferred

that they be fully efficient in that they attain semiparametric efficiency bounds (see Chamberlain, 1987; Newey, 1990; Severini and Tripathi, 2001) that are extensions of Cramer–Rao lower bounds or the Gauss–Markov theorem to semiparametric models.

There are many semiparametric models, and for each model there can be several different ways to obtain estimators. Partial linear and single index models are two leading examples that are also the building blocks for more general models.

The partial linear model specifies the conditional mean to be the usual linear regression function plus an unspecified nonlinear component, so:

$$\mathrm{E}[y_i|\mathbf{x}_i, \mathbf{z}_i] = \mathbf{x}_i'\boldsymbol{\beta} + \lambda(\mathbf{z}_i), \tag{14.17}$$

where the scalar function $\lambda(\cdot)$ is unspecified. An example is the estimation of a demand function for electricity, where $\mathbf{z}$ reflects time of day or weather indicators such as temperature. A second example is a sample selection model where $\lambda(\mathbf{z})$ is the expected value of a model error, conditional on the sample selection rule. In applications interest may lie in $\boldsymbol{\beta}$, $\lambda(\mathbf{z})$ or both. Various estimators for the partial linear model have been proposed. The differencing method proposed by Robinson (1988) estimates $\boldsymbol{\beta}$ by OLS regression of $(y_i - \widehat{m}_{yi})$ on $(\mathbf{x}_i - \widehat{\mathbf{m}}_{\mathbf{x}i})$, where $\widehat{m}_{yi}$ and $\widehat{\mathbf{m}}_{\mathbf{x}i}$ are predictions from nonparametric regression of, respectively, y and $\mathbf{x}$ on $\mathbf{z}$. Robinson used kernel estimates that may need to be oversmoothed. Other methods that additionally estimate $\lambda(z)$, at least for scalar z, include a generalization of the cubic smoothing spline estimator and using a series approximation for $\lambda(z)$.

The single index model specifies the conditional mean to be an unknown scalar function of a linear combination of the regressors, with:

$$\mathrm{E}[y_i|\mathbf{x}_i] = g(\mathbf{x}_i'\boldsymbol{\beta}), \tag{14.18}$$

where the scalar function $g(\cdot)$ is unspecified and the parameters $\boldsymbol{\beta}$ are then only identified up to location and scale. An example is a binary choice model with $\Pr[y = 1|\mathbf{x}] = g(\mathbf{x}'\boldsymbol{\beta})$ where $g(\cdot)$ is unknown. The single index formulation is attractive as the marginal effect of a change in the jth regressor is $g'(\mathbf{x}_i'\boldsymbol{\beta})\beta_j$, so that the ratio of parameter estimates equals the ratio of marginal effects. Estimators for the single index model include an average derivative estimator, a density weighted average derivative estimator (see Powell, Stock and Stoker, 1989), and semiparametric least squares.

Microeconometricians have focused on semiparametric estimation for limited dependent variable models – binary choice with an unspecified function for the probabilities, censored regression and sample selection. Nonparametric and semiparametric methods are also used in the treatment effects literature detailed in section 14.5.1. The literature is vast. References include the applied study by Bellemare, Melenberg and van Soest (2002), and books by Pagan and Ullah (1999) and Li and Racine (2007). The latter book is accompanied by many routines in R for nonparametric and semiparametric regression.

14.4 Statistical inference

There have been considerable advances in statistical inference methods, even for the standard LS, IV and ML estimators (MLEs).

The most notable change is the use of robust statistical inference, notably robust standard error computation, that relies on distributional assumptions that are as weak as possible. Various model specification tests have been developed, such as the Hausman test and White's information matrix test. The bootstrap provides an alternative way to perform statistical inference that can be simpler than conventional asymptotic methods. Furthermore, the bootstrap can produce more accurate asymptotic approximations for test statistics that lead to tests with actual size close to nominal size in small samples.

14.4.1 Robust inference for Wald tests

Analysis begins with the cross-section case of independent observations, before moving to clustered observations, which includes short panels.

Consider an m-estimator $\widehat{\boldsymbol{\theta}}$ that maximizes with respect to $\boldsymbol{\theta}$ the objective function $Q_N(\boldsymbol{\theta}) = N^{-1}\sum_i q(y_i, \mathbf{x}_i, \boldsymbol{\theta})$. For ML estimation $q(\cdot)$ is the log-density, and for least squares estimation $q(\cdot)$ is minus the squared error (or a rescaling of this). The m-estimator solves the first-order conditions:

$$N^{-1}\sum\nolimits_i \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}) = \mathbf{0}, \tag{14.19}$$

where $\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}) = \partial q(y_i, \mathbf{x}_i, \boldsymbol{\theta})/\partial\boldsymbol{\theta}$. Under suitable assumptions, notably that $\mathrm{E}[\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta})] = \mathbf{0}$ in the population, it can be shown that $\widehat{\boldsymbol{\theta}}$ is $\sqrt{N}-$consistent, with limit distribution:

$$\sqrt{N}(\widehat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0) \xrightarrow{d} \mathcal{N}[\mathbf{0}, \mathbf{A}_0^{-1}\mathbf{B}_0\mathbf{A}_0'^{-1}], \tag{14.20}$$

where $\mathbf{A}_0 = \operatorname{plim} N^{-1}\sum_i \partial\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta})/\partial\boldsymbol{\theta}'\Big|_{\boldsymbol{\theta}_0}$ and $\mathbf{B}_0 = \operatorname{plim} N^{-1}\sum_i \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}_0)\mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta}_0)'$, and $\boldsymbol{\theta}_0$ is the value of $\boldsymbol{\theta}$ in the DGP.

Inference is based on $\widehat{\boldsymbol{\theta}}$ being asymptotically normally distributed with mean $\boldsymbol{\theta}_0$ and estimated asymptotic variance matrix of sandwich form:

$$\widehat{\mathbf{V}}[\widehat{\boldsymbol{\theta}}] = N^{-1}\widehat{\mathbf{A}}^{-1}\widehat{\mathbf{B}}\widehat{\mathbf{A}}'^{-1}, \tag{14.21}$$

where $\widehat{\mathbf{A}}$ and $\widehat{\mathbf{B}}$ are consistent estimates of $\mathbf{A}_0$ and $\mathbf{B}_0$. The Wald test statistic for $H_0 : \theta_j = r$ is then $W = (\widehat{\theta}_j - r)/s_j$, where s_j is the jth diagonal entry of $\widehat{\mathbf{V}}[\widehat{\boldsymbol{\theta}}]$, and $W \overset{a}{\sim} \mathcal{N}[0, 1]$ under H_0. The more general hypothesis $H_0 : \mathbf{c}(\boldsymbol{\theta}) = \mathbf{0}$ is tested using $W = \mathbf{c}(\widehat{\boldsymbol{\theta}})'(\widehat{\mathbf{R}}\widehat{\mathbf{V}}[\widehat{\boldsymbol{\theta}}]\widehat{\mathbf{R}}')^{-1}\mathbf{c}(\widehat{\boldsymbol{\theta}})$, where $\widehat{\mathbf{R}} = \partial\mathbf{c}(\boldsymbol{\theta})/\partial\boldsymbol{\theta}'\Big|_{\widehat{\boldsymbol{\theta}}}$ and $W \overset{a}{\sim} \chi^2(rank[\mathbf{R}])$ under H_0.

There are several possible ways to form $\widehat{\mathbf{A}}$ and $\widehat{\mathbf{B}}$, depending in part on the strength of the distributional assumptions made. Robust variance estimates are those that rely on minimal distributional assumptions, provided $N \to \infty$.

Given data independent over i, the robust variance matrix estimate uses:

$$\widehat{\mathbf{A}} = N^{-1} \sum_i \left. \frac{\partial \mathbf{h}(\mathbf{w}_i, \boldsymbol{\theta})}{\partial \boldsymbol{\theta}'} \right|_{\widehat{\boldsymbol{\theta}}},$$
$$\widehat{\mathbf{B}} = N^{-1} \sum_i \mathbf{h}(\mathbf{w}_i, \widehat{\boldsymbol{\theta}}) \mathbf{h}(\mathbf{w}_i, \widehat{\boldsymbol{\theta}})'. \tag{14.22}$$

The resulting standard errors are called robust standard errors. In some cases the Hessian $\widehat{\mathbf{A}}$ in (14.22) may be replaced by the expected Hessian, and $\widehat{\mathbf{B}}$ may use a degrees-of-freedom correction such as $(N-q)^{-1}$ rather than N^{-1}.

A leading example is the heteroskedastic-consistent estimate of the variance-covariance matrix of the OLS estimator. Then $q_i(\boldsymbol{\beta}) = -\frac{1}{2}(y_i - \mathbf{x}_i'\boldsymbol{\beta})^2$, where the multiple $\frac{1}{2}$ is added for convenience, so that $\mathbf{h}_i(\boldsymbol{\beta}) = \partial q_i / \partial \boldsymbol{\beta} = (y_i - \mathbf{x}_i'\boldsymbol{\beta})\mathbf{x}_i$, and $\partial \mathbf{h}_i(\boldsymbol{\beta}) / \partial \boldsymbol{\beta}' = -\mathbf{x}_i \mathbf{x}_i'$. It follows that:

$$\widehat{\mathbb{V}}[\widehat{\boldsymbol{\beta}}_{\text{OLS}}] = \left[\sum_i \mathbf{x}_i \mathbf{x}_i'\right]^{-1} \left[\sum_i \widehat{u}_i^2 \mathbf{x}_i \mathbf{x}_i'\right] \left[\sum_i \mathbf{x}_i \mathbf{x}_i'\right]^{-1}, \tag{14.23}$$

where $\widehat{u}_i = (y_i - \mathbf{x}_i'\widehat{\boldsymbol{\beta}})$.

For ML estimation use of (14.22) relaxes the traditional information matrix equality assumption that $\mathbf{A}_0 = -\mathbf{B}_0$, which gives the simplification $\mathbf{A}_0^{-1}\mathbf{B}_0\mathbf{A}_0^{-1} = -\mathbf{A}_0^{-1}$. Failure of the information matrix equality generally implies inconsistency of the MLE. Then $\boldsymbol{\theta}_0$ needs to be reinterpreted as a "pseudo-true value," which is the value of $\boldsymbol{\theta}$ that maximizes the probability limit of $1/N$ times the log-likelihood function. However, the MLE does retain consistency in many standard models with specified density in the linear exponential family, notably linear, Poisson, logit and probit, provided the conditional mean function is correctly specified. Robust standard errors are then especially applicable.

For independent errors the key early reference is White (1980), who proposed the special case (14.23). Robust standard errors have been applied to many estimators, including instrumental variables and generalized method of moments (see (14.3)). T. Amemiya (1985) and Newey and McFadden (1994) provide quite general treatments of inference and estimation (see also White, 1984).

The estimates in (14.22) can be extended to clustered data. In that case observations are grouped into clusters, with correlation permitted within a cluster but independence assumed across clusters. An example is panel data where the cluster unit is the individual: observations for a given individual over time are correlated, but observations across individuals are independent. Let $c = 1, \ldots, C$ denote clusters and let $j = 1, \ldots, N_c$ denote the N_c observations in cluster c. Then the cluster-robust variance matrix estimate is (14.21), where $\widehat{\mathbf{A}}$ is again given in (14.22) but now:

$$\widehat{\mathbf{B}} = N^{-1} \sum_{c=1}^{C} \sum_{j=1}^{N_c} \sum_{k=1}^{N_c} \mathbf{h}(\mathbf{w}_{jc}, \widehat{\boldsymbol{\theta}}) \mathbf{h}(\mathbf{w}_{kc}, \widehat{\boldsymbol{\theta}})'. \tag{14.24}$$

This estimator, proposed by Liang and Zeger (1986), permits both error heteroskedasticity and quite flexible error correlation within cluster. It has largely supplanted the use of a more restrictive random effects or error components model,

although it does require $C \to \infty$. It is essential to control for clustering, as failure to do so can lead to greatly under estimated standard errors (see Moulton, 1990). With few clusters the asymptotic normal distribution can perform poorly. Small sample corrections include using the T_{C-1} distribution, using a cluster bootstrap with asymptotic refinement (Cameron, Gelbach and Miller, 2008), and using an alternative estimator that, under some assumptions, is exactly T_{C-2} distributed as $N_c \to \infty$ (Donald and Lang, 2007). Wooldridge (2003) provides a survey that is updated and newer results given in Wooldridge (2006). Cameron, Gelbach and Miller (2006) propose an extension of (14.24) to multi-way clustering.

Cluster-robust variance matrix estimators have also been proposed for models where $\mathbf{h}_i(\boldsymbol{\theta})$ is spatially correlated. Driscoll and Kraay (1998) do so for panel data where the time dimension is large. Conley (1999) presents a quite general estimator.

Models for clustered or spatial data may allow the conditional mean to be affected, in addition to conditional correlations, and then standard estimators become inconsistent. For clustered data one can use a model with cluster-specific fixed effects, analogous to fixed effects for panel data. For spatial data recent references include Anselin (2001) and Lee (2004).

The theory for robust inference is well-established and, in the independent observations case at least, is well incorporated into microeconometrics practice. In particular, for LS problems it is standard to estimate by OLS and then use robust standard errors, even though there may be efficiency loss compared to doing feasible generalized least squares (GLS). Note, however, that one can still employ feasible GLS but then compute robust standard errors that guard against misspecification of the model for the error variance matrix.

14.4.2 Hypothesis tests

For hypotheses on parameters of the form:

$$H_0 : \mathbf{c}(\boldsymbol{\theta}) = \mathbf{0}$$
$$H_a : \mathbf{c}(\boldsymbol{\theta}) \neq \mathbf{0},$$

the classical tests in the likelihood framework are the Wald, Lagrange multiplier (LM), and likelihood ratio tests. For a correctly specified likelihood function these tests are first-order asymptotically equivalent under the null hypothesis and under local alternatives, so choice between them is one of convenience.

More recent work has focused on generalization to the non-likelihood framework, and on finite-sample properties of the tests.

The Wald test has become the most popular of these three tests, as it generalizes easily to non-likelihood models and is most easily robustified as detailed in section 14.4.1. But it does have the limitation of lack of invariance to parameterization. For example, a test of $H_0 : \theta_1/\theta_2 = 1$ will lead in finite samples to a Wald test statistic that differs from that for the equivalent hypothesis $H_0 : \theta_1 - \theta_2 = 0$. A bootstrap with asymptotic refinement (see section 14.4.4), should reduce this invariance.

The LM or score test is less commonly used, in part because it is usually implemented by a convenient auxiliary regression that has poor finite sample properties.

Specifically, Monte Carlo studies find considerable over-rejection due to the finite sample test size being considerably larger than the asymptotic size. A bootstrap with asymptotic refinement, however, can correct this problem. The LM test can be extended to non-likelihood settings, and can be robustified.

The likelihood ratio test generally does not extend to non-likelihood settings, though it does for optimal GMM estimation. Newey and West (1987) generalize the three classical tests from the likelihood framework to the GMM framework.

14.4.3 Model specification tests

Various model specification tests have been developed that do not rely on hypothesis tests of the form $\mathbf{c}(\boldsymbol{\theta}) = \mathbf{0}$.

The Hausman (1978) test contrasts two estimators that may be the same under a null hypothesis and differ under an alternative hypothesis. For example, one can compare OLS to the 2SLS estimator and conclude that there is endogeneity if the two estimators differ. Denote the two estimators by $\widehat{\boldsymbol{\theta}}$ and $\widetilde{\boldsymbol{\theta}}$, and test H_0 : plim$(\widehat{\boldsymbol{\theta}} - \widetilde{\boldsymbol{\theta}}) = \mathbf{0}$ using the statistic:

$$H = (\widehat{\boldsymbol{\theta}} - \widetilde{\boldsymbol{\theta}})'(\widehat{\mathrm{V}}[\widehat{\boldsymbol{\theta}} - \widetilde{\boldsymbol{\theta}}])^{-1}[\widehat{\boldsymbol{\theta}} - \widetilde{\boldsymbol{\theta}}],$$

which is chi-squared distributed under H_0. Implementation requires estimating the variance matrix of the difference in the estimators. The original approach was to assume that one estimator, say $\widehat{\boldsymbol{\theta}}$, is efficient under the null, in which case $\mathrm{V}[\widehat{\boldsymbol{\theta}} - \widetilde{\boldsymbol{\theta}}] = \mathrm{V}[\widetilde{\boldsymbol{\theta}}] - \mathrm{V}[\widehat{\boldsymbol{\theta}}]$. This is the standard method used today, even though it is generally incorrect since, from section 14.4.1, most applied studies use heteroskedastic-robust or cluster-robust standard errors that presume the estimator is, in fact, inefficient. One should instead use alternative methods to estimate $\mathrm{V}[\widehat{\boldsymbol{\theta}} - \widetilde{\boldsymbol{\theta}}]$, such as the bootstrap.

Moment tests are tests of whether or not a population moment condition is supported by the data. Specifically, they test:

$$H_0 : \mathrm{E}[\mathbf{m}(\mathbf{w}_i, \boldsymbol{\theta})] = \mathbf{0}$$
$$H_a : \mathrm{E}[\mathbf{m}(\mathbf{w}_i, \boldsymbol{\theta})] \neq \mathbf{0}.$$

An obvious test is based on whether the corresponding sample moment $\widehat{\mathbf{m}} = N^{-1} \sum_i \mathbf{m}(\mathbf{w}_i, \widehat{\boldsymbol{\theta}})$ is close to zero. The test statistic is:

$$M = \widehat{\mathbf{m}}'(\widehat{\mathrm{V}}[\widehat{\mathbf{m}}])^{-1}\widehat{\mathbf{m}},$$

where M is chi-squared distributed under H_0 and the challenge is to estimate $\widehat{\mathrm{V}}[\widehat{\mathbf{m}}]$.

One leading example is an overidentifying restrictions (OIR) test. Then GMM estimation based on $\mathrm{E}[\mathbf{m}(\mathbf{w}_i, \boldsymbol{\theta})] = \mathbf{0}$ cannot exactly impose $\widehat{\mathbf{m}} = \mathbf{0}$ if the model is overidentified. If GMM with an optimal weighting matrix is used then Hansen (1982) showed that M is chi-squared distributed under H_0 with degrees of freedom equal to the number of overidentifying restrictions.

A second class of examples are conditional moment tests, where some model restrictions are used in estimation while other restrictions, not imposed in

estimation, are used for specification testing. For example, in linear regression of y on $\mathbf{x}_1$, the hypothesis that $\mathbf{x}_2$ can be excluded as a regressor implies $\mathrm{E}[(y - \mathbf{x}_1'\boldsymbol{\beta}_1)|\mathbf{x}_2] = 0$. This can be specified as a test of $H_0 : \mathrm{E}[(y - \mathbf{x}_1'\boldsymbol{\beta}_1)\mathbf{x}_2] = \mathbf{0}$. Here it can be difficult to obtain $\widehat{\mathrm{V}}[\widehat{\mathbf{m}}]$, though auxiliary regressions are available to compute an asymptotically equivalent version of M in the special case that $\widehat{\boldsymbol{\theta}}$ is the MLE. Examples of conditional moment tests, proposed by Newey (1985) and Tauchen (1985), include the information matrix test of White (1982) and chi-squared goodness-of-fit tests.

The Hausman test and OIR tests are routinely used in GMM applications. Conditional moment tests are less commonly used, even though they are easy to implement in likelihood settings, where they would seem especially useful due to concerns of reliance on distributional assumptions. One reason is that the convenient auxiliary regressions used to compute them can have poor finite-sample size properties, but this can be rectified by a bootstrap with asymptotic refinement (see, for example, Horowitz, 1994). A second reason is the more practical one that, especially with large samples, any model is quite likely to be rejected at conventional 5% significance levels.

For model selection when models are nested the standard hypothesis testing methods can be used. For model selection with non-nested models there is an extensive literature that is not addressed here. A recent survey is provided by Pesaran and Weeks (2001).

14.4.4 Bootstrap

Inference in microeconometrics is based on asymptotic results that provide only an approximation given typical sample sizes. The bootstrap, introduced by Efron (1979), provides an alternative approximation by Monte Carlo simulation.

The motivation of the bootstrap is to view the data in hand, or the fitted DGP, as the population. Then draw B resamples from this population, and for each resample compute a relevant statistic. The empirical distribution of the resulting B statistics is used to approximate the distribution of the original statistic.

The most common use of the bootstrap is as a way to calculate standard errors. The data $\mathbf{w}_1, \ldots, \mathbf{w}_N$ are assumed to be i.i.d. The bootstrap standard error procedure is:

1. Do the following B times:
   - Draw a bootstrap resample $\mathbf{w}_1^*, \ldots, \mathbf{w}_N^*$ by sampling with replacement from the original data (called a paired bootstrap).
   - Obtain estimate $\widehat{\theta}^*$ of θ, where for simplicity θ is scalar.
2. Use the B estimates $\widehat{\theta}_1^*, \ldots, \widehat{\theta}_B^*$ to approximate the distribution of $\widehat{\theta}$. In particular, the bootstrap estimate of the standard error of $\widehat{\theta}$ is:

$$s_{\widehat{\theta},\mathrm{Boot}} = \sqrt{\frac{1}{B-1}\sum_{b=1}^{B}(\widehat{\theta}_b^* - \bar{\widehat{\theta}}^*)^2}, \tag{14.25}$$

where $\bar{\widehat{\theta}}^* = B^{-1}\sum_{b=1}^{B}\widehat{\theta}_b^*$. This is simply the standard deviation of $\widehat{\theta}_1^*, \ldots, \widehat{\theta}_B^*$.

This method is convenient whenever standard errors are difficult to obtain by conventional methods. Leading examples are (i) two-step estimators when estimation at the first step complicates inference at the second step; (ii) Hausman tests that require computation of the variance of the difference between two estimators when neither estimator is efficient under the null hypothesis; and (iii) estimation with clustered errors when a package does not compute cluster-robust standard errors (in this case a cluster bootstrap that resamples over clusters is used). Given bootstrap standard errors, a standard Wald test of $H_0 : \theta = \theta_0$ uses $t = (\widehat{\theta} - \theta_0)/s_{\widehat{\theta},\text{Boot}}$ and asymptotic normal critical values.

The preceding bootstrap is theoretically no better than usual first-order asymptotic theory. The attraction is the practical one of convenience.

Some bootstraps, however, provide a better asymptotic approximation, called an asymptotic refinement. The econometrics literature focuses on asymptotic refinement for test statistics. Consider a test of $H_0 : \theta = \theta_0$ with nominal significance level or nominal size α. An asymptotic approximation yields an actual rejection rate or true size $\alpha + O(N^{-j})$, where $O(N^{-j})$ means is of order N^{-j} and $j > 0$, with often $j = 1/2$ or $j = 1$. Then the true size goes to α as $N \to \infty$. Larger j is preferred, however, as then convergence to α is faster. A method with asymptotic refinement (or higher-order asymptotics) is one that yields j larger than that obtained using conventional asymptotics. The hope is that such asymptotic refinement will lead to tests with true size closer to α for moderate sample sizes, though this is not guaranteed. Asymptotic refinement may be possible if the bootstrap is applied to an asymptotically pivotal statistic, meaning one with asymptotic distribution that does not depend on unknown parameters.

The bootstrap standard error procedure does not lead to asymptotic refinement for the Wald test. Nor does the percentile method which rejects $H_0 : \theta = \theta_0$ if θ_0 falls outside the lower $\alpha/2$ and upper $\alpha/2$ quantiles of the bootstrap estimates $\widehat{\theta}_1^*, \ldots, \widehat{\theta}_B^*$. The problem is that $\widehat{\theta}$ is bootstrapped and $\widehat{\theta}$ is not asymptotically pivotal, since even under H_0 its asymptotic normal distribution depends on an unknown parameter (the variance).

Instead, the Wald statistic itself should be bootstrapped, as $t = (\widehat{\theta} - \theta_0)/s_{\widehat{\theta}}$ is asymptotically pivotal, since it is asymptotically $\mathcal{N}[0, 1]$ under H_0, an asymptotic distribution with no unknown parameters. The bootstrap-t or percentile-t procedure for a two-sided test of $H_0 : \theta = \theta_0$ at level α is:

1. Do the following B times:

   - Draw a bootstrap resample $\mathbf{w}_1^*, \ldots, \mathbf{w}_N^*$ by sampling with replacement from the original data (called a paired bootstrap).
   - Obtain an estimate $\widehat{\theta}^*$, standard error $s_{\widehat{\theta}^*}$ and t-statistic $t^* = (\widehat{\theta}^* - \widehat{\theta})/s_{\widehat{\theta}^*}$.

2. Use the B statistics $t_1^*, \ldots, t_B^*$ to approximate the distribution of $t = (\widehat{\theta} - \theta_0)/s_{\widehat{\theta}}$. For an equal-tailed (or nonsymmetric) test reject H_0 if the original sample t-statistic falls outside the lower $\alpha/2$ and upper $\alpha/2$ quantiles of the bootstrap estimates

$t_1^*, \ldots, t_B^*$. For a symmetric test reject H_0 if the original sample t-statistic falls outside the α quantile of $|t_1^*|, \ldots, |t_B^*|$.

Note that t^* in step 1 is centered on $\widehat{\theta}$ as the bootstrap views the original sample, with $\theta = \widehat{\theta}$, as the DGP. For equal-tailed two-sided tests (or for one-sided tests) this procedure leads to asymptotic refinement with true size $\alpha + O(N^{-1})$, rather than $\alpha + O(N^{-0.5})$, using bootstrap standard errors (or standard errors obtained using equation (14.21)). For a two-sided symmetrical test (or a chi-squared test) the corresponding rates are instead, respectively, $\alpha + O(N^{-1.5})$ and $\alpha + O(N^{-1})$.

There are as many ways to bootstrap as there are different ways to obtain resamples, and there are many ways to use these resamples.

The resampling method used above is called a paired bootstrap, as often $\mathbf{w}_i = (y_i, \mathbf{x}_i)$ and here both y_i and $\mathbf{x}_i$ are being resampled. By contrast, a residual bootstrap, for a model with additive error, holds $\mathbf{x}_i$ fixed and resamples over residuals $\widehat{u}_1, \ldots, \widehat{u}_N$ to yield resampled values $\mathbf{w}_i^* = (y_i^*, \mathbf{x}_i)$, where $y_i^* = \mathbf{x}_i'\widehat{\boldsymbol{\beta}} + \widehat{u}_i^*$. A parametric bootstrap uses distributional knowledge, such as a specified distribution for $y_i|\mathbf{x}_i$, to resample y_i given $\mathbf{x}_i$. For clustered data any resampling is over clusters. For hypothesis tests it is best, if possible, to impose H_0 in drawing the bootstrap sample. More bootstrap replications are needed when the goal of the bootstrap is asymptotic refinement for a test statistic.

Much development of the bootstrap has been done in the statistics literature. The econometrics literature is surveyed in Horowitz (2001), and MacKinnon (2002) provides much useful practical advice. Econometric studies have focused on bootstraps for estimation methods used mainly by econometricians. For overidentified GMM models one should recenter so that the population moment condition is imposed in the sample; see Hall and Horowitz (1996).

The bootstrap needs to be used with caution, as standard bootstraps can provide inconsistent standard error estimates for nonsmooth estimators and for less than $\sqrt{N}$-consistent estimators. This has led to a currently active literature. Abrevaya and Huang (2005) consider the maximum score estimator, Abadie and Imbens (2008) consider matching treatment effects estimators, and Moreira, Porter and Suarez (2004) consider IV with weak instruments. Sub-sampling, due to Politis and Romano (1994), works in a wider range of settings than the bootstrap.

In applied microeconometrics the main use of the bootstrap is to obtain standard errors. Bootstraps with asymptotic refinement are rarely done, as sample sizes are felt to be fairly large. But a bootstrap with asymptotic refinement can correct for many well-documented problems associated with standard tests, including the lack of invariance to parameterization for the Wald test and the poor finite-sample performance of auxiliary regressions used in computing LM tests and conditional moment tests.

14.5 Causation

The preceding sections presented estimation and inference methods for quite general regression models. Econometrics is distinguished by a desire to go beyond

correlative data summary to obtaining estimates of a causative effect, meaning measures of how an outcome changes in response to exogenous changes in a regressor. The current microeconometrics toolkit contains many methods to do so.

The "treatment effects" or "natural experiment" approach seeks to measure causation by extending randomized experiment methods to observational data. This major innovation in microeconometrics research uses a potential outcomes notation that differs from the simultaneous equations framework developed at the Cowles Commission. Developments have also been made in other more traditional methods to tease out causation, notably instrumental variables estimation, use of panel data, and estimation of structural models.

14.5.1 Treatment effects

The treatment effects literature focuses on the simplest case of estimating the causal effect of a binary regressor. A stereotypical example is to consider the impact on earnings of participation in a training program. The terminology of a medical trial is used. Enrollment in a training program is viewed as treatment, having no training is viewed as control, and the objective is to estimate the causative effect of the treatment on the outcome variable, earnings.

The ideal way to calculate this effect is to observe earnings for a person with the training, observe earnings for the same person without training, and subtract. But this is impossible. Instead the outcome is observed in only one state, while the other state is a hypothetical unobserved value, called a potential outcome or counterfactual.

The randomized experiment approach solves the inability to observe the counterfactual by comparing average outcomes, rather than individual outcomes, for two groups that are randomly assigned to either treatment or control. This approach is used at times in the social sciences, in social experiments. But most economics studies must instead rely on observational data.

The treatment effects literature seeks to extend the experimental approach to nonrandomized settings. Again averages across groups are compared, but now individuals select their treatment. Different assumptions about the nature of the self-selection of treatment and data availability lead to different methods to compute average effects of treatment. A key consideration is whether or not it is reasonable to assume that self-selection can be controlled for using observed variables, or whether self-selection additionally depends on unobservables. The latter case requires much stronger assumptions to make progress.

The following framework is used. The binary treatment variable d takes value 1 if treatment is assigned and value 0 if untreated (a control). The observed outcome of interest y is a continuous variable that then takes values:

$$y_i = \begin{cases} y_{1i} & \text{if treated } (d_i = 1) \\ y_{0i} & \text{if control } (d_i = 0). \end{cases} \tag{14.26}$$

The individual treatment effect is defined to be:

$$\alpha_i = (y_{1i} - y_{0i}). \tag{14.27}$$

Note that (14.26) and (14.27) imply:

$$y_i = d_i y_{1i} + (1 - d_i) y_{0i} = y_{0i} + \alpha_i d_i. \tag{14.28}$$

Since only one of y_{1i} and y_{0i} are observed, α_i is not observable. Instead, the goal is to estimate population averages of α_i, notably the average treatment effect (ATE):

$$\alpha_{\text{ATE}} = \text{E}[\alpha_i], \tag{14.29}$$

and the average treatment effect on the treated (ATET):

$$\alpha_{\text{ATET}} = \text{E}[\alpha_i | d_i = 1]. \tag{14.30}$$

These are conceptually quite different quantities. ATET gives the average gain in earnings for a person who actually receives training. ATE gives the earnings gain averaged across those who did and those who did not receive the training.

The evaluation problem can be illustrated by decomposing ATET into two terms as:

$$\alpha_{\text{ATET}} = \{\text{E}[y_{1i} | d_i = 1] - \text{E}[y_{0i} | d_i = 0]\} - \{\text{E}[y_{0i} | d_i = 1] - \text{E}[y_{0i} | d_i = 0]\}. \tag{14.31}$$

A naive estimate of α_{ATET} uses just the first term. But this ignores the second term, a selection term that arises if the treated and untreated are different in that, on average, they would have different untreated outcome. Methods differ according to whether this selection term can be solely controlled for by regressors, or whether it additionally depends on unobservables.

Given regressors $\mathbf{x}$, similar average effects can be defined, now varying with regressors. The ATE is:

$$\alpha_{\text{ATE}}(\mathbf{x}) = \text{E}[\alpha_i | \mathbf{X}_i = \mathbf{x}]. \tag{14.32}$$

and the ATET is:

$$\alpha_{\text{ATET}}(\mathbf{x}) = \text{E}[\alpha_i | \mathbf{X}_i = \mathbf{x}, d_i = 1]. \tag{14.33}$$

Treatment effects are called heterogeneous if these quantities vary with the evaluation point $\mathbf{x}$, and are called homogeneous if $\alpha_{\text{ATE}}(\mathbf{x}) = \alpha_{\text{ATET}}(\mathbf{x}) = \alpha$. In practice, researchers usually report estimates of the population measures $\alpha_{\text{ATE}} = \text{E}[\alpha_{\text{ATE}}(\mathbf{x})]$ and $\alpha_{\text{ATET}} = \text{E}[\alpha_{\text{ATET}}(\mathbf{x})]$ that average across individuals with different characteristics. For example, individual-level estimates of $\widehat{\alpha}_{\text{ATE}}(\mathbf{x}_i)$ lead to $\widehat{\alpha}_{\text{ATE}} = N^{-1} \sum_{i=1}^{N} \widehat{\alpha}_{\text{ATE}}(\mathbf{x}_i)$.

A critical simplifying assumption, discussed further below, is that selection is on observables only. Assuming conditional independence, outcomes are independent of treatment after conditioning on regressors, so that:

$$f(y_{ji} | \mathbf{x}_i, d_i = 1) = f(y_{ji} | \mathbf{x}_i, d_i = 0) = f(y_{ji} | \mathbf{x}_i), j = 0, 1. \tag{14.34}$$

This assumption of exogenous selection of treatment (given $\mathbf{x}$) is often written as $y_{0i}, y_{1i} \perp d_i | \mathbf{x}_i$ and has several other names, including unconfoundedness and ignorability. For some purposes it can be weakened to apply to only y_{0i} or to

apply only to conditional means (and not the entire distribution). The assumption implies that:

$$\alpha_{\text{ATET}}(\mathbf{x}) = \text{E}[y_{1i}|\mathbf{X}_i = \mathbf{x}, d_i = 1] - \text{E}[y_{0i}|\mathbf{X}_i = \mathbf{x}, d_i = 0], \tag{14.35}$$

where the second-term conditions on $d_i = 0$, rather than $d_i = 1$ as in the original definition (14.33).

The matching approach for estimating treatment effects is based on (14.35) and compares sample averages of y_1 and y_0 for individuals with the same level of $\mathbf{x}$. This permits treatment effects to be heterogeneous and provides nonparametric estimates of their average. In practice, however, such estimates become noisy or impossible as $\mathbf{x}$ will take many values if it is continuous or high dimensional. One can instead use nonparametric methods, such as kernel weighting, that permit use of individuals with similar but not exactly the same level of $\mathbf{x}$. But more common is to match on the probability of treatment conditional on $\mathbf{x}$, known as the propensity score:

$$p(\mathbf{x}_i) = \Pr[d_i = 1|\mathbf{x}_i], \tag{14.36}$$

since Rosenbaum and Rubin (1983) showed that the conditional independence assumption carries over to conditioning on the propensity score (that is, $y_{0i}, y_{1i} \perp d_i \mid p(\mathbf{x}_i)$). For example, nearest-neighbor propensity score matching uses:

$$\widehat{\alpha}_{\text{ATET}} = N_1^{-1} \sum_{i:d_i=1} (y_{1i} - y_{0j}),$$

where $N_1 = \sum_{i=1}^{N} d_i$ and y_{0j} is the outcome for the nearest neighbor, the untreated observation with propensity score closest to that for y_{1i}. Other propensity score matching methods included kernel and stratification methods that average over several outcomes with similar propensity score. By estimating the propensity score using a flexible model, such as a semiparametric binary model or a logit model with interactions, it is more likely that observables only may determine selection. The propensity scores must have suitable common support over treatment and controls in order for matching to be feasible. For ATET it must be that $p(\mathbf{x}_i) < 1$, that is, for any value of the regressors it is possible to not receive treatment, while for ATE the requirement is that $0 < p(\mathbf{x}_i) < 1$. Note that if treatment effects are heterogeneous and matching is valid, the estimates obtained are very problem specific and not necessarily generalizable to other settings.

An alternative method is to specify and estimate a more restrictive regression model for the outcome. An obvious model is:

$$y_i = \alpha d_i + \mathbf{x}_i'\boldsymbol{\beta} + u_i, \tag{14.37}$$

which imposes the constraint that the treatment effect α is homogeneous. OLS estimation of (14.37) yields a consistent estimate of the treatment effect α, assuming conditional independence and that (14.37) is correctly specified. This is called the control function approach, as the regressors $\mathbf{x}$ here include regressors that control for selection into treatment (that is, explain d) as well as regressors that directly

explain y in the absence of treatment. This more parametric method has the advantage over matching of not requiring common support for the propensity score and permitting extrapolation beyond just the sample at hand.

The preceding methods rely on the untestable assumption of conditional independence, and presume that the dataset is rich with many control variables, since observables alone are assumed sufficient to control for treatment selection. Should these conditions fail, which will be the case in many potential applications, the previous methods are invalid. For example, the OLS estimator in the simple homogeneous effects model (14.37) is inconsistent if the treatment indicator variable is correlated with the error term even after conditioning on regressors $\mathbf{x}$. It is then necessary to allow for treatment to additionally depend on unobservable individual heterogeneity, with different methods used to control or eliminate the unobservables.

Panel data fixed effects estimators, possible if data are available for more than one period, control for unobserved heterogeneity by assuming that only the time-invariant component is correlated with treatment. A panel data version of the homogeneous effects model (14.37) is:

$$y_{it} = \alpha d_{it} + \mathbf{x}_{it}'\boldsymbol{\beta} + \phi_i + \delta_t + \varepsilon_{it}, \tag{14.38}$$

where here $\mathbf{x}_{it}$ does not include a constant and the intercept has both an individual-specific component ϕ_i and a time-specific component δ_t. Assume that treatment d_{it} is correlated with the unobservable ϕ_i, so OLS is inconsistent, but is uncorrelated with u_{it}. Then α can be consistently estimated by OLS estimation of the first differences model:

$$\Delta y_{it} = \alpha \Delta d_{it} + \Delta \delta_t + \Delta \mathbf{x}_{it}'\boldsymbol{\beta} + \Delta \varepsilon_{it}, \tag{14.39}$$

or by estimation of a mean differences model (the fixed effects estimator), since ϕ_i has been eliminated. This standard method presumes panel data are available and is restricted to homogeneous treatment effects.

The related differences-in-differences method is applicable to repeated cross-sections, as well as panel data. For simplicity, suppose there are just two periods, say $t = a$ (after) and $t = b$ (before), and that all individuals are untreated in the first period and some are treated in the second period. Let $\bar{y}_{jt}$ denote the average outcome for treatment group $j = 0, 1$ in period $t = a, b$. The outcome changes over time by $(\bar{y}_{1a} - \bar{y}_{1b})$ in the treated group and by $(\bar{y}_{0a} - \bar{y}_{0b})$ in the untreated group. The differences in these differences provides an estimate of ATET, called the differences-in-differences estimator. This estimator is the OLS estimator of α in the model:

$$y_{it} = \gamma + \alpha d_i + \beta e_t + u_{it}, \ t = a, b,$$

where d_i is a binary treatment indicator and e_t is a binary time period indicator. Consistency of this estimator requires strong assumptions regarding the role of unobservables. In terms of (14.38) it is assumed that treatment selection does not depend on ε_{it} and that, while it may depend on ϕ_i, on average $\text{plim}(\bar{\phi}_{ja} - \bar{\phi}_{jb}) = 0$. The method can be extended to estimate heterogeneous effects $\alpha_{\text{ATET}}(\mathbf{x})$ by

grouping on $\mathbf{x}$ and then calculating within each group the four relevant averages of y.

Sample selection models explicitly specify a distribution for the unobservables. These introduce a latent variable to explain treatment choice, where the latent variable includes an unobserved component (or error) that is correlated with the error in the outcome equation. A linear model that permits heterogeneous effects and selection on unobservables is:

$$\begin{aligned} y_{1i} &= \mathbf{x}_i'\boldsymbol{\beta}_1 + u_{1i} \\ y_{0i} &= \mathbf{x}_i'\boldsymbol{\beta}_0 + u_{0i} \\ d_i^* &= \mathbf{z}_i'\boldsymbol{\gamma} + v_i, \end{aligned} \tag{14.40}$$

where $d_i = 1$ if the latent variable $d_i^* > 0$, and $d_i = 0$ otherwise. A homogeneous effects version restricts $y_{1i} = y_{0i}$ aside from a difference of α in the intercept. Under the assumption that (u_{0i}, u_{1i}, v_i) are joint normal (with $\sigma_v^2 = 1$), some algebra yields:

$$\begin{aligned} \mathrm{E}[y_{1i}|\mathbf{x}, d^* > 0] &= \mathbf{x}_i'\boldsymbol{\beta}_1 + \sigma_{1v}\lambda(\mathbf{z}_i'\boldsymbol{\gamma}), \\ \mathrm{E}[y_{0i}|\mathbf{x}, d^* \leq 0] &= \mathbf{x}_i'\boldsymbol{\beta}_0 - \sigma_{0v}\lambda(-\mathbf{z}_i'\boldsymbol{\gamma}), \end{aligned} \tag{14.41}$$

where $\lambda(\mathbf{z}'\boldsymbol{\gamma}) = \phi(\mathbf{z}'\boldsymbol{\gamma})/\Phi(\mathbf{z}'\boldsymbol{\gamma})$ is an inverse Mills ratio term, with $\phi()$ and $\Phi()$ denoting the standard normal density and distribution functions, and $\sigma_{jv} = \mathrm{Cov}[u_{ji}, v_i]$. From (14.41) consistent estimates of $\boldsymbol{\beta}_1$ and σ_{1v} can be obtained by OLS estimation for the treated sample of y_1 on $\mathbf{x}$ and $\lambda(\mathbf{z}'\widehat{\boldsymbol{\gamma}})$, where $\widehat{\boldsymbol{\gamma}}$ is obtained by probit regression of d on $\mathbf{z}$. Similarly, OLS regression for the untreated sample of y_0 on $\mathbf{x}$ and $-\lambda(-\mathbf{z}'\widehat{\boldsymbol{\gamma}})$ gives consistent estimates of $\boldsymbol{\beta}_0$ and σ_{0v}. These estimates can then be used to estimate:

$$\alpha_{\mathrm{ATET}}(\mathbf{x}, \mathbf{z}) = \mathbf{x}_i'(\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0) + (\sigma_{0v} - \sigma_{1v})\lambda(\mathbf{z}_i'\boldsymbol{\gamma}).$$

The fundamental weakness of this sample selection approach is its reliance on distributional assumptions. These assumptions can be modified and relaxed, but even then the assumptions are still felt to be too strong.

Yet another method for control for selection on unobservables is instrumental variables estimation. Returning to the homogeneous effects model (14.37), the problem is that the regressor d is correlated with the error u. Assuming there is an instrument z that does not belong in the model, so $\mathrm{E}[u|\mathbf{x}, z] = 0$, but is correlated with the treatment indicator d, the treatment effect α can be consistently estimated by IV regression of y on $\mathbf{x}$ and d with instruments $\mathbf{x}$ and z.

A related method is the local average treatment effect (LATE) estimator. Begin with the homogeneous effects model with dependence on $\mathbf{x}$ dropped for simplicity, so that:

$$y_i = \beta + \alpha d_i + u_i. \tag{14.42}$$

Assume there is an instrument z with $\mathrm{E}[u|z] = 0$ and define $p(z) = \Pr[d = 1|Z = z] = \mathrm{E}[d|Z = z]$. Then:

$$\mathrm{E}[y|z] = \beta + \alpha p(z).$$

Evaluating at two points z and z' and subtracting yields the LATE:

$$\alpha_{\text{LATE}}(z) = \frac{\text{E}[y|z] - \text{E}[y|z']}{p(z) - p(z')}. \tag{14.43}$$

This can be estimated by comparing averages of the outcome y and treatment indicator d at two different values of the instrument z. If z is binary then this estimate is the same as the IV estimate. The estimate can be extended to heterogeneous effects, provided $p(z)$ is monotonic in z. Then it differs from IV and will vary with the points of evaluation z and z'. A more general treatment effect is the marginal treatment effect (MTE):

$$\alpha_{\text{MTE}}(\mathbf{x}, z) = \left. \frac{\partial \text{E}[y|\mathbf{x}, Z]}{\partial \Pr[d = 1|\mathbf{x}, Z]} \right|_{Z=z},$$

which gives the mean treatment effect for those at the margin of choosing treatment. ATE, ATET and LATE can be shown to be different weighted averages of MTE.

A final method is regression discontinuity (RD) design. Suppose treatment occurs when a variable s crosses a threshold $\bar{s}$, so that $d = 1(s > \bar{s})$, and the outcome y also depends on s. For example, a government program to improve school outcomes may be applied to schools in low-income areas. A method is developed to calculate a score, and schools with a score below a certain threshold receive the government program while those with a higher score do not. A complication is that school outcome will directly depend on this score. The obvious approach is to compare y for those with s just less than $\bar{s}$ to those with s just greater than $\bar{s}$, but this will use only a small fraction of the data. Instead use $\widehat{\alpha}$ from the least squares regression:

$$y_i = \beta + \alpha d_i + \gamma h(s_i) + u_i, \tag{14.44}$$

where $h(\cdot)$ is a flexible function that is specified (for example, polynomial) or is estimated by nonparametric methods. Given the discrete nature of the discontinuity at $\bar{s}$ it is clear that the method can also be used when effects are heterogeneous and will estimate ATE $= \text{E}[\alpha_i|s_i]$ under mild additional assumptions. Another extension is to fuzzy designs where the threshold $\bar{s}$ is not sharp, as some individuals with $s < \bar{s}$ are treated and some with $s > \bar{s}$ are untreated. Intuitively, if a fraction f of the population in the immediate vicinity of $\bar{s}$ switch from untreated to treated then ATE is estimated by f times the estimated OLS coefficient of d in (14.44). This adaptation is qualitatively similar to that for LATE in (14.43).

The literature on treatment effects is vast. Econometricians have contributed to the literature on all the preceding methods, and the sample selection, IV and LATE methods originated in econometrics. Early econometrics papers, that generally did not explicitly use the current treatment effects framework, include Ashenfelter (1978), Heckman (1978, 1979), Heckman and Robb (1985), Lalonde (1986) and Björklund and Moffitt (1982). Heckman, Ichimura and Todd (1997) and Dehejia and Wahba (1999) emphasize matching methods. Abadie and Imbens (2006) provide results for inference. Bertrand, Duflo and Mullainathan (2004) demonstrate

that when difference-in-difference methods are used with panel data it is critical that one uses cluster-robust standard errors that cluster on the treatment unit, often the state, as the treatment regressor is highly correlated over time. Hausman and Kuersteiner (2008) consider more efficient GLS estimation in this setting. Imbens and Angrist (1994) introduce LATE and Björklund and Moffitt (1982) and Heckman and Vytlacil (2005) introduce MTE. Hahn, Todd and Van der Klaauw (2001) provide theory for RD methods; Ludwig and Miller (2007) provide a detailed application, and Imbens and Lemieux (2008) provide a survey. More recent research provides distribution theory when a nonparametric component is used and seeks to extend methods to nonlinear models (for example, Athey and Imbens, 2006), and to multiple treatments. Brief surveys include Smith (2000), Blundell and Dias (2002) and Angrist (2008), while lengthier surveys include Heckman, Lalonde and Smith (1999) and Angrist and Krueger (1999). The forthcoming book by Angrist and Pischke (2009) focuses on treatment effects methods.

14.5.2 Instrumental variables methods

Consider the linear model:

$$y_i = \mathbf{x}_i'\boldsymbol{\beta} + u_i, \tag{14.45}$$

where $\text{Cor}[\mathbf{x}_i, u_i] \neq \mathbf{0}$ so that OLS is inconsistent. Assume there exists an instrument $\mathbf{z}_i$ such that $\text{Cor}[\mathbf{z}_i, u_i] = \mathbf{0}$. The IV estimator for a just-identified model, considered for simplicity, is:

$$\widehat{\boldsymbol{\beta}}_{\text{IV}} = (\mathbf{Z}'\mathbf{X})^{-1}\mathbf{Z}'\mathbf{y}. \tag{14.46}$$

If $\text{Cor}[\mathbf{z}_i, u_i] = \mathbf{0}$ then $\widehat{\boldsymbol{\beta}}_{\text{IV}}$ is asymptotically normal with mean $\boldsymbol{\beta}$ and:

$$\text{V}[\widehat{\boldsymbol{\beta}}_{\text{IV}}] = (\mathbf{Z}'\mathbf{X})^{-1}\mathbf{Z}'\Sigma\mathbf{Z}(\mathbf{X}'\mathbf{Z})^{-1}, \tag{14.47}$$

where $\Sigma = \text{E}[\mathbf{u}\mathbf{u}'|\mathbf{Z}]$. This estimator is easily extended to overidentified models, and to nonlinear models as a special case of GMM.

The applied literature has included many creative examples of instrument use. For example, in earnings–schooling regression a proposed instrument for schooling is distance to college, as this may be related to college attendance but may not directly effect earnings. Another possible instrument is birth month, which may be related to years of schooling as it determines age of school entry and hence years of schooling before a person reaches the minimum school leaving age.

This interest in the use of IV methods has been somewhat diminished by recognition of the problems that arise when instruments are weakly correlated with the regressor(s) being instrumented.

A weak instrument is one for which $\text{Cor}[\mathbf{z}_i, \mathbf{x}_i]$ is small. More precisely, suppose there is one endogenous regressor and several exogenous regressors. Then the instrument for the endogenous regressor is weak if the correlation between the endogenous regressor and the instrument is low after partialing out the effect of the other exogenous regressors. Then it is well known that $\widehat{\boldsymbol{\beta}}_{\text{IV}}$ will be imprecisely estimated. Two other complications can arise.

First, suppose that $\text{Cor}[\mathbf{z}_i, u_i]$ is close to zero rather than exactly zero. Then not only is the IV estimator inconsistent, but it can be more inconsistent than the

OLS estimator. For example, in the simple case of a scalar regressor x and scalar instrument z, suppose the correlation between x and z is 0.1. Then IV becomes more inconsistent than OLS if the correlation between z and u exceeds a mere 0.1 times the correlation between x and u. This result, emphasized by Bound, Jaeger and Baker (1995), has led to increased scrutiny of assumptions regarding the validity of an instrument in any particular application.

Second, even if Cor$[\mathbf{z}_i, u_i]$ equals zero, regular asymptotic theory performs poorly in finite samples if the instrument is weak. Theoreticians established key results early. Applied researchers to subsequently highlight the problem were Nelson and Startz (1990) and Bound, Jaeger and Baker (1995). Staiger and Stock (1997) provided influential theory.

Third, regular asymptotic theory performs poorly in finite samples when there are many instruments, so that the model is greatly overidentified. This situation can arise for estimators based on conditioning on a large information set, in panel settings where regressors from other periods are valid instruments in the current period, or if an underlying instrument is interacted with exogenous regressors to generate many instruments.

There is a large theoretical literature on inference with weak instruments, including new estimators and new testing procedures (see Andrews, Moreira and Stock, 2007). Andrews and Stock (2007) provide a recent survey, and Flores-Luganes (2007) compares many of the different methods by Monte Carlo simulation and use of actual data.

14.5.3 Panel data

Panel data are repeated observations on the same cross-section units, typically individuals or firms, for several time periods. The cross-section units are usually assumed to be independent, though this assumption may be less appropriate if the cross-section units are states or countries.

An obvious advantage of panel data is that they permit increased precision in estimation, due to an increased number of observations. It is important, however, that one control for likely correlation of observations over time for a given cross-section unit. The usual method is to use cluster-robust standard errors described in section 14.4.1.

The microeconometrics literature has focused on a second advantage of panel data, that it provides a way to identify causation even if there is selection on unobservables, provided the unobservables are time invariant.

The fixed effects linear panel model specifies:

$$y_{it} = \mathbf{x}_{it}'\boldsymbol{\beta} + \alpha_i + \varepsilon_{it},\ i = 1, \ldots, N,\ t = 1, \ldots, T, \tag{14.48}$$

where α_i and ε_{it} are unobserved. It is assumed that the idiosyncratic error ε_{it} is uncorrelated with $\mathbf{x}_{it}$, but the individual-specific error α_i is potentially correlated with $\mathbf{x}_{it}$. Note that, while α_i is called a "fixed effect" in the literature, this term is misleading as it is being treated as random. Microeconometricians focus on short panels, with $N \to \infty$ but T permitted to be small (for a static linear model it is sufficient that $T \geq 2$).

To relate this to the treatment effects literature, $\mathbf{x}_{it}$ may include a binary treatment d_{it} that is correlated with the error term $\alpha_i + \varepsilon_{it}$ (selection on unobservables), but only with the component α_i of the error term that is time invariant. For example, an individual may self-select into a training program due to unobserved high ability, but this high ability is assumed to be time invariant.

Pooled OLS regression of y_{it} on $\mathbf{x}_{it}$ will lead to inconsistent estimation of $\boldsymbol{\beta}$, due to correlation of regressors with the error. The random effects estimator of $\boldsymbol{\beta}$, the feasible GLS estimator of (14.48) under the assumption that both α_i and ε_{it} are i.i.d., is also inconsistent if, in fact, α_i is correlated with $\mathbf{x}_{it}$. For this reason many microeconometric studies shy away from random effects models that are widely used in other fields.

Estimation of transformed models that eliminate α_i can lead to consistent estimation. The fixed-effects or within estimator is obtained by OLS estimation of the within-model:

$$(y_{it} - \bar{y}_i) = (\mathbf{x}_{it} - \bar{\boldsymbol{x}}_i)'\boldsymbol{\beta} + (u_{it} - \bar{u}_i). \tag{14.49}$$

A standard procedure is to use cluster-robust standard errors from this regression, assuming T is small and $N \to \infty$. Hansen (2007a) presents asymptotic theory that additionally allows $T \to \infty$ and Hansen (2007b) considers more efficient GLS estimation. The first differences estimator is obtained by OLS estimation of the first differences model:

$$\Delta y_{it} = \Delta \mathbf{x}_{it}'\boldsymbol{\beta} + \Delta u_{it}. \tag{14.50}$$

Note that in both cases only the coefficients of time-varying regressors can be identified.

Extension to nonlinear models is possible only for some specific models, as there is an incidental parameters problem. The asymptotics rely on $N \to \infty$, so the number of parameters (k regression coefficients plus N fixed effects α_i) is going to infinity with the sample size. Some models permit transformations that eliminate α_i, while others do not. For nonlinear models with additive error the within and first differences transformations can again be used. For binary outcomes fixed effects estimation is possible for the logit model (see Chamberlain, 1980), but not the probit model. For count data, Hausman, Hall and Griliches (1984) presented fixed effects estimation for the Poisson model and a particular parameterization of the negative binomial model. The Poisson fixed effects estimator does not require that the data be Poisson distributed, as it is consistent provided the conditional mean is correctly specified. An active area of research is developing methods for general nonlinear fixed effects panel models that, while inconsistent due to the incidental parameters problem, are less inconsistent than existing methods (see, for example, Arellano and Hahn, 2007).

Panel data also provide the opportunity to model individual-level dynamic behavior, since the individual is observed at more than one point in time. A simple dynamic linear fixed effects model includes a lagged dependent variable, so that:

$$y_{it} = \rho y_{i,t-1} + \mathbf{x}_{it}'\boldsymbol{\beta} + \alpha_i + \varepsilon_{it},\ i = 1, \ldots, N,\ t = 1, \ldots, T. \tag{14.51}$$

An important result is that the fixed effects and first differences estimators of this model are inconsistent. Instrumental variables estimation of the first differences estimator is possible, using $y_{i,t-2}$ as an instrument for $(y_{i,t} - y_{i,t-1})$. Holtz-Eakin, Newey and Rosen (1988) and Arellano and Bond (1991) proposed using additional lags as instruments and estimating by GMM using an unbalanced set of instruments.

For nonlinear dynamic models fixed effects estimation is possible for the logit model (see Chamberlain, 1985; Honore and Kyriazidou, 2000), for the Poisson model (see Blundell, Griffiths and Windmeijer, 2002), and for some duration models (see Chamberlain, 1985; Van den Berg, 2001).

14.5.4 Structural models

The classic linear simultaneous equations model (SEM) has deliberately not been discussed in this section on causation, as the SEM is rarely used in microeconometric studies. Many causal studies are interested in the marginal effect of a single regressor on a single dependent variable. In that case 2SLS regression of the single equation of interest is simply instrumental variables estimation, already discussed, which itself has deficiencies, leading to increased use of the other methods given in this section. Finally, the linear SEM does not extend readily to nonlinear models and, in cases where it does, such as simultaneous equation tobit models, the distributional assumptions are very strong.

Another type of structural modeling is microeconometric models based on economic models of utility or profit maximization. Early references include Heckman (1974), MaCurdy (1981) and Dubin and McFadden (1984). The more recent labor literature most commonly uses structural economic models to explain employment dynamics (see, for example, Keane and Wolpin, 1997). Structural modeling is more often used in industrial organization (Reiss and Wolak, 2007, provide a survey).

14.6 Heterogeneity

A loose definition of heterogeneity is that data differs across observations. In a regression context this heterogeneity may be due to regressors (observables) or due to unobservables.

To begin with, consider heterogeneity due directly to observed regressors. For the linear regression model $y_i = \mathbf{x}_i'\boldsymbol{\beta} + u_i$ with $\mathrm{E}[u_i|\mathbf{x}_i] = 0$, $\mathrm{E}[y_i|\mathbf{x}_i] = \mathbf{x}_i'\boldsymbol{\beta}$ so that heterogeneity induces heterogeneity in the conditional means, though not in the marginal effects $\partial \mathrm{E}[y_i|\mathbf{x}_i]/\partial \mathbf{x}_i = \boldsymbol{\beta}$. Nonlinearity in the conditional mean, e.g. $\mathrm{E}[y_i|\mathbf{x}_i] = \exp(\mathbf{x}_i'\boldsymbol{\beta})$, will induce marginal effects that differ across individuals. Even simple parametric nonlinear models such as probit and tobit have this feature. The standard method is to present a single summary statistic. Often the marginal effect is evaluated at $\mathbf{x} = \bar{\mathbf{x}}$, but for most purposes a better single measure is the sample average of the individual marginal effects. Single index models, that is, $\mathrm{E}[y_i|\mathbf{x}_i] = g(\mathbf{x}_i'\boldsymbol{\beta})$, have the advantage that the ratio of marginal effects for two different regressors equals the ratio of the corresponding parameters, and does not depend on the regressor values. Thus if one coefficient is twice another then the corresponding

marginal effect is twice as large. Quite flexible modeling of heterogeneity in $\mathrm{E}[y_i|\mathbf{x}_i]$ and the associated marginal effects is possible using nonparametric regression of y on $\mathbf{x}$. This yields very noisy estimates for high dimension $\mathbf{x}$, leading to the use instead of semiparametric methods such as those given in section 14.3.6.

More challenging is controlling for unobserved heterogeneity that is due to factors other than the regressors. Different individuals then have different responses even if the individuals have the same value of $\mathbf{x}$. Failure to control for this unobserved heterogeneity can lead to inconsistent parameter estimates and associated marginal effects. A simple example is omitted variables bias in the linear regression model, where the omitted variables form part of the unobserved heterogeneity. The source of the unobserved heterogeneity can also matter. In particular, in structural models of economic behavior a distinction is made as to whether or not the unobserved (to the econometrician) heterogeneity is known to the decision maker.

Meaningful discussion of unobserved heterogeneity requires the statement of an underlying structural relationship to be estimated in the presence of unobserved heterogeneity. Wooldridge (2005, 2008) provides a fairly general framework. Suppose that interest lies in a conditional mean $m(\mathbf{x}, u) = \mathrm{E}[y|\mathbf{x}, u]$, or more formally:

$$m(\mathbf{x}, u) = \mathrm{E}[Y|\mathbf{X} = \mathbf{x}, U = u],$$

where u is unobserved and for simplicity is a scalar. Ideally $m(\mathbf{x}, u)$ would be estimated but, instead, analysis is restricted to what Blundell and Powell (2004) call the average structural function (ASF):

$$m(\mathbf{x}) = \mathrm{E}_U[m(x, U)],$$

which integrates out the unobserved heterogeneity. Often, interest lies in how ASF changes as the jth regressor, say, changes. This is the average partial effect (APE):

$$\frac{\partial m(\mathbf{x})}{\partial x_j} = \mathrm{E}_U\left[\frac{\partial m(x, U)}{\partial x_j}\right].$$

Unobserved heterogeneity poses a problem because the ASF $m(\mathbf{x})$ in general differs from the conditional mean $\mathrm{E}[y|\mathbf{x}] = \mathrm{E}_{U|\mathbf{x}}[m(x, U)]$, and hence APE differs from $\partial \mathrm{E}[y|\mathbf{x}]/\partial x_j$, but it is only $\mathrm{E}[y|\mathbf{x}]$ that is identified from the observed data.

The simplest assumption, and one commonly made, is that u is independent of $\mathbf{x}$, as then $\mathrm{E}[y|\mathbf{x}] = m(\mathbf{x})$. In a model with additive heterogeneity, analysis is particularly straightforward. If $m(\mathbf{x}, u) = g(\mathbf{x}, \boldsymbol{\beta}) + u$ then $\mathrm{E}[y|\mathbf{x}] = g(\mathbf{x},\boldsymbol{\beta})$ given u independent of $\mathbf{x}$ with mean zero. Analysis is more complicated if unobserved heterogeneity enters in a nonlinear manner. For example, if $m(\mathbf{x}, u) = g(\mathbf{x}'\boldsymbol{\beta} + u)$ then $\mathrm{E}[y|\mathbf{x}] = \mathrm{E}_u[g(\mathbf{x}'\boldsymbol{\beta} + u)]$ will typically require specification of the distribution of u and integration over this. In some cases analytical expressions can be obtained. In other cases numerical methods are used. If u is low dimensional (in many applications it is a scalar) then Gaussian quadrature methods work well. Otherwise the simulation methods given in sections 14.3.3 and 14.3.4 can be used. Examples include negative binomial models for counts obtained by a Poisson–gamma mixture, Weibull–gamma mixtures for durations, random utility models for binary and

multinomial data (where u is now a vector) and normal mixtures for linear and nonlinear panel data. While often the unobserved heterogeneity is interpreted as a random intercept, this can be generalized to random slopes (a random coefficients model). An alternative is finite mixtures models, used particularly in duration and count data analysis.

Panel data offer the opportunity to permit u to be dependent on $\mathbf{x}$. In that case u_{it} is decomposed into a time-varying component that is independent of $\mathbf{x}_{it}$ and a time-invariant component that may be correlated with $\mathbf{x}_{it}$. Fixed effects estimators for these models have been discussed in section 14.5.3. It is important to note that in nonlinear models these methods identify $\boldsymbol{\beta}$ but not ASF, so that the APEs are only estimated up to scale.

Panel data also offer the possibility of distinguishing between persistence in behavior over time due to unobserved heterogeneity and persistence in behavior over time due to true state dependence. For example, rather than the static linear model $y_{it} = \mathbf{x}_{it}'\boldsymbol{\beta} + u_i + \varepsilon_{it}$, where correlation of u_i with $\mathbf{x}_{it}$ causes problems, a more appropriate model may be a dynamic model $y_{it} = \rho y_{i,t-1} + \mathbf{x}_{it}'\boldsymbol{\beta} + \varepsilon_{it}$, where there is now no complication of unobserved heterogeneity. These models have quite different structural interpretations with quite different policy consequences. For example, high persistence of unemployment given regressors may be due to stigma attached to being unemployed (state dependence) or may be due to unobserved low ability (unobserved heterogeneity).

The treatment effects literature allows for unobserved heterogeneity. By assuming that selection is on observables it is possible to estimate ATET($\mathbf{x}$), which is the APE for the treatment variable.

Wooldridge (2005, 2008) proposes the use of proxy variables to identify the ASF and APE. For simplicity, consider the linear model $y = \mathbf{x}'\boldsymbol{\beta} + u$. If $\mathrm{E}[u|\mathbf{x}] = 0$, then $m(\mathbf{x}) = \mathrm{E}[y|\mathbf{x}] = \mathbf{x}'\boldsymbol{\beta}$ so unobserved heterogeneity causes no problem. Now consider an omitted variables situation where $u = \mathbf{z}'\boldsymbol{\gamma} + \varepsilon$ with $\mathrm{E}[\varepsilon|\mathbf{x}] = 0$ but $\mathrm{E}[\mathbf{z}|\mathbf{x}] \neq \mathbf{0}$. The ASF is $m(\mathbf{x}) = \mathbf{x}'\boldsymbol{\beta} + \mathrm{E}[\mathbf{z}]'\boldsymbol{\gamma}$, whereas the conditional mean $\mathrm{E}[y|\mathbf{x}] = \boldsymbol{\beta} + \mathrm{E}[\mathbf{z}|\mathbf{x}]'\boldsymbol{\gamma}$. These terms differ unless $\mathrm{E}[\mathbf{z}|\mathbf{x}] = \mathrm{E}[\mathbf{z}]$, the case where the unobserved heterogeneity is independent of $\mathbf{x}$. A weaker assumption than independence is to assume that there is a proxy variable $\mathbf{w}$ for $\mathbf{z}$ with the properties that (i) $\mathbf{x}$ and $\mathbf{z}$ are independent conditional on $\mathbf{w}$ so $\mathrm{E}[\mathbf{z}|\mathbf{x}, \mathbf{w}] = \mathrm{E}[\mathbf{z}|\mathbf{x}]$, and (ii) $\mathrm{E}[y|\mathbf{x}, \mathbf{w}, \mathbf{z}, \varepsilon] = \mathrm{E}[y|\mathbf{x}, \mathbf{w}, \varepsilon]$, so that $\mathbf{z}$ is redundant in the original model. Then $\mathrm{E}[y|\mathbf{x}, \mathbf{w}] = \mathbf{x}'\boldsymbol{\beta} + \mathrm{E}[\mathbf{z}|\mathbf{w}]'\boldsymbol{\gamma}$, which can be identified by regression of y on $\mathbf{x}$ and $\mathbf{z}$. Taking the expected value with respect to $\mathbf{w}$ then gives the desired ASF. Wooldridge (2005) generalizes this approach to nonlinear models and argues that, even though failure to control for unobserved heterogeneity may lead to inconsistent parameter estimates, it is still possible in some cases to consistently estimate the ASF and APE.

There is also a growing literature on heterogeneity in nonparametric models: see, for example, Matzkin (2008). A simple approach is to start with the conditional cumulative distribution function (c.d.f.) $F(y|\mathbf{x})$, which can be nonparametrically estimated. Define $u = F(y|\mathbf{x})$, then u is uniformly distributed on $(0, 1)$ and hence uncorrelated with $\mathbf{x}$. Inverting yields $y = F^{-1}(u|\mathbf{x}) = G(\mathbf{x}, u)$. This provides a decomposition into observables $\mathbf{x}$ and unobservables u that is independent of $\mathbf{x}$,

a separable model. But this is not a structural model in the sense of the ASF given earlier.

Controlling for unobserved heterogeneity is an active area in microeconometrics, as much of the variation in the outcome is due to unobserved factors since, typically, $R^2 < 0.5$. It is particularly important when there is sample selection or self-selection. For example, in OLS regression we essentially require only that $\mathrm{E}[u|\mathbf{x}] = 0$, whereas if the sample is truncated or censored, much stronger assumptions on u are needed even if semiparametric methods are used. Heckman (2000, 2005) and related papers explicitly consider heterogeneity and structural estimation (see also Blundell and Powell, 2004; Wooldridge, 2005).

14.7 Data issues

Microeconometric data are often survey data that come from sampling schemes more complicated than simple random sampling, and key variables can be mismeasured or even missing due to nonresponse. These issues are generally ignored in applied work. Ignoring the sampling scheme is reasonable in the many cases where the sampling scheme or nonresponse mechanism leads to a sample that is nonrepresentative only of the regressors, while maintaining representativeness of the dependent variable conditional on regressors. It is also reasonable to ignore measurement error if it is classical measurement error in the dependent variable in a linear model. In other cases standard estimators are often inconsistent and alternative estimators are needed.

14.7.1 Sampling schemes

Survey data often use stratified and clustered sampling to lower interview costs and to provide more precise estimates for population sub-groups, such as regions with relatively few people, than would otherwise be the case. The extensive sample survey literature, initially focused on estimation of population means but then extended to the regression case, has generally been ignored by the econometrics literature.

The first issue raised by survey sampling schemes is that the sample is no longer representative of the population. For inference on a single variable it is necessary to adjust for this. For example, average earnings in a nonrepresentative sample will be an inconsistent estimate of population mean earnings. For regression analysis, adjustment is necessary if the sample is nonrepresentative for the dependent variable after conditioning on regressors (endogenous stratification), but may not be necessary if the sample is nonrepresentative only for the regressors (exogenous stratification).

For endogenous stratification, where stratification is on the dependent variable in a regression, standard estimation methods lead to inconsistent parameter estimates.

Consider stratification in a likelihood framework. Let the conditional distribution of y given $\mathbf{x}$ be denoted $f(y|\mathbf{x}, \theta)$. Usually the joint density of y and $\mathbf{x}$ is $g(y, \mathbf{x}|\boldsymbol{\theta}) = f(y|\mathbf{x}, \boldsymbol{\theta}) \times g(\mathbf{x})$, where the parameters in $g(\mathbf{x})$ are suppressed. Under

exogenous sampling $g(\mathbf{x})$ does not involve $\boldsymbol{\theta}$, so that inference on $\boldsymbol{\theta}$ can be based on the conditional log-likelihood based only on $f(y|\mathbf{x}, \boldsymbol{\theta})$.

Under endogenous stratification, however, it can be shown that $g(y, \mathbf{x}|\boldsymbol{\theta})$ takes a more complicated form, and ML estimation needs to be based on the joint log-likelihood based on $g(y, \mathbf{x}|\boldsymbol{\theta})$. Standard estimators that instead continue to use $f(y|\mathbf{x}, \boldsymbol{\theta})$ are inconsistent. Examples include truncated regression (for example, hours of work are modeled and only workers are surveyed), choice-based sampling (for example, commute mode choice is modeled and bus-riders are deliberately oversampled as there are relatively few bus-riders), on site sampling and case-control studies. Much of the econometrics literature has focused on choice-based sampling in discrete choice models, with estimation by weighted MLE (see Manski and Lerman, 1977), or more efficient GMM methods, (see Imbens, 1992). A more general presentation for endogenous stratification is given by Imbens and Lancaster (1996). Wooldridge (2001) considers inverse-probability weighted estimators for m-estimators.

Stratified surveys usually provide sample weights that can be used to obtain population representative statistics. Under exogenous stratification, these sample weights need not be used in the typical situation where correct specification of a regression model is assumed. For example, assume that the regression function is linear in $\mathbf{x}$, so that $y = \mathbf{x}'\boldsymbol{\beta} + u$, $\mathrm{E}[u|\mathbf{x}] = 0$ and $\mathrm{E}[y|\mathbf{x}] = \mathbf{x}'\boldsymbol{\beta}$. Then OLS is consistent even if the regressors $\mathbf{x}$ are not representative of the population in $\mathbf{x}$. The reason for using these weights in estimation is if we wish to relax the assumption that $\mathrm{E}[y|\mathbf{x}] = \mathbf{x}'\boldsymbol{\beta}$, due to nonlinearity or because $\boldsymbol{\beta}$ varies across strata. Then weighted OLS should be used as it provides an estimate of the so-called census coefficient $\boldsymbol{\beta}^*$ that has probability limit equal to the regression coefficient that would be obtained by regression of y on $\mathbf{x}$ using the entire population (see DuMouchel and Duncan, 1983). For example, a weighted OLS regression of earnings on years of schooling provides a consistent estimate of the population marginal effect on earnings of one more year of schooling, without assuming that the model is linear. Note that even if unweighted estimation is appropriate, weights may still be used in making predictions from the model. For example, if $\mathrm{E}[y|\mathbf{x}]$ is nonlinear in $\mathbf{x}$ then marginal effects vary with evaluation point $\mathbf{x}$, so that weights should be used to compute an estimate of the population marginal effect.

A big reason for stratification is to improve efficiency of estimates of the population mean of a single variable, such as earnings or unemployment, when the mean of that variable differs across strata. This efficiency gain can carry over to regression, and some regression packages include commands to do so. These are widely used in biostatistics but not in econometrics, in part because the efficiency gains are felt to be small and in part because not all datasets provide the necessary information on the strata. Bhattacharya (2005) presents results for m-estimation and a good discussion of the issues.

In addition to stratification, survey methods often induce dependence for sub-groups of observations. For example, several households on the same block may be interviewed. Then data in that sub-group are likely to be positively correlated and, even after controlling for regressors, model errors are likely to be

positively correlated. The standard procedure in econometrics is to use estimators that ignore the clustering and base inference on cluster-robust standard errors, presented in section 14.4.1. More efficient estimation is possible using feasible GLS estimators that model the error correlation. In particular, hierarchical linear models or multilevel models are often used in other social science disciplines but are seldom used in econometrics. If clustering is felt to induce correlation of errors with regressors, then cluster-specific fixed effects, analogous to an individual-specific fixed effect in a panel data model, may also be used.

14.7.2 Missing data

The starting point for analysis of missing data is the terminology and assumptions made about the nature of the process leading to missing data on w_i, say, due to Rubin (1976). These have many similarities with the potential outcomes model, where the unknown counterfactual can also be viewed as a missing data problem. If the probability of w_i being missing depends on neither its own value or on other data in the data set then w_i is missing completely at random (MCAR), and missing data on w_i causes no problems aside from efficiency loss. If the probability of w_i being missing depends on other data in the data set, but not its own value, then w_i is missing at random (MAR), and missing data may lead to estimator inconsistency. If w_i is MAR, then it is possible to adjust for missingness if the missing data mechanism is ignorable, meaning that the parameters of the missing data mechanism are unrelated to the parameters that we estimate, similar to weak exogeneity.

Simple corrections for missing data include dropping an observation if any variable is missing (listwise deletion or case deletion) and simple imputation methods such as using the sample average or predictions from a fitted regression model. These corrections are valid if data are MCAR or the missing data are regressors only that are MAR with probability that is independent of the dependent variable.

The modern approach is to use multiple imputation methods that regard missing data as random variables and replaces with draws from an assumed underlying distribution. Let $\mathbf{W} = (\mathbf{W}_{obs}, \mathbf{W}_{miss})$ denote the data partitioned into observed and missing observations, and suppose $\mathbf{W}$ has density $f(\mathbf{W}|\boldsymbol{\theta})$. The multiple imputation method imputes $\mathbf{W}_{miss}$ under the assumption of MAR with ignorable missingness. There are several ways to make imputations. A preferred, though computationally expensive, method is to use data augmentation and MCMC methods. Given an sth round estimate of $\boldsymbol{\theta}^{(r)}$, we impute $\mathbf{W}_{miss}^{(r+1)}$ by making a draw from $f(\mathbf{W}_{miss}|\mathbf{W}_{obs}, \boldsymbol{\theta}^{(r)})$. Then a new estimate $\boldsymbol{\theta}^{(r+1)}$ is obtained by drawing from $f(\boldsymbol{\theta}|\mathbf{W}_{obs}, \mathbf{W}_{miss}^{(r+1)})$. The chain is continued to convergence, giving an imputed value for $\mathbf{W}_{miss}$. Suppose we obtain imputed value $\mathbf{W}_{miss}^{(I)}$ and then obtain the MLE based on $f(\mathbf{W}_{obs}, \mathbf{W}_{miss}^{(I)}|\boldsymbol{\theta})$. This will overstate estimator precision as it fails to account for the uncertainty created by imputation of $\mathbf{W}_{miss}^{(I)}$. Multiple imputation overcomes this by obtaining m different imputed values for $\mathbf{W}_{miss}$ and hence m estimates $\widehat{\boldsymbol{\theta}}_r$, $r = 1, \ldots, m$, with associated variance matrices $\widehat{\mathbf{V}}_r = \widehat{\mathbf{V}}[\widehat{\boldsymbol{\theta}}_r]$. For further details see Little and Rubin (1987), Rubin (1987) and Schafer (1997).

Microeconometrics applications rarely use multiple imputation methods, in part due to concern that missingness may be for nonignorable reasons, such as endogenous stratification discussed in section 14.7.1. Wooldridge (2007) considers use of inverse-probability weighting estimators when data are missing and provides a link with the framework of Rubin (1976).

14.7.3 Measurement error

Standard results for measurement error consider the linear regression model with classical measurement error in regressors. OLS coefficients are then inconsistent and understate the magnitude of the true coefficient. More recent work has considered nonlinear regression models and, in some cases, nonclassical measurement error.

Suppose $y = \beta x^* + u$, with error u uncorrelated with x^*, but we observe x rather than x^* and regress y on x. Then, from Angrist and Krueger (1999), the OLS estimator $\widehat{\beta} = [\sum_i x_i^2]^{-1} \sum_i x_i y_i = [\sum_i x_i^2]^{-1} \sum_i x_i(\beta x_i^* + u_i)$ is in general inconsistent as:

$$\text{plim}\widehat{\beta} = [\text{V}[x]]^{-1}\text{Cov}[x, x^*]\beta = \lambda\beta, \tag{14.52}$$

where $\lambda = \text{Cov}[x, x^*]/\text{V}[x]$ is the reliability ratio of x as a measure of x^*, and we have assumed that $\text{plim}N^{-1} \sum_i x_i u_i = 0$. This assumption that x is uncorrelated with u requires the additional assumption that u is uncorrelated with the measurement error $v = x - x^*$, in addition to the usual assumption that the model error u is uncorrelated with x^*.

The size of the inconsistency depends on the size of the reliability ratio, which has been measured in various survey validation studies. Angrist and Kruger (1999, p. 1346) present a summary table with reliability ratios for log annual earnings, annual hours and years of schooling ranging from 0.71 to 0.94. Bound, Brown and Mathiowetz (2001, pp. 3749–830) summarize many validation studies for labor-related data that also indicate that measurement error is large enough to lead to appreciable bias in OLS coefficients.

Result (14.52) makes few assumptions beyond independence of measurement error and model error. Textbook treatments of measurement error emphasize the classical measurement error model, a more restrictive model that assumes:

$$y = \beta x^* + u,\ u \sim iid\left[0, \sigma_u^2\right]$$

$$x = x^* + v,\ v \sim iid\left[0, \sigma_v^2\right] \quad \text{and} \quad x^* \sim iid\left[0, \sigma_{x^*}^2\right]. \tag{14.53}$$

Then $\text{plim}\widehat{\beta} = \lambda\beta$, where $\lambda = \sigma_{x^*}^2/(\sigma_{x^*}^2 + \sigma_v^2) = 1/(1 + s)$ and where $s = \sigma_v^2/\sigma_{x^*}^2$ is the noise-to-signal ratio. Since $s \geq 0$, $\widehat{\boldsymbol{\beta}}$ is downward biased asymptotically towards zero, a bias called attenuation bias. The attenuation bias is reduced if additional (correctly measured) regressors are included, and is increased if panel data are used with estimation by differencing methods such as the within-estimator.

There are several ways to secure identification of $\boldsymbol{\beta}$. These include instrumental variables methods (assuming availability of an instrument z that is correlated with x^* but not with the model error u), use of replicated data or validation sample data to estimate key sample cross-moments, and use of additional distributional assumptions, such as symmetry of the error. Bounds on $\boldsymbol{\beta}$ can also be obtained using reverse regression. Wansbeek and Meijer (2000) review many identification methods. Few studies correct for measurement error, however, in part due to lack of necessary data or reluctance to make strong assumptions about the nature of the measurement error.

The preceding methods do not generalize easily and in a systematic way to nonlinear models. Carroll, Ruppert and Stefanski (1995) summarize the statistics literature and Hausman (2001) considers the econometrics literature. For measurement error in regressors in nonlinear regression with additive error, an early reference is Y. Amemiya (1985) and a more recent reference is Schennach (2004). For nonlinear models with nonadditive errors, such as discrete outcome and count models, measurement error in the dependent variable can also cause problems. For example, Hausman, Abrevaya and Scott-Morton (1998) consider mismeasurement in the dependent variable in binary outcome models, taking a parametric approach with strong assumptions.

The classical measurement error model maintains that the measurement error is i.i.d. Some work relaxes this. An early example is that, for a binary regressor, the measurement error is necessarily correlated with the true value, since the only way to mismeasure a value of 0 is as a 1, and vice versa. Mahajan (2006) gives a quite general treatment for binary regressors. Kim and Solon (2005) consider standard linear panel estimators when measurement error in a regressor is negatively correlated with the true value.

14.8 Conclusion

Microeconometricians are very ambitious in their desire to obtain marginal effects that can be given a causative interpretation, permit individual heterogeneity and are obtained under minimal assumptions. The associated statistical inference should also rely on minimal assumptions. This has led to a literature and toolkit that is quite advanced for an area of applied statistics.

This survey has of necessity been selective. The methods used in labor economics and public economics have been emphasized. General approaches have been presented, with specialization usually to the linear model. For econometrics methods for specific types of data – binary, multinomial, durations and counts – good starting points are the specialized monographs by, respectively, Maddala (1983), Train (2003), Lancaster (1990), and Cameron and Trivedi (1998), as well as the more general texts cited in the introduction and Cameron and Trivedi (2008). The chapters by Greene and Jones in this volume are also highly relevant.

Acknowledgments

This chapter draws considerably on Cameron and Trivedi (2005). Earlier versions were presented at the Japanese Statistical Society 75th Anniversary Symposium on Applied Microeconometrics, University of Tokyo, September 2006, and at the 23rd Annual Summer Meeting of the Society for Political Methodology, UC Davis, July 2006. The author benefitted from comments of conference participants, from sabbatical leave at UC Berkeley, and from discussions with Bryan Graham, Michael Jansson, Oscar Jorda, Guido Kuersteiner, Jim Powell and Paul Ruud.

Computational Considerations in Empirical Microeconometrics: Selected Examples

David T. Jacho-Chávez and Pravin K. Trivedi

Abstract

The substance and style of modern microeconometrics is shaped by its role in analyses of public policy issues. Computational considerations have proved to be an important influence on the methodology and scope of empirical analyses that address these issues. To be convincing to a wide readership the empirical analyses need to be based on representative data and flexible modeling approaches. In this chapter we illustrate, through a variety of empirical examples, how modelers handle the complexities that arise from the richness of survey data and the heterogeneity in behavior of market participants. After introductory sections on data and programming languages, the remainder of the chapter covers many leading computationally intensive econometric techniques. These are illustrated by means of specific numerical examples. An algorithmic format is used to describe the computational features.

15.1 Introduction

Since the 1980s there has been a huge growth in the availability of both census and survey data, in part due to the expansion of electronic recording and collection of data. As data, computational power, and modeling opportunities have grown, so have the variety and complexity of the modeling objectives of empirical researchers. These developments have created modeling opportunities and challenges that were largely absent when only aggregated market-level data were available.

Explosive growth in the volume and types of data has also given rise to numerous methodological issues. Certain features of micro-data are also ultimately responsible for added computational complexity. Sample survey data, the raw material of microeconometrics, are often subject to problems of sample selection, measurement errors, incomplete and/or missing data, all of which generate additional uncertainty about the econometric specifications used by empirical researchers and impede the empirical generalizations from sample to population. One response to these issues is that empirical researchers often explore several modeling strategies, leading to additional computational complexity.

Model specification, estimation, testing, and then revision are essential components of a modeling cycle. Whether econometric models are intended to be exploratory and descriptive, or whether they aim to quantify structural relationships, computation is central to every step in the modeling cycle. Important features of modern applied econometrics include the following:

- **Disaggregation**. Microeconometrics is about regression-based modeling of economic relationships using data at the levels of individuals, households, and firms. The low level of aggregation in the data has immediate implications for the functional forms used to model the relationships of interest. Disaggregation

brings out heterogeneity of individuals, firms, and organizations. Modeling such heterogeneity is often essential for making valid inferences. While aggregation usually reduces noise and leads to smoothing, disaggregation leads to loss of continuity and smoothness, and increases the range of variation in the data. For example, household average weekly consumption of (say) meat is likely to vary smoothly, while that of an individual household in a given week may frequently be zero, and may also switch to positive values from time to time. As Pudney (1989) has pointed out, micro-data exhibit "holes, kinks and corners." Discreteness and nonlinearity of response are intrinsic to microeconometrics, and they contribute to an increase in computational complexity relative to linear models.

- **Model complexity**. Empirical microeconometrics is closely tied to issues of public policy. Attempts to strengthen the policy relevance of models typically increase the complexity of the models. For example, one may be interested not only in the average impact of a policy change, but also in its distribution. The greater the heterogeneity in response, the greater the relevance of the latter. One feature of such complexity is that potentially models have high dimension. A multiple equation nonlinear regression model with scores of variables is not at all unusual.
- **Restrictions**. Strong functional form and distributional restrictions are not favored. Instead, non- and semiparametric models, or flexible parametric models, are preferred.
- **Robustness**. Models whose conclusions are not very sensitive to modeling assumptions are preferred. Robustness comparisons between competing specifications are an important part of the modeling cycle.
- **Testing and evaluation**. Model testing and evaluation, generally requiring additional computational effort, are integral parts of the search for robust specifications.
- **Asymptotic approximations**. Traditionally, inference about economic relations relied heavily on large sample approximations, but with additional computational effort it is often possible to improve the quality of such approximations. Increasingly, applied econometricians engage in such improvements.
- **Computing advances**. Breathtaking advances in the speed and scope of computing encourage applied econometricians to experiment with computationally more ambitious projects. Avoiding a technique purely because it is computationally challenging is no longer regarded as a serious argument.

In this chapter we selectively and illustratively survey how computational advances have influenced, and in turn are influenced by, the style and direction of modern applied microeconometrics. Although it is fascinating to do so, we do not systematically take a historical perspective on econometric computation. The interested reader is directed to Berndt (1991, pp. 1–10) and the articles by Renfro (2004b) and Slater (2004). To limit the potentially vast scope of this article, we restrict the coverage to a few selected topics whose discussion is illustrated with specific data-based examples. We do not cover the important developments in Bayesian computation

(see, e.g., Chib, 2004; Geweke, 2005). The preliminary issues are tackled in sections 15.2 and 15.3. Section 15.4 discusses the advantages of flexible functional forms generated using non- and semiparametric methods. Section 15.5 illustrates some of the ways in which heterogeneous responses are modeled and how resampling methods are used in the related econometric inference. Section 15.6 illustrates the use of simulation assisted estimation in handling endogenous regressors in a simultaneous nonlinear model of choice and outcomes. Section 15.7 concludes.

15.2 Preliminary

A computer has become the standard tool of the trade for most applied econometricians. It is unimaginable how today's empirical analyses and advances could have been performed without one. However, a byproduct of this matrimony between computing and applied econometrics is today's necessity that empirical researchers should know and understand many definitions and specialized computer science jargon. In this section, we provide a quick introduction to essential concepts, terminology and practical considerations that most researchers come into contact with while working with a computer.

15.2.1 Programming languages

A computer programming language can be thought of as a set of characters, along with rules to combine them into words and symbols, that can be used to express detailed instructions to a computer. Most programming languages used by economists are *high-level languages*, in the sense that they are not generally specific to a computer central processing unit (CPU), but instead they are portable across different computer hardware. These high-level languages can generally be divided into compiled languages and interpreted languages.

Compiled programming languages require a computer program, called *compiler*, to translate human-readable text instructions, called *source code*, into a *low-level language* such as assembly language or machine language. Most *third-generation programming languages* (3GL), such as C, C++ and Fortran, are compiled languages. Computer programs written in these languages need to be compiled first, and then executed.

Interpreted programming languages are implemented by a computer program called *interpreter*. The interpreter executes instructions written in these languages. Popular object-oriented *fourth-generation programming languages* (4GL), such as GAUSS™ (Aptech Systems, Inc., Black Diamond, Washington), MATLAB® (The MathWorks™, Natick, Massachusetts), R (R Development Core Team, Vienna, Austria), and Stata® (StataCorp LP, College Station, Texas) are interpreted languages.

The interested reader is recommended to consult articles by Nerlove (2004) and Renfro (2004a) for a comprehensive list and history of programming languages used in econometrics up to 2004.

15.2.1.1 Characteristics

Researchers are often faced with the dilemma of what programming language to use. Although the final decision is mostly a matter of taste and time constraints, the following should serve as guidelines:

- **Portability**. Source code written in 4GLs requires a local installation of the relevant compiler for their implementation. Since these languages are often proprietary, this could make sharing and replicability inconvenient.[1] On the other hand, after compilation, 3GL's executable files do not require any kind of formal installation onto a computer's permanent storage device to be executed and can be sent to others by e-mail, enabling it to be used on multiple computers.
- **Complexity**. Compiled programming languages are general purpose languages. They often only include primitive mathematical functions and, with the exception of Fortran, they solely provide uniform pseudo-random number generators. On the other hand, interpreted languages are conceived with a specific purpose in mind. They admit a richer set of data types than integer and double precision numbers. Multidimensional arrays are also native objects in some of these languages. Standard econometrics and mathematical techniques are seldom implemented in compiled languages, but they are plentiful in interpreted languages.
- **Expandability**. Both 3GL and 4GL can readily be expanded by the inclusion of *libraries* and *packages*. Libraries are collections of special purpose algorithms. Examples include the IMSL libraries of Visual Numerics Inc. for C and Fortran, and NAG Fortran Library subroutines of the Numerical Analysis Group. Packages are collections of programs linked together. Examples include packages in R, and modules in Stata.
- **Efficiency**. A main disadvantage of interpreted languages is that applications run slower than if they had been compiled, especially iterative algorithms that require loops iterated many times, e.g., bootstrapping and cross-validation. This is because the interpreter must analyze each statement in the source code each time it is executed, and then perform the desired action, whereas the compiled code simply performs the action. Furthermore, 3GL such as C and Fortran permit better control of dynamic memory allocation that can potentially speed up many implementations.[2]

However, it is no longer the case that researchers must choose between 3GL and 4GL when facing a programming task. Modern computing environments allow the inclusion of C or Fortran subroutines, via *foreign language interface*, into 4GL such as GAUSS, MATLAB, R, Stata and vice versa, as well as the possibility of *parallelization*.

15.2.2 Foreign language interface

Parts or chunks of source code written in an interpreted language can be rewritten in C or Fortran, and then compiled into a library (*dynamic link library* in MS Windows®, or *share object* in *NIX[3] platforms). This compiled library can then be

dynamically loaded by the original program to speed up overall execution. Furthermore, since some interpreted languages are written in C, it is not surprising that native C code can make use of libraries in local installations of these interpreted languages' compilers.[4]

15.2.3 Parallelization

Standard 4GL performs *serial* computations, i.e., instructions are executed one after another on a single computer having a single CPU. However, the advent of *clusters*,[5] workstations and single computers with multiple processors have made parallel computing a tangible possibility to most economists. *Parallel computing* is the simultaneous use of more than one CPU to execute a program or solve a computational problem. The problem is broken into parts that can be solved concurrently. Each part is further broken down to a series of instructions that are executed simultaneously on different CPUs. This is achieved by using a language-independent communications protocol known as *Message Passing Interface* (MPI).

Parallel computing means that computations that would otherwise take hours or days could be performed in minutes or hours. Computational algorithms that allow parallelization commonly involve iterative loops that can be performed independently of each other. Examples include most resampling methods, such as the bootstrap, or set search algorithms often used in cross-validation methods in non/semiparametric techniques (see section 15.4.1.1 for an illustration). Creel (2005) discusses many other econometric examples that allow for parallel computation, such as Monte Carlo simulation, maximum likelihood (ML) and generalized method of moments (GMM) estimation.

Most 4GL used in econometrics either allow the parallelization of procedures or make full use of multiprocessor computers. Examples include `MatlabMPI` in MATLAB, `Rmpi`, and `Snow` in R for the former, and Stata/MP® for the latter.

15.3 Computing and modeling

There are many ways in which more memory and computing power can potentially improve the quality of empirical analysis in microeconometrics.

The first context is that of the storage and manipulation of large complex datasets, and in providing numerical, graphical and visual displays of data in ways that provide valuable insights into the pattern and structure within such datasets.

The second context is that of solving (especially) high-dimensional optimization problems that arise in model estimation. Estimation of many standard microeconometric models involves solution of nonlinear equations by iterative methods, which are generically referred to as optimizers. Efficient optimizers that can handle high-dimensional problems are essential in microeconometric modeling.

Increasingly, computer-intensive methods such as Monte Carlo simulators are an important tool for studying the finite sample properties of estimators and tests. Simulation is also an essential component in estimating model parameters, as in the case of simulation-assisted optimization and Markov chain Monte Carlo (MCMC) methods used in Bayesian modeling.

Fourth, computer-intensive resampling methods, such as the bootstrap and jackknife, are increasingly used as substitutes for analytically complex computations such as sample estimates of asymptotic variances.

Finally, cross-validation is another computer-intensive tool that is useful not only for parameter tuning (as illustrated in section 15.4) but also for model evaluation and comparison.

In the remainder of this section we define and outline each type of application.

15.3.1 Data summary and visualization

A starting point of almost any empirical microeconometric application involves providing data summaries. The most common manifestation of this takes the form of a table of sample moments, such as means, variances, skewness and kurtosis. However, visual data summaries, such as histograms and kernel (marginal) density plots, are often a more efficient way of providing information (see, e.g., Huynh and Jacho-Chávez, 2007). The kernel density estimator is a generalization of the histogram estimate using *kernel* weights, $k(\cdot)$, that integrate to 1. These weights depend on a smoothing parameter, h, called the *bandwidth*, and $2h$ is the *window width* (see section 15.4.1 for definitions and examples). Given $k(\cdot)$ and h the estimator is easy to implement, and if the estimator is evaluated at r distinct values, then computation of the kernel estimator requires at most nr operations when the kernel has unbounded support. However, as is evident even in the most elementary computation of a histogram, constructing such visual displays involves the choice of bin size, and the results may be sensitive to the choice of h. This motivates the search for another estimator that treats h like an unknown parameter, i.e., cross-validation. Such a method is inherently more computer-intensive, as will be shown in section 15.4. An extension of this concept, also considered in the next section, is the estimator of the conditional probability density function, which also involves considerations similar to those in the estimation of marginal densities.

15.3.2 Numerical optimization

Microeconometrics frequently employs an estimator $\widehat{\boldsymbol{\theta}}$ that maximizes a stochastic objective function $Q_n(\boldsymbol{\theta})$, where usually $\widehat{\boldsymbol{\theta}}$ solves the first-order conditions $\partial Q_n(\boldsymbol{\theta})/\partial \boldsymbol{\theta} = \mathbf{0}$; n being the sample size. The objective function may be a likelihood for parametric models, a weighted sum of squares function for semiparametric models, or a linear function subject to inequality restrictions when the objective function has an L_1 (e.g., least absolute deviations) rather than an L_2 (e.g., sum of squared residuals) norm. For many nonlinear models there is no closed-form solution of the first-order conditions, only a nonlinear system of equations in the unknown $\boldsymbol{\theta}$. Estimation algorithms use iterative methods to solve the first-order conditions. Iterative methods involve an updating rule for obtaining a new estimate, $\widehat{\boldsymbol{\theta}}_{s+1}$, given a current estimate $\widehat{\boldsymbol{\theta}}_s$. Historically, iterative procedures constituted a computational challenge, but now they are standard. When the objective function is in the L_2 norm, gradient methods are most common. Non-gradient

methods are used in the L_1 norm case, quantile regression (QR) being a leading example.

Gradient methods use an iterative updating rule:

$$\widehat{\boldsymbol{\theta}}_{s+1} = \widehat{\boldsymbol{\theta}}_s + \mathbf{A}_s \mathbf{g}_s, \qquad s = 1, \ldots, S, \tag{15.1}$$

where $\mathbf{A}_s = \mathbf{A}(\widehat{\boldsymbol{\theta}}_s)$ is a $q \times q$ matrix, and $\mathbf{g}_s = \partial Q_n(\boldsymbol{\theta})/\partial \boldsymbol{\theta}\big|_{\widehat{\boldsymbol{\theta}}_s}$ is the $q \times 1$ gradient vector evaluated at $\widehat{\boldsymbol{\theta}}_s$. The iterative process continues until it converges. Convergence is usually defined in terms of an arbitrarily small value of either $|Q_n(\widehat{\boldsymbol{\theta}}_{s+1}) - Q_n(\widehat{\boldsymbol{\theta}}_s)|$ or $|\widehat{\boldsymbol{\theta}}_{s+1} - \widehat{\boldsymbol{\theta}}_s|$. Gradient methods differ by their choice of matrix $\mathbf{A}_s$, as summarized in Table 15.1. Some methods, most notably Newton–Raphson and the method of scoring, use second derivatives of the objective function, whereas others, most notably BHHH (Berndt–Hall–Hall–Hausman), is based on the gradient function only. The derivatives may be computed using either the analytical expressions, which are then programmed in the algorithm, or numerical derivatives, which is often a default option. The numerical derivatives are computed using:

$$\frac{\Delta Q_n(\widehat{\boldsymbol{\theta}}_s)}{\Delta \theta_j} = \frac{Q_n(\widehat{\boldsymbol{\theta}}_s + \tau \mathbf{e}_j) - Q_n(\widehat{\boldsymbol{\theta}}_s - \tau \mathbf{e}_j)}{2\tau}, \quad j = 1, \ldots, q, \tag{15.2}$$

Table 15.1 Some standard gradient-based iteration methods

$\mathbf{A}(\widehat{\boldsymbol{\theta}}_s)$	*Reference*
$-\left.\dfrac{\partial^2 Q_n(\boldsymbol{\theta})}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}^\top}\right\vert_{\widehat{\boldsymbol{\theta}}_s}$	Newton–Raphson
$-\mathrm{E}\left[\dfrac{\partial^2 Q_n(\boldsymbol{\theta})}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}^\top}\right]\Bigg\vert_{\widehat{\boldsymbol{\theta}}_s}$	Method of scoring
$-\sum_{i=1}^n \dfrac{\partial q_i(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}} \dfrac{\partial q_i(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}^\top}\Big\vert_{\widehat{\boldsymbol{\theta}}_s}$	Berndt–Hall–Hall–Hausman (BHHH)
$\mathbf{I}_q$	Steepest descent
$\mathbf{A}_s = \mathbf{A}_{s-1} + \dfrac{\delta_{s-1}\delta_{s-1}^\top}{\delta_{s-1}^\top \gamma_{s-1}} + \dfrac{\mathbf{A}_{s-1}\gamma_{s-1}^\top \gamma_{s-1}\mathbf{A}_{s-1}}{\gamma_{s-1}^\top \mathbf{A}_{s-1}\gamma_{s-1}}$, where $\delta_{s-1} = \mathbf{A}_{s-1}\mathbf{g}_{s-1}$; $\gamma_{s-1} = \mathbf{g}_s - \mathbf{g}_{s-1}$	Davidon–Fletcher–Powell (DFP)
$\mathbf{A}_s = \mathbf{A}_{s-1} + \dfrac{\delta_{s-1}\delta_{s-1}^\top}{\delta_{s-1}^\top \gamma_{s-1}} + \dfrac{\mathbf{A}_{s-1}\gamma_{s-1}^\top \gamma_{s-1}\mathbf{A}_{s-1}}{\gamma_{s-1}^\top \mathbf{A}_{s-1}\gamma_{s-1}}$ $-(\gamma_{s-1}^\top \mathbf{A}_{s-1}\gamma_{s-1})\eta_{s-1}\eta_{s-1}^\top$, where $\eta_{s-1} = (\delta_{s-1}/\delta_{s-1}^\top \gamma_{s-1}) - (\mathbf{A}_{s-1}\gamma_{s-1}/\gamma_{s-1}^\top \mathbf{A}_{s-1}\gamma_{s-1})$	Boyden–Fletcher–Goldfarb–Shannon (BFGS)

where τ is small and $\mathbf{e}_j = [0, \ldots, 0, 1, 0, \ldots, 0]^\top$ is a K-vector with unity in the jth row and zeros elsewhere. In theory, τ should be chosen such that $\partial Q_n(\boldsymbol{\theta})/\partial\theta_j = \lim_{\tau\to 0} \Delta Q_n(\boldsymbol{\theta})/\Delta\theta_j$. Although, in principle, analytical derivatives are preferred, numerical approximations produce virtually identical results in many regular cases.

Whether the application of a gradient based optimizer turns out to be computationally demanding depends upon many factors, including the following: (i) dimension of $\boldsymbol{\theta}$; (ii) whether the objective function is well approximated by a quadratic expansion in the neighborhood of the optimum; (iii) whether $\boldsymbol{\theta}$ is robustly identified in the sample; and (iv) whether the iterative algorithm starts sufficiently close to the optimum. Conversely, convergence can be slow when the dimension of $\boldsymbol{\theta}$ is high, some components of $\boldsymbol{\theta}$ are weakly identified in the data, and/or the objective function admits multiple maxima or a flat region around the maximum, and the starting values for the update equation are poor. If an objective function is difficult to maximize, e.g., due to multiple local optima, non-gradient methods may be used, such as simulated annealing and genetic algorithms. A leading example is kernel-based cross-validation (see, e.g., algorithms 15.4.1.1.1 and 15.4.1.2.1 below), where Powell's direction set search algorithm is also a viable alternative (see Press *et al.*, 1992, section 10.5, pp. 412–20).

Another example of a case where a gradient-based method is inappropriate is the least absolute deviation (LAD) regression or the quantile regression. In the case of LAD regression, the objective function $Q_n(\boldsymbol{\theta}) = n^{-1}\sum_i |y_i - \mathbf{x}_i^\top \boldsymbol{\beta}|$ has no derivative. In the case of quantile regression, the objective function is minimized over $\boldsymbol{\beta}_q$; i.e.:

$$Q_n(\boldsymbol{\beta}_q) = \sum_{i:\, y_i \geq \mathbf{x}_i^\top \beta}^{n} q|y_i - \mathbf{x}_i^\top \boldsymbol{\beta}_q| + \sum_{i:\, y_i < \mathbf{x}_i^\top \beta}^{n} (1-q)|y_i - \mathbf{x}_i^\top \boldsymbol{\beta}_q| \tag{15.3}$$

$$= \sum \rho_q(u_q), \tag{15.4}$$

where $0 < q < 1$, $\rho_q(\lambda) = (q - \mathbb{I}(q < 0))\lambda$ denotes the check function, $\mathbb{I}(\cdot)$ represents the indicator function that equals 1 if its argument is true and 0 otherwise, and the notation $\boldsymbol{\beta}_q$ emphasizes that, for different choices of q, different values of $\boldsymbol{\beta}$ are obtained.

The estimator defined by the minimand $\min_{\boldsymbol{\beta}_q} Q_n(\boldsymbol{\beta}_q)$ is an M-estimator and, as such, its asymptotic properties are well established (see Amemiya, 1985). The optimization problem has an interpretation in the GMM framework as well as in a linear programming (LP) framework (see Buchinsky, 1995). To see the LP representation, the QR is written thus:

$$\begin{aligned} y_i &= \mathbf{x}_i^\top \boldsymbol{\beta}_q + u_{iq} \\ &= \mathbf{x}_i^\top (\boldsymbol{\beta}_q^{[1]} - \boldsymbol{\beta}_q^{[2]}) + (\varepsilon_{iq}^{[1]} - \varepsilon_{iq}^{[2]}), \end{aligned}$$

where $\beta_{q,j}^{[1]} \geq 0$, $\beta_{q,j}^{[2]} \geq 0$, $j = 1, \ldots, K$, and $\varepsilon_{iq}^{[1]} \geq 0$, $\varepsilon_{iq}^{[2]} \geq 0$, $i = 1, \ldots, n$. The optimization problem can be expressed as that of minimizing a linear objective

function subject to linear equality constraints:

$$\min_{\mathbf{c}^\top \mathbf{z}} \mathbf{c}^\top \mathbf{z}, \text{ subject to } \mathbf{A}\mathbf{z} = \mathbf{y},\ \mathbf{z} \geq \mathbf{0},$$

where $\mathbf{A} = [\mathbf{X}, -\mathbf{X}, \mathbf{I}_n, -\mathbf{I}_n]$, $\mathbf{y} = [y_1, \ldots, y_n]^\top$, $\mathbf{z} = [\boldsymbol{\beta}_q^{[1]}, \boldsymbol{\beta}_q^{[2]}, \varepsilon_q^{[1]}, \varepsilon_q^{[2]}]^\top$, $\mathbf{c}^\top = [\mathbf{0}^\top, \mathbf{0}^\top, q\iota^\top, (1-q)\iota^\top]$, $\mathbf{X} = [\mathbf{x}_1, \ldots, \mathbf{x}_n]^\top$, $\mathbf{0}$ is a vector of zeros, ι is a vector of 1s, and $\mathbf{I}_n$ is the identity matrix of order n.

The classic method for solving the linear program is the simplex method, which is guaranteed to yield a solution in a finite number of simplex iterations. When n is of the order of several thousands, an efficient computational algorithm is essential. A number of alternative algorithms have been proposed, including a computationally efficient one due to Barrodale and Roberts (1973), thus making QR a suitable method for practical application in large samples. Point estimation is actually a lesser computational challenge than the calculation of variances. Bootstrap methods for variance estimation, often used in preference to analytical expressions, contribute to computational intensity; an example is given in section 15.2.

15.3.3 Simulation-assisted estimation

The role of simulation in theoretical econometrics is well established (see Doornik, 2006). Its use in empirical microeconometrics is more recent but growing rapidly (see McFadden and Ruud, 1994; Gouriéroux and Monfort, 1996). First, MCMC methodology, which is simulation-based, is now standard in modern Bayesian estimation. Second, estimation of several leading microeconometric models, e.g., the multinomial probit (MNP), involve calculation of probability integrals that can be efficiently estimated using simulation methods. Third, empirical microeconometric models often include a latent variable to capture the effects of unobserved heterogeneity (UH). These too lead naturally to simulation-based estimation. We consider two leading applications of simulation-based estimation.

15.3.3.1 MNP example

Consider the MNP model with m choices and with the utility of the jth choice given by:

$$U_j = V_j + \varepsilon_j, \qquad j = 1, 2, \ldots, m, \tag{15.5}$$

where the errors $\boldsymbol{\varepsilon} = [\varepsilon_1, \ldots, \varepsilon_m]^\top$ are joint normally distributed, $\boldsymbol{\varepsilon} \sim \mathcal{N}[\mathbf{0}, \Sigma]$. Usually the linear specifications $V_j = \mathbf{x}_j^\top \boldsymbol{\beta}$ or $V_j = \mathbf{x}^\top \boldsymbol{\beta}_j$ are used. This is an additive random utility model. The covariance matrix Σ is subject to normalization and identification restrictions because U_j is latent. The standard practice is to choose U_1 as the benchmark alternative and place one restriction on Σ.

In estimating the model by ML, a problem is that there is no closed form expression for the choice probabilities. For an m-choice MNP model the choice probabilities are $(m-1)$-fold integrals, e.g.:

$$p_1 = \Pr[y = 1] = \int_{-\infty}^{-\widetilde{V}_{m1}} \cdots \int_{-\infty}^{-\widetilde{V}_{21}} f(\widetilde{\varepsilon}_{21}, \ldots \widetilde{\varepsilon}_{m1}) d\widetilde{\varepsilon}_{21} \ldots d\widetilde{\varepsilon}_{m1},$$

where the $\sim$ denotes normalization relative to the first alternative. When $m > 3$, this integral is difficult to evaluate numerically. An alternative is to use simulation methods. One well-known simulator is the GHK simulator due to Geweke (1992), Hajivassiliou, McFadden and Ruud (1994) and Keane (1994) (see Train, 2003, for details). In this context the maximum simulated likelihood (MSL) estimator maximizes:

$$\widehat{\mathcal{L}}_n(\boldsymbol{\beta}, \Sigma) = \sum_{i=1}^{n} \sum_{j=1}^{m} y_{ij} \ln \widehat{p}_{ij},$$

where the $\widehat{p}_{ij}$ are obtained using the GHK or other simulator. For consistent estimation we require that the number of draws in the simulator $S \to \infty$ as well as $n \to \infty$. Because the method is computationally burdensome, a great deal of work has been done on improving the simulator and on developing other models that are good substitute specifications but are easier to estimate (e.g., McFadden and Train, 2000).

15.3.3.2 Heterogeneity example

Suppose the conditional density $h(y_i|\mathbf{x}_i, \boldsymbol{\theta}, \mathbf{u}_i)$ for an observation involves a continuous separable UH term $\mathbf{u}_i$, assumed to be independent of $\mathbf{x}_i$, with density $g(\mathbf{u}_i)$. Then the marginal density is defined by the integral:

$$f(y_i|\mathbf{x}_i, \boldsymbol{\theta}) = \int h(y_i|\mathbf{x}_i, \boldsymbol{\theta}, \mathbf{u}_i) g(\mathbf{u}_i) d\mathbf{u}_i, \tag{15.6}$$

which needs to be estimated numerically if there is no closed form solution.

An unbiased and consistent estimator $\widehat{f}_i$ of f_i is the direct Monte Carlo simulator:

$$\widehat{f}(y_i|\mathbf{x}_i, \mathbf{u}_{iS}, \boldsymbol{\theta}) = \frac{1}{S} \sum_{s=1}^{S} h(y_i|\mathbf{x}_i, \boldsymbol{\theta}, \mathbf{u}_i^s), \tag{15.7}$$

which averages $h(y_i|\mathbf{x}_i, \boldsymbol{\theta}, \mathbf{u}_i^s)$ over the S draws, where $\mathbf{u}_i^s$, $s = 1, \ldots, S$, are independent draws from $g(\mathbf{u}_i)$. Estimators superior to this direct estimator are also available.

The MSL estimator $\widehat{\boldsymbol{\theta}}_{\text{MSL}}$ maximizes:

$$\widehat{L}_n(\boldsymbol{\theta}) = \sum_{i=1}^{n} \ln \widehat{f}(y_i|\mathbf{x}_i, \boldsymbol{\theta}, \mathbf{u}_{iS}). \tag{15.8}$$

If $\widehat{f}(\cdot)$ is differentiable in $\boldsymbol{\theta}$ then $\widehat{\boldsymbol{\theta}}_{\text{MSL}}$ can be computed using the standard gradient methods mentioned above. This MSL estimator is asymptotically equivalent to the ML estimator if $S, n \to \infty$ and $\sqrt{n}/S \to 0$, and has a limit normal distribution.

The MSL method is one of the simplest simulation-based estimators. Just as the MSL method parallels ML estimation, the method of simulated moments (MSM) parallels the method of moments. For space reasons we do not elaborate on the distinctions between these methods.

A direct application of the MSL method sometimes leads to very slow convergence of the simulated likelihood function. Simulation-acceleration techniques are

available. An example is the method that uses quasi-random draws based on Halton sequences described in Bhat (2001) and Train (2003).[6] Halton sequences have two desirable properties vis-á-vis the standard pseudo-random draws. First, they are designed to give more even coverage over the domain of the mixing distribution. Second, the simulated probabilities are negatively correlated over observations. This negative correlation reduces the variance in the simulated likelihood function. Under suitable regularity conditions (see Bhat, 2001), the integration error using pseudo-random sequences is in the order of n^{-1} as compared to pseudo-random sequences where the convergence rate is $n^{-1/2}$. An example of an MSL estimator using Halton quasi-random draws is given in section 15.6.

15.3.4 Resampling methods

Empirical microeconometrics depends heavily on asymptotic theory to justify point and interval estimation procedures because exact results are generally not available. Sometimes an investigator may be interested in some function of estimates and data for which even the asymptotic result may not be available. In some cases only an approximation to the asymptotic approximation may be available. The availability of an asymptotic approximation is no guarantee that it provides a good approximation to the sampling distribution of an estimator. Motivated by these difficulties, econometricians increasingly use computer-intensive resampling methods to obtain estimates of the moments of the asymptotic distribution. The bootstrap and jackknife are two leading examples, but only the first is sketched here.

There exists a wide range of bootstrap methods (see, e.g., Davidson and MacKinnon, 2006). The simplest bootstrap methods can support statistical inference when conventional methods, such as variance estimation, are difficult to implement, either because a formula is not available or because it is computationally intractable. Another, more complicated, bootstrap attempts to provide asymptotic refinements that can lead to an improvement over the asymptotic results. Applied researchers are most often interested in the first, simpler, application of the bootstrap.

The basic idea behind the bootstrap is to approximate the distribution of a statistic by a simulation in which one samples from the empirical or the fitted distribution of the data. That is, one uses a given sample repeatedly to derive the sampling properties of statistics of interest. Bootstrap methods rely on asymptotic theory for their validity.

Consider, in the context of the regression of $y_i|\mathbf{x}_i$, $i = 1, \ldots, n$, the problem of inference on a parameter $\boldsymbol{\theta}$, $\boldsymbol{\theta} = \phi(\boldsymbol{\beta})$, where $\phi(\boldsymbol{\beta})$ is a continuous function of the regression parameters $\boldsymbol{\beta}$. The bootstrap algorithm for the variance of $\boldsymbol{\theta}$ is explained in algorithm 15.3.4.0.1.

A computationally simpler alternative to the bootstrap variance is an estimate obtained by the so-called delta method, based on a first-order Taylor approximation of $\phi(\boldsymbol{\beta})$. In some applications this method can yield very poor results, whereas the bootstrap may be more robust.

Algorithm 15.3.4.0.1 Bootstrap variance estimation – implementation

1. Given data $(\mathbf{y}_i, \mathbf{x}_i)$, $i = 1, \ldots, n$, draw (with replacement) a bootstrap sample of size n, denoted $(\mathbf{y}_1^*, \mathbf{x}_1^*), \ldots, (\mathbf{y}_n^*, \mathbf{x}_n^*)$.
2. Calculate the estimate $\widehat{\boldsymbol{\theta}}^*$ of $\boldsymbol{\theta}$.
3. Repeat steps 1–2 B independent times, where B is a large number, obtaining B bootstrap replications of the statistic of interest, such as $\widehat{\boldsymbol{\theta}}_1^*, \ldots, \widehat{\boldsymbol{\theta}}_B^*$.
4. Use these B bootstrap replications to obtain the bootstrap variance $\mathrm{V}_B(\widehat{\boldsymbol{\theta}}) = B^{-1} \sum (\widehat{\boldsymbol{\theta}}_j^* - \overline{\widehat{\boldsymbol{\theta}}^*})^2$, where $\overline{\widehat{\boldsymbol{\theta}}^*} = B^{-1} \sum \widehat{\boldsymbol{\theta}}_j^*$. (It is assumed that the asymptotic variance of $\widehat{\boldsymbol{\theta}}$ exists.)

In implementing a bootstrap, details generally vary with the specific application. For example, bootstrap samples may be drawn differently, the value of B may vary, and the target statistic of interest may or may not involve asymptotic refinement.

Section 15.5.1 provides an example that compares standard errors of quantile regression parameters obtained using an analytical formula with those from a bootstrap.

15.3.5 Structural models based on dynamic programming

Dynamic programming (DP) models represent a relatively new strand in structural microeconometric models. The special appeal of the approach comes from the potential of this class of models to address issues relating to new policies or old policies in a new environment. Further, the models are dynamic in the sense that they can incorporate expectational factors and intertemporal dependence between decisions. From a computational viewpoint these models are an order of magnitude more complex than most other methods. What follows is merely a bare-bones sketch of the approach.

The DP approach is rooted in detailed structural specifications derived from strong theoretical specifications and contrasts sharply with the looser "atheoretical" models. The distinctive characteristics of this approach include: a close integration with underlying theory; an assumption of rational optimizing agents; extensive use of assumptions and restrictions necessary to support the close integration of the empirical model with the underlying theory; a high level of parameterization of the model; concentration on causal parameters that play a key role in policy simulation and evaluation; and an approach to the estimation of model parameters that is substantially different from the standard approaches used in estimating moment condition models.

There are many studies that follow the dynamic programming approach. Representative examples are Rust (1987); Hotz and Miller (1993); Keane and Wolpin (1994). Some key features of DP models can be studied using a model due to Rust and Phelan (1997), which provides an empirical analysis of how the incentives and constraints of the US social security and Medicare insurance system affects the labor supply of older workers.

The main components of the DP model are as follows. State variables are denoted by s_t, control variables by d_t. β is the intertemporal discount factor. In implementation all continuous state variables are discretized – a step which greatly expands the dimension of the problem. Hence all continuous choices become discrete choices, d_t is a discrete choice sequence, and the choice set is finite. There is a single period utility function $u_t(s_t, d_t, \boldsymbol{\theta}_u)$ and $p_t(s_{t+1}|s_t, d_t, \boldsymbol{\theta}_p, \alpha)$ denotes the probability density of transitions from s_t to s_{t+1}. The optimal decision sequence is denoted by $\boldsymbol{\delta} = (\delta_0, \ldots, \delta_T)^\top$, where $d_t = \delta_t(s_t)$, and is the optimal solution that maximizes the expected discounted utility:

$$V_t(s) = \max_{\boldsymbol{\delta}} E_{\boldsymbol{\delta}}\{\textstyle\sum_{j=t}^{T} \beta^{j-t} u_j(s_j, d_j, \boldsymbol{\theta}_u)|s_t = s\}. \tag{15.9}$$

Estimation of the model typically uses the likelihood function:

$$\begin{aligned} L(\boldsymbol{\theta}) &= L(\beta, \boldsymbol{\theta}_u, \boldsymbol{\theta}_p) \\ &= \textstyle\prod_{i=1}^{n} \prod_{t=1}^{T} P_t(d_t^i|x_t^i, \boldsymbol{\theta}_u) p_t(x_t^i|x_{t-1}^i, d_{t-1}^i, \boldsymbol{\theta}_p), \end{aligned} \tag{15.10}$$

where $\boldsymbol{\theta} = (\boldsymbol{\theta}_u^\top, \boldsymbol{\theta}_p^\top)^\top$, and assumptions are invoked to separate the parameters in the transition probability $p_t(s_{t+1}|s_t, d_t, \boldsymbol{\theta}_p, \alpha)$ from those in the utility function $u_t(s_t, d_t, \boldsymbol{\theta}_u)$.

DP models are typically high dimensional. To handle the dimensionality issue a popular estimation strategy has two steps: (1) estimate $\boldsymbol{\theta}_p$ using a first-stage partial likelihood function involving only products of the p_t terms; (2) estimate $\boldsymbol{\theta}_p$ by solving the DP problem numerically, using a nested fixed point (NFXP) algorithm, applied to the partial likelihood function consisting of only products of p_t; (see, e.g., Rust, 1986, 1987, 1994, 1997). Given the enormous computational burden of a high-dimensional dynamic discrete choice model, a great deal of recent research seeks ways of making it more manageable; e.g., Aguirregabiria and Mira (2002) provide survey methods which avoid repeated full solution of the structural model in estimation, and the application of simulation and approximation methods (see, e.g., Aguirregabiria and Mira, 2007).

15.4 Non/semiparametric methods

In many situations of interest in economics, we are interested in identifying and estimating particular aspects of the joint distribution of a random vector $[y, \mathbf{x}^\top]$ based on a sample $\{y_i, \mathbf{x}_i^\top\}$, $i = 1, \ldots, n$, where $y \in \mathbb{R}$ and $\mathbf{x}$ is a mixture of continuous variables, $\mathbf{x}^c = [x^1, \ldots, x^{q_1}] \in \mathbb{R}^{q_1}$, and discrete, $\mathbf{x}^d = \left[x^{q_1+1}, \ldots, x^q\right]^\top \in S^d$, where S^d is the support of $\mathbf{x}^d$, and $q_2 = q - q_1$. For example, our aim could be to analyze the relationship between y and $\mathbf{x}$ encapsulated in the conditional mean function $E[y|\mathbf{x}] = m(\mathbf{x})$, the conditional density function $f(y|\mathbf{x})$, or on a finite-dimensional vector of parameters $\boldsymbol{\beta} \in \mathbb{R}^q$, leaving other aspects of the distribution unspecified. The available methods, such as kernels, rely on averaging observations which are closer to those we want to make inference about. A weighting function,

called a kernel, provides the necessary weights, and a smoothing parameter, known as the bandwidth, defines how close observations are to each other. A very comprehensive introduction to such methods can be found in Pagan and Ullah (1999), Li and Racine (2007), Yatchew (2003) and Racine and Ullah (2006). Kernel methods are by nature computationally intensive. The number of operations necessary for their application grows exponentially with the number of data points and variables used. In this section we illustrate with real data the computational issues arising from the implementation of kernel smoothing in applied non/semiparametric analysis of cross section information. Unless otherwise stated, all calculations were performed using the `np` and `gam` libraries of Hayfield and Racine (2007) and Hastie (2006) respectively, written in `R` version 2.4.1 or above. We use a Pentium IV (HT) processor, running at 3.20 GHz.

15.4.1 Nonparametric estimation

For two particular points, $\mathbf{x}_i = [\mathbf{x}_i^c, \mathbf{x}_i^d]$ and $\mathbf{x}_j = [\mathbf{x}_j^c, \mathbf{x}_j^d]$, let us define the functions:

$$K(\mathbf{x}_i^c, \mathbf{x}_j^c; h) = \prod_{l=1}^{q_1} \frac{1}{h_l} k\left(\frac{x_i^l - x_j^l}{h_l}\right), \tag{15.11}$$

$$L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda) = \prod_{l=1}^{q_2} l(x_i^l, x_j^l; \lambda_l), \tag{15.12}$$

where i indexes the "estimation data" and j the "evaluation data," which are typically the same. The kernel function $k(\cdot)$ for continuous variables satisfies $\int k(u)\, du = 1$ and some other regularity conditions depending on its order, p, and $h = [h_1, \ldots, h_{q_1}]^\top$ is a vector of smoothing parameters satisfying $h_s \to 0$ as $n \to \infty$ for $s = 1, \ldots, q_1$. Similarly, the kernel function $l(\cdot)$ for discrete variables lies between 0 and 1, and $\lambda = \left[\lambda_1, \ldots, \lambda_{q_2}\right]^\top$ is a vector of smoothing parameters such that $\lambda_s \in [0, 1]$, and $\lambda_s \to 0$ as $n \to \infty$ for $s = 1, \ldots, q_2$ (see, e.g., Li and Racine, 2003).

Functions (15.11) and (15.12) are the building blocks of kernel smoothing. For example, the Nadaraya–Watson estimator of $m(\cdot)$ evaluated at $\mathbf{x}_j$ is $\widehat{m}(\mathbf{x}_j) = \sum_{i=1, i\neq j}^n y_i K(\mathbf{x}_i^c, \mathbf{x}_j^c; h) L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda) / \sum_{i=1, i\neq j}^n K(\mathbf{x}_i^c, \mathbf{x}_j^c; h) \times L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)$.

15.4.1.1 Example: kernel density estimation

The marginal density function of $\mathbf{x}$ can be estimated at evaluation point $\mathbf{x}_i$ as:

$$\widehat{f}(\mathbf{x}_j) = (n-1)^{-1} \sum_{i=1}^n K(\mathbf{x}_i^c, \mathbf{x}_j^c; h) \times L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda). \tag{15.13}$$

We are interested in estimating the density of the average annual earnings in 1988 (measured in 1982 US dollars) of a random sample from two age groups: 19–26 (1,109 observations) and 30–32 (1,479 observations). This sample is a sub-set of a larger dataset considered in Mills and Zandvakili (1997). In this case, $q_1 = 1$ and $q_2 = 0$, and algorithm 15.4.1.1.1 illustrates the necessary steps.

Algorithm 15.4.1.1.1 Conditional density estimation – implementation

1. Select function $k(\cdot)$ in (15.11), and choose the smoothing parameter h by cross-validation maximum likelihood, i.e., select h to minimize:
$$\mathcal{L}_{[h]} = \sum_{i=1}^{n} \log \widehat{f}_{-i}(\mathbf{x}_i^c),$$
where $\widehat{f}_{-i}(\cdot)$ equals (15.13) after replacing $\sum_{i=1}^{n}$ by $\sum_{i=1;\, i\neq j}^{n}$.
2. Using h, found in the previous step, calculate $\widehat{f}(\mathbf{x}_i^c)$ in (15.13) for each $i = 1, \ldots, n$.
3. Plot (if feasible) or present summary statistics.

Parallelization

Since the above algorithm relies on local averaging, the computational order of step 2 is $O\left(n^2 q\right)$. Data-driven methods, such as bandwidth selection by cross-validation, performed in step 1, add an additional order of computational magnitude. The burden increases as the amount of available data rises. These numerical demands can potentially overwhelm the computational resources of modern day desktop workstations. For these reasons, although approximations are available (see, e.g., Silverman, 1982; Scott and Sheather, 1985) parallelization, as discussed in section 15.2.3, is an attractive alternative (see, e.g., Racine, 2002).

We proceed to implement algorithm 15.4.1.1.1 for each dataset using a high-performance computer cluster. Each implementation uses 10 multiple starts to numerically minimize $\mathcal{L}_{[h]}$ in step 1, and 1,000 bootstrap replications of step 2 to calculate a 95% confidence interval. The first experiment uses a single node with its 2×2.0 GHz quad-core Intel Xeon 5335 processor, i.e., two processors, and takes 27 minutes and 19 seconds of CPU time. The second experiment uses eight nodes with two of the above processors each, i.e., 16 processors in total, and takes 2 minutes and 52 seconds for completion. Computational time is reduced roughly 10 times by parallelization.[7] Both experiments provide the exact same result, i.e., Figure 15.1.

Both distributions are left-skewed, but earnings of young individuals show a larger right tail. Unlike their older counterparts, the distribution of average annual earnings for 19–26-year-old individuals seems to be a mixture of at least three heterogeneous groups.

15.4.1.2 Example: conditional density estimation

To illustrate the computational intensity of fully nonparametric methods, we consider the estimation of the conditional probability density function (p.d.f.) of vector $\mathbf{x}^c$ given another vector $\mathbf{x}^d$, i.e.:

$$\widehat{f}(\mathbf{x}_i^c | \mathbf{x}_i^d) \equiv \widehat{f}(\mathbf{x}_i^c, \mathbf{x}_i^d) / \widehat{p}(\mathbf{x}_i^d), \tag{15.14}$$
$$= \frac{\sum_{j=1}^{n} K(\mathbf{x}_i^c, \mathbf{x}_j^c; h) L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}{\sum_{j=1}^{n} L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}.$$

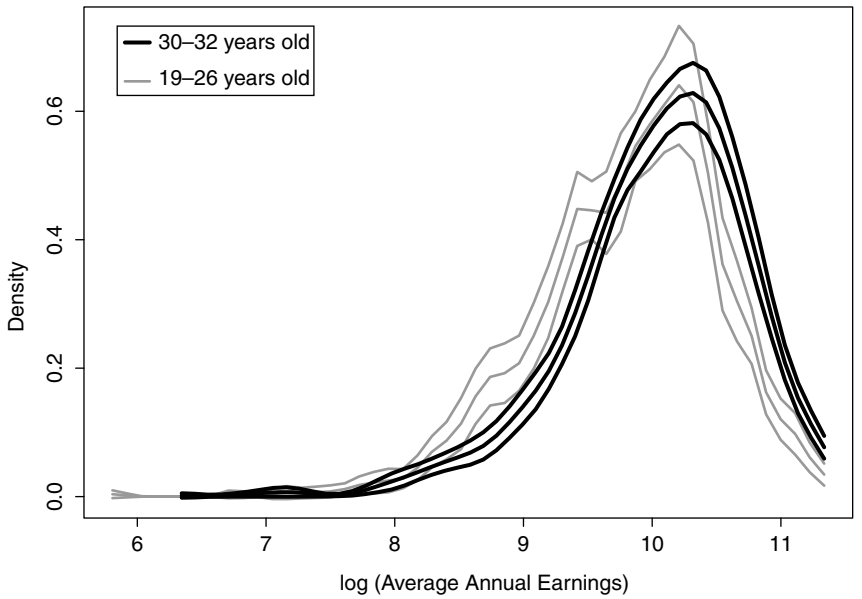

Figure 15.1 Marginal probability density functions

Algorithm 15.4.1.2.1 implements the necessary steps.

Algorithm 15.4.1.2.1 Conditional density estimation – implementation

1. Select functions $k(\cdot)$ and $l(\cdot)$ in (15.11) and (15.12), and vectors of smoothing parameters h and λ by cross-validation maximum likelihood, i.e., select $[h_1, \ldots, h_{q_1}, \lambda_1, \ldots, \lambda_{q_2}]$ to minimize:

$$\mathcal{L}_{[h,\lambda]} = \sum_{j=1}^{n} \log \widehat{f}_{-i}(\mathbf{x}_i^c | \mathbf{x}_i^d),$$

   where $\widehat{f}_{-i}(\cdot)$ equals (15.14) after replacing $\sum_{j=1}^{n}$ by $\sum_{j=1;\, j\neq i}^{n}$.
2. Using h and λ found in the previous step, calculate $\widehat{f}(\mathbf{x}_i^c | \mathbf{x}_i^d)$ in (15.14) for each $i = 1, \ldots, n$.
3. Plot (if feasible) or present summary statistics.

Using 453 observations of individual transportation mode choices in Croissant (2006) (dataset `Mode`), we estimate the conditional joint density of preferred transportation mode's cost, x_1, and time, x_2, given observed choices: car ($x^d = 1$), carpool ($x^d = 2$), bus ($x^d = 3$), and rail ($x^d = 4$). The results are shown in Figure 15.2. The estimated joint p.d.f.s are multi-modal. This might indicate that other characteristics besides cost influence transportation mode choices.

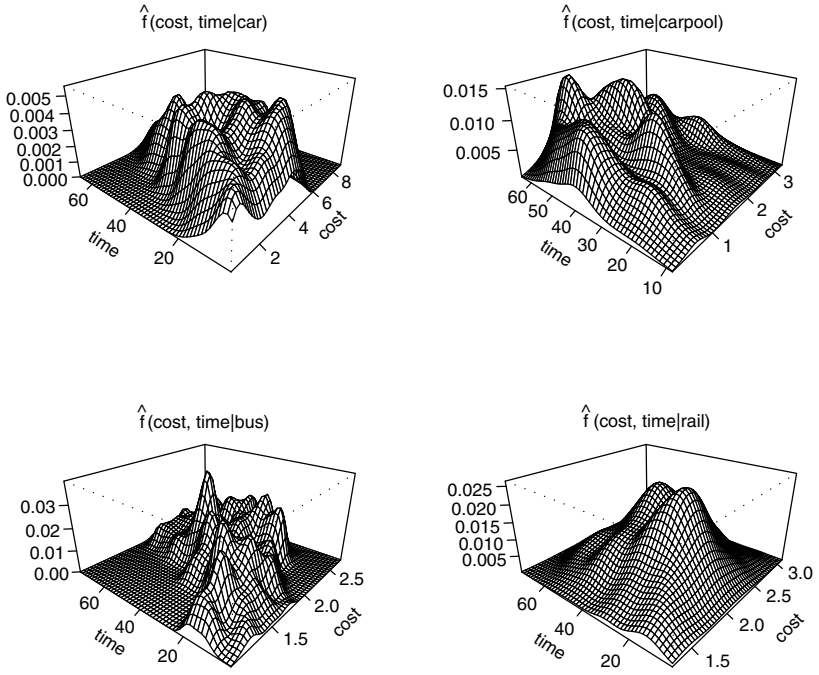

Figure 15.2 Multivariate conditional p.d.f.

15.4.1.3 Example: additive models

Kernels, as well as many other nonparametric methods, do not perform well when q is large. The sparseness of data in this setting inflates the variance of the estimates, and the numerical accuracy of estimates rapidly decreases with the number of regressors. This problem is sometimes referred to as the "curse of dimensionality." Computationally, the curse of dimensionality means that for kernel methods, as q becomes large relative to a fixed sample size n, division by 0 becomes more frequent in the calculation of $\widehat{m}(\mathbf{x})$.

To overcome these difficulties, Stone (1985) proposed additive models, i.e.:

$$m(\mathbf{x}) = m_1\left(x_1^c\right) + \cdots + m_{q_1}\left(x_{q_1}^c\right),$$

where the x_l^cs are all univariate continuous variables, and the $m_l(\cdot)$ are unknown functions for $l = 1, \ldots, q_1$. A benefit of an additive model is that estimates of the individual terms explain how the dependent variable changes with the corresponding independent variables. Suppose $q_1 = 4$, then the following identities:

$$E[y - m_2(x_2^c) - m_3(x_3^c) - m_4(x_4^c)|x_1^c] = m_1(x_1^c),$$
$$E[y - m_1(x_1^c) - m_3(x_3^c) - m_4(x_4^c)|x_2^c] = m_2(x_2^c),$$

$$E[y - m_1(x_1^c) - m_2(x_2^c) - m_4(x_4^c)|x_3^c] = m_3(x_3^c), \text{ and}$$
$$E[y - m_1(x_1^c) - m_2(x_2^c) - m_3(x_3^c)|x_4^c] = m_4(x_4^c),$$

imply the backfitting algorithm 15.4.1.3.1.

Algorithm 15.4.1.3.1 Standard backfitting algorithm – implementation

1. Select initial estimates $\widehat{m}_1^{[0]}(x_1^c), \ldots, \widehat{m}_4^{[0]}(x_4^c)$, say $\widehat{m}_l^{[0]}\left(x_l^c\right) = 0$ for all $l = 1, \ldots, 4$.
2. For step $s = 1, 2, \ldots$, obtain:

$$m_1^{[s]}(x_1^c) = \widehat{E}[y_i - \widehat{m}_2^{[s-1]}(x_2^c) - \widehat{m}_3^{[s-1]}(x_3^c) - \widehat{m}_4^{[s-1]}(x_4^c)|x_{1;i}^c = x_1^c],$$
$$\vdots = \vdots$$
$$m_4^{[s]}(x_4^c) = \widehat{E}[y_i - \widehat{m}_1^{[s-1]}(x_1^c) - \widehat{m}_2^{[s-1]}(x_2^c) - \widehat{m}_3^{[s-1]}(x_3^c)|x_{4;i}^c = x_4^c],$$

   where, for a random variable a_i, $\widehat{E}[a_i|x_{l;i}^c = x_l^c]$ is the univariate kernel estimator of $E[a_i|x_{l;i}^c = x_l^c]$ using bandwidth h_l.
3. Continue iterations in step 2. until a pre-specified convergence criterion is reached.

Suppose it takes d iterations for the above algorithm to converge, then the rate of convergence of $\sum_{l=1}^4 \widehat{m}_l^{[d]}\left(x_l^c\right)$ is the same as if the regression model were a function of a single continuous variable instead.

We use a cross-section of 872 observations from Switzerland (see Gerfin, 1996) in order to illustrate the methodology. Whether or not a woman participates in the labor market, $E[y = 1|\mathbf{x}] \equiv \Pr[\mathbf{x}]$, is modeled as:

$$\log\left\{\frac{\Pr[\mathbf{x}]}{1 - \Pr[\mathbf{x}]}\right\} = \sum_{l=1}^{4} m_l\left(x_l\right),$$

where x_1 is the log of non-labor income (LNNLINC), x_2 is age in years divided by 10 (AGE), x_3 is the number of years of formal education (EDUC), and x_4 is the number of children (NC). Figure 15.3 illustrates the results. Each panel shows the regressors' individual effects on their entire observed support. Both LNNLINC and AGE certainly have quadratic effects, while the estimated effects of EDUC and NC might suffer from boundary effects.

Marginal integration is an alternative to backfitting (see, e.g., Linton and Nielsen, 1995; Linton and Härdle, 1996).

15.4.2 Semiparametric estimation

Another way to alleviate the curse of dimensionality is to finitely parameterize certain aspects of the joint distribution of y and $\mathbf{x}$, e.g., its mean, while allowing others to remain unknown, e.g., the conditional variance $\text{var}(y|\mathbf{x})$. The object of

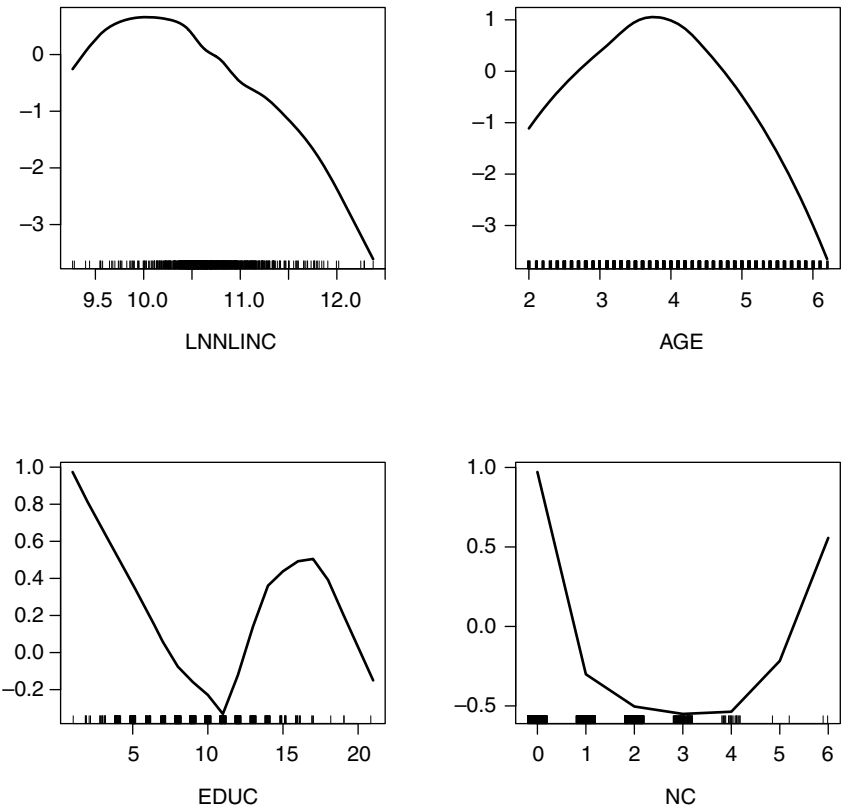

Figure 15.3 Generalized additive model: labor force participation

interest then becomes a finite dimensional parameter, whose estimator is numerically calculated in multiple stages with fully nonparametric calculations in the first stages. This is known as semiparametric estimation, and its use is becoming increasingly popular with the advent of faster and cheaper computing. Although we only discuss a few of these estimators, a more complete exposition can be found in, e.g., Horowitz (1998), Pagan and Ullah (1999), and Li and Racine (2007).

15.4.2.1 Example: efficient estimation with heteroskedasticity of unknown form

The heteroskedastic linear model specifies $E[y|\mathbf{x}] = \mathbf{x}^\top \boldsymbol{\beta}$ and $\text{var}(y|\mathbf{x}) = \sigma^2(\mathbf{x})$, where the variance function $\sigma^2(\cdot)$ is left unspecified. Robinson (1987) proposed a semiparametric feasible generalized least squares (GLS) estimator $\widehat{\boldsymbol{\beta}}$ that requires the nonparametric estimation of $\sigma_i^2 \equiv \sigma^2(\mathbf{x}_i)$ in:

$$\widehat{\boldsymbol{\beta}} = (\textstyle\sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^\top \widehat{\sigma}_i^{-2})^{-1} (\sum_{i=1}^n \mathbf{x}_i y_i \widehat{\sigma}_i^{-2}), \tag{15.15}$$

by k-nearest neighbor methods. In particular, let $R_{x_s} \equiv R_n(x_s)$ denote the Euclidean distance between x_s and its k_s-th nearest neighbor among $x_{s;i}$, for $i = 1, \ldots, n$ and

$s = 1, \ldots, q_1$, then:

$$\widehat{\sigma}_i^2 = \frac{\sum_{j=1}^n \widehat{u}_j^2 K(\mathbf{x}_i^c, \mathbf{x}_j^c; R_{\mathbf{x}^c}) L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}{\sum_{j=1}^n K(\mathbf{x}_i^c, \mathbf{x}_j^c; R_{\mathbf{x}^c}) L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}, \tag{15.16}$$

where $\widehat{u}_j^2$ is the residual from first-stage ordinary least squares (OLS) regression of y_i on $\mathbf{x}_i$. Robinson (1987) showed that (15.15) is adaptive when $k_1 = \cdots = k_{q_1}$, $k(u) = (1/2) \times \mathbb{I}(|u| \leq 1)$, and $(\mathbf{x}_i^d, \mathbf{x}_j^d)$ is empty in (15.11), (15.12), and (15.16). Its asymptotic variance can be estimated as:

$$\widehat{\text{asy. var}}(\widehat{\boldsymbol{\beta}}) = (\textstyle\sum_{i=1}^n \mathbf{x}_i \mathbf{x}_i^\top \widehat{\sigma}_i^{-2})^{-1}. \tag{15.17}$$

For illustration we will fit a linear hedonic pricing model of house attributes using data collected by Ho (1995) of 92 detached homes in the Ottawa area that were sold in 1987. The data file contains continuous variables such as sale price (SALEPRIX), average neighborhood income (AVGINC), distance to highway (DISTHWY), lot size (LOTAREA), square footage of usable space (USESPACE), location coordinate in the south (SOUTH), and west (WEST). It also contains discrete variables such as indicators for the presence of fire place (FIREPLAC), garage (GARAGE), luxurious bath (LUXBATH), and the number of bedrooms (NRBED). Using SALEPRIX as y and the remaining variables as regressors $\mathbf{x}$, algorithm 15.4.2.1.1 provides implementation details.

Algorithm 15.4.2.1.1 Semiparametric feasible GLS – implementation

1. Regress y on $\mathbf{x}$ by simple OLS and save the fitted squared residuals, $\{\widehat{u}_i^2\}_{i=1}^n$.
2. Select functions $k(\cdot)$ and $l(\cdot)$ in (15.11) and (15.12), and choose vectors of smoothing parameters k and λ by leave-one-out cross-validation, i.e., select $[h_1, \ldots, h_{q_1}, \lambda_1, \ldots, \lambda_{q_2}]$ to minimize:

$$CV_{[k,\lambda]} = \textstyle\sum_{i=1}^n \left[\widehat{u}_i^2 - \widehat{\sigma}_{-i}^2\right]^2,$$

   where $\widehat{\sigma}_{-i}^2$ equals (15.16) after replacing $\sum_{j=1}^n$ by $\sum_{j=1;\, j\neq i}^n$.
3. Using k and λ found in the previous step, calculate $\widehat{\sigma}_i^2$ in (15.16) for each $i = 1, \ldots, n$.
4. Calculate (15.15) and (15.17).

The results are presented in Table 15.2. The first column shows the results from running simple OLS with corrected standard errors. The second column presents results using algorithm 15.4.2.1.1. Although there is not much difference between parameter point estimates, the estimated standard errors have been reduced dramatically.

Table 15.2 Hedonic prices of housing attributes: estimated models

	(1) OLS		*(2) Semip. FGLS*		*(3) Partially linear*

Notes: s represents the squared root of the estimated variance of the regression. FGLS = feasible generalized least squares.

15.4.2.2 Example: partially linear model

The partially linear model specifies $E[y|\mathbf{z},\mathbf{x}] = \mathbf{z}^\top\boldsymbol{\beta} + g(\mathbf{x})$, where $g(\mathbf{x})$ is left unspecified, and $\mathbf{z} = [z_1,\ldots,z_p] \in \mathbb{R}^p$. In particular, assuming that, for $u = y - \mathbf{z}^\top\boldsymbol{\beta} - g(\mathbf{x})$, $E[u|\mathbf{z},\mathbf{x}] = 0$, and $\text{var}(u|\mathbf{z},\mathbf{x}) = \sigma^2(\mathbf{z},\mathbf{x})$, and after observing that $E[y|\mathbf{x}] = E[\mathbf{z}|\mathbf{x}]^\top\boldsymbol{\beta} + g(\mathbf{x})$, Robinson (1988) proposed an estimator $\widehat{\boldsymbol{\beta}}$ that requires the nonparametric estimation of $E[y_i|\mathbf{x}_i]$, and $E[\mathbf{z}_i|\mathbf{x}_i]$, $i = 1,\ldots,n$, in:

$$\widehat{\boldsymbol{\beta}} = \left(\sum_{i=1}^n (\mathbf{z}_i - \widehat{E}[\mathbf{z}_i|\mathbf{x}_i])(\mathbf{z}_i - \widehat{E}[\mathbf{z}_i|\mathbf{x}_i])^\top\right)^{-1}\left(\sum_{i=1}^n (\mathbf{z}_i - \widehat{E}[\mathbf{z}_i|\mathbf{x}_i])(y_i - \widehat{E}[y_i|\mathbf{x}_i])\right), \tag{15.18}$$

by the Nadaraya–Watson estimator, i.e., for vectors of smoothing parameters h and λ:

$$\widehat{E}[y_i|\mathbf{x}_i] = \frac{\sum_{j=1}^n y_i K(\mathbf{x}_i^c, \mathbf{x}_j^c; h) L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}{\sum_{j=1}^n L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}, \tag{15.19}$$

$$\widehat{E}[z_{l;i}|\mathbf{x}_i] = \frac{\sum_{j=1}^n z_{l;i} K(\mathbf{x}_i^c, \mathbf{x}_j^c; h) L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}{\sum_{j=1}^n L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}, \text{ for } l = 1,\ldots,p. \tag{15.20}$$

Its asymptotic variance can be estimated consistently by:

$$\widehat{\text{asy. var}}(\widehat{\boldsymbol{\beta}}) = n^{-1}\widehat{\Phi}^{-1}\widehat{\Omega}\widehat{\Phi}^{-1}, \tag{15.21}$$

where $\widehat{\Phi} = n^{-1}\sum_{i=1}^{n}(\mathbf{z}_i - \widehat{E}[\mathbf{z}_i|\mathbf{x}_i])(\mathbf{z}_i - \widehat{E}[\mathbf{z}_i|\mathbf{x}_i])^{\top}$, and $\widehat{\Omega} = n^{-1}\sum_{i=1}^{n}\widehat{u}_i^2(\mathbf{z}_i - \widehat{E}[\mathbf{z}_i|\mathbf{x}_i])(\mathbf{z}_i - \widehat{E}[\mathbf{z}_i|\mathbf{x}_i])^{\top}$, with $\widehat{u}_i = y_i - \mathbf{z}_i^{\top}\widehat{\boldsymbol{\beta}} - \widehat{g}(\mathbf{x}_i)$, and:

$$\widehat{g}(\mathbf{x}_i) = \frac{\sum_{j=1}^{n}(y_i - \mathbf{z}_i^{\top}\widehat{\beta})K(\mathbf{x}_i^c, \mathbf{x}_j^c; h)L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}{\sum_{j=1}^{n} L(\mathbf{x}_i^d, \mathbf{x}_j^d; \lambda)}. \tag{15.22}$$

Algorithm 15.4.2.2.1 makes precise the necessary steps for the above calculations.

Algorithm 15.4.2.2.1 Partially linear model – implementation

1. For each $l = 1, \ldots, p$, select functions $k(\cdot)$ and $l(\cdot)$ in (15.11) and (15.12), and choose vectors of smoothing parameters h and λ by leave-one-out cross-validation, i.e., select $[h_1, \ldots, h_{q_1}, \lambda_1, \ldots, \lambda_{q_2}]$ to minimize:

$$CV_{[h,\lambda]} = \sum_{i=1}^{n}\left[y_i - \widehat{E}_{-i}[y_i|\mathbf{x}_i]\right]^2$$
$$CV_{[h,\lambda]} = \sum_{i=1}^{n}\left[z_{l;i} - \widehat{E}_{-i}[z_{l;i}|\mathbf{x}_i]\right]^2,$$

   where $\widehat{E}_{-i}$ equals (15.19) and (15.20) after replacing $\sum_{j=1}^{n}$ by $\sum_{j=1;\, j\neq i}^{n}$.
2. Using the bandwidths found in the previous step, calculate (15.19) and (15.20) for each data point $i = 1, \ldots, n$.
3. Calculate (15.18) and (15.21).
4. Select functions $k(\cdot)$ and $l(\cdot)$ in (15.11) and (15.12), and choose vectors of smoothing parameters h and λ by leave-one-out cross-validation, i.e., select $[h_1, \ldots, h_{q_1}, \lambda_1, \ldots, \lambda_{q_2}]$ to minimize:

$$CV_{[h,\lambda]} = \sum_{i=1}^{n}\left[y_i - \mathbf{z}_i^{\top}\widehat{\beta} - \widehat{E}_{-i}[y_i - \mathbf{z}_i^{\top}\widehat{\beta}|\mathbf{x}_i]\right]^2,$$

   where $\widehat{E}_{-i}$ equals (15.19) after replacing y_i by $y_i - \mathbf{z}_i^{\top}\widehat{\beta}$ and $\sum_{j=1}^{n}$ by $\sum_{j=1;\, j\neq i}^{n}$.
5. Calculate (15.22) using the bandwidths found in the previous step for each $i = 1, \ldots, n$.

Since house location (WEST and SOUTH) has no natural parametric effect in housing prices, we proceed to include a two-dimensional nonparametric effect, $g(\cdot)$, in the hedonic pricing model of housing attributes in section 15.4.2.2. The results are presented in column 3 of Table 15.2.

15.4.2.3 Example: binary choice model

The binary choice model specifies the following relationship:

$$y = \mathbb{I}(\mathbf{x}^{\top}\boldsymbol{\beta} + u > 0), \tag{15.23}$$

where $\mathbb{I}$ is the indicator function, and u represents unobserved characteristics with continuous symmetric distribution $F(\cdot)$ which is assumed independent of $\mathbf{x}$. It then

follows that:

$$\Pr[y = 1|\mathbf{x}] = E[y|\mathbf{x}] = F(\mathbf{x}^\top \boldsymbol{\beta}), \tag{15.24}$$

where $\mathbf{x}^\top \boldsymbol{\beta}$ is known as a *single index*. In parametric probit and logit models, the unknown parameter $\boldsymbol{\beta}$ in (15.23) is obtained by numerically maximizing the log-likelihood function:

$$\sum_{i=1}^{n} \{y_i \log[F(\mathbf{x}_i^\top \boldsymbol{\beta})] + (1 - y_i) \log[1 - F(\mathbf{x}_i^\top \boldsymbol{\beta})]\}, \tag{15.25}$$

where $F(\cdot)$ is assumed to be a normal or logistic distribution function respectively. Column 1 in Table 15.3 shows results from fitting a probit model to female labor participation decisions in Portugal, using 2,339 observations taken from Martins (2001). The regressors include variables such as the number of children younger than 18 living in the family (CHILD), the number of children younger than three years of age (YCHILD), the number of years of formal schooling (EDU), the log of the husband's monthly wages (LNHW), women's age divided by 10 and 100 respectively (AGE and AGE2). The model does not include a constant and the coefficient multiplying AGE has been normalized to be equal to one for comparison purposes.

Notice that all regressors, except the number of years of formal schooling, have a negative effect on the probability that a woman works for wages.

If $F(\cdot)$ is unknown, then $F(\mathbf{x}^\top \boldsymbol{\beta})$ is observationally equivalent to $\overline{F}\left(\mathbf{x}^\top \boldsymbol{\beta} - a\right)$, and $\widetilde{F}\left(\mathbf{x}^\top (\boldsymbol{\beta}/c)\right)$, with $\overline{F}(u) = F(u + a)$ and $\widetilde{F}(u) = F(c \cdot u)$ respectively $\forall a, c \in \mathbb{R}$. Under these circumstances, restrictions are needed to identify the unknown vector of parameters $\boldsymbol{\beta}$. For example, the so called location-scale normalization sets any intercept in $\mathbf{x}^\top \boldsymbol{\beta}$ equal to 0, and the coefficient of a continuous regressor (say the first regressor x_1) equal to 1.

Let us define $\widetilde{\mathbf{x}}^c = [x_2^c, \ldots, x_{q_1}^c]$, $\widetilde{\mathbf{x}} = [\widetilde{\mathbf{x}}^c, \mathbf{x}^d]$, $\mathbf{x} = [x_1, \widetilde{\mathbf{x}}]$, $\widetilde{\boldsymbol{\beta}} = [\beta_2, \ldots, \beta_{q_1}, \beta_{q_1+1}, \ldots, \beta_{q_2}]^\top$, and $\boldsymbol{\beta} \equiv (1, \widetilde{\boldsymbol{\beta}}^\top)$. Semiparametric methods have been shown to

identify and consistently estimate $\widetilde{\boldsymbol{\beta}}$ when $F(\cdot)$ is only known to be a non-constant smooth function on the support of $\mathbf{x}^\top\boldsymbol{\beta}$; and varying the values of $\mathbf{x}^d$ does not divide the support of $\mathbf{x}^\top\boldsymbol{\beta}$ into disjoint subsets (see Horowitz, 1998).

Note that, for given $\boldsymbol{\beta}$, a consistent nonparametric estimator of (15.24) is:

$$\widehat{F}(\mathbf{x}_i^\top\boldsymbol{\beta}) = \frac{\sum_{j=1}^n y_i k((\mathbf{x}_i^\top\boldsymbol{\beta} - \mathbf{x}_j^\top\boldsymbol{\beta})/h)}{\sum_{j=1}^n k((\mathbf{x}_i^\top\boldsymbol{\beta} - \mathbf{x}_j^\top\boldsymbol{\beta})/h)}. \tag{15.26}$$

Klein and Spady's estimator

Klein and Spady (1993) proposed estimating $\boldsymbol{\beta}$ by maximizing (15.25) after replacing $F(\mathbf{x}_i^\top\boldsymbol{\beta})$ by $\widehat{F}_{-i}(\mathbf{x}_i^\top\boldsymbol{\beta})$, where $\widehat{F}_{-i}(\mathbf{x}_i^\top\boldsymbol{\beta})$ is like $\widehat{F}(\mathbf{x}_i^\top\boldsymbol{\beta})$ but with $\sum_{j=1}^n$ replaced by $\sum_{j=1;\, j\neq i}^n$ in (15.26). Computationally, the maximization must be performed numerically by solving the first order conditions of the problem. Under regularity conditions, Klein and Spady showed that the resulting estimator $\widehat{\boldsymbol{\beta}}$ has an asymptotic normal distribution. Furthermore, they showed that the asymptotic variance of their estimator attains the semiparametric efficiency bound, and that it can be consistently estimated by:

$$\widehat{\text{asy. var}}(\widehat{\boldsymbol{\beta}}) = \left(\sum_{i=1}^n \widetilde{\mathbf{x}}_i\widetilde{\mathbf{x}}_i^\top [\widehat{F}_{-i}^{(1)}(\mathbf{x}_i^\top\widehat{\boldsymbol{\beta}})]^2 / [\widehat{F}_{-i}(\mathbf{x}_i^\top\widehat{\boldsymbol{\beta}})(1-\widehat{F}_{-i}(\mathbf{x}_i^\top\widehat{\boldsymbol{\beta}}))]\right)^{-1}, \tag{15.27}$$

where $\widehat{F}_{-i}^{(1)}(\cdot)$ is the first derivative of $\widehat{F}_{-i}(\cdot)$. Algorithm 15.4.2.3.1 describes the necessary steps.

Algorithm 15.4.2.3.1 Klein and Spady (1993) – implementation

1. Select function $k(\cdot)$ in (15.26), and numerically find jointly the bandwidth h and vector of coefficients $\boldsymbol{\beta}$ that minimizes the leave-one-out estimated log-likelihood:

$$\sum_{i=1}^n \{y_i \log[\widehat{F}_{-i}(\mathbf{x}_i^\top\boldsymbol{\beta})] + (1-y_i)\log[1-\widehat{F}_{-i}(\mathbf{x}_i^\top\boldsymbol{\beta})]\},$$

   where $\widehat{F}_{-i}(\cdot)$ equals (15.26) after replacing $\sum_{j=1}^n$ by $\sum_{j=1;\, j\neq i}^n$.
2. Using the bandwidth and vector of coefficients found in the previous step, calculate $\widehat{F}_{-i}^{(1)}(\cdot)$ and $\widehat{F}_{-i}(\cdot)$ at each data point $i = 1, \ldots, n$.
3. Calculate (15.27).

Column 2 in Table 15.3 shows results from applying the above methodology to the modeling of female labor force participation decisions. Although signs coincide with those of the fully parametric model (column 1), their magnitudes and standard errors are remarkably different. Martins (2001) pointed out that this considerable efficiency gain may occur because the semiparametric model is sufficiently perturbed from the usual probit specification for women with low index values.

Ichimura's estimator

The semiparametric least squares (SLS) estimator of Ichimura (1993) numerically minimizes:

$$\sum_{i=1}^{n}[y_i - \widehat{F}_{-i}(\mathbf{x}_i^\top \boldsymbol{\beta})]^2, \tag{15.28}$$

with respect to $\boldsymbol{\beta}$, where, as before, $\widehat{F}_{-i}(\cdot)$ is the kernel estimator for the unknown link function $F(\cdot)$. The resulting estimator, $\widehat{\boldsymbol{\beta}}$, is asymptotically normally distributed, and its asymptotic variance can be consistently estimated by:

$$\widehat{\text{asy. var}}(\widehat{\boldsymbol{\beta}}) = n^{-1}\widehat{\Gamma}^{-1}\widehat{\Sigma}\widehat{\Gamma}^{-1}, \tag{15.29}$$

where:

$$\widehat{\Gamma} = n^{-1}\sum_{i=1}^{n}\widetilde{\mathbf{x}}_i\widetilde{\mathbf{x}}_i^\top[\widehat{F}_{-i}^{(1)}(\mathbf{x}_i^\top\widehat{\boldsymbol{\beta}})]^2, \text{ and} \tag{15.30}$$

$$\widehat{\Sigma} = n^{-1}\sum_{i=1}^{n}\widetilde{\mathbf{x}}_i\widetilde{\mathbf{x}}_i^\top[\widehat{F}_{-i}^{(1)}(\mathbf{x}_i^\top\widehat{\boldsymbol{\beta}})]^2[y_i - \widehat{F}_{-i}(\mathbf{x}_i^\top\boldsymbol{\beta})]^2. \tag{15.31}$$

Column 3 in Table 15.3 presents the results of applying algorithm 15.4.2.3.2 to our example.

Algorithm 15.4.2.3.2 Ichimura (1993) – implementation

1. Select function $k(\cdot)$ in (15.26), and numerically find jointly the bandwidth h and vector of coefficients $\boldsymbol{\beta}$ that minimizes the semiparametric least squares objective function (15.28).
2. Using the bandwidth and vector of coefficients found in the previous step, calculate $\widehat{F}_{-i}^{(1)}(\cdot)$ and $\widehat{F}_{-i}(\cdot)$ at each data point $i = 1, \ldots, n$.
3. Calculate (15.29), (15.30) and (15.31).

The results differ mainly in the magnitude of the effects of each regressor as well as in their precision. Both semiparametric estimators provide estimates of the participation probabilities (Part. prob.) closer to the actual 1,400 women in the sample that are observed to work for wages. The parametric probit specification overestimates this quantity.

It should be emphasized that, unlike Klein and Spady's estimator, Ichimura's is applicable to a wider range of problems where the response y_i is not only binary, but takes on different discrete or continuous values.

15.4.2.4 Further considerations

The numerical stability of likelihood cross-validated bandwidths in step 1 in algorithms 15.4.1.1.1 and 15.4.1.2.1 might be affected by outliers. However, the suggested likelihood cross-validated method may work well for thin-tailed distributions.

In the semiparametric models discussed above, the first-order asymptotic distribution of the normalized and centered estimators does not depend on the

smoothing parameter(s). Therefore, at least asymptotically, any sequence of smoothing parameters is going to give a consistent estimator as long as it satisfies certain conditions. However, this observation does not necessarily imply that such an estimator is going to be optimal in the mean squared error (MSE) sense (see, e.g., Linton, 1995; Härdle, Hall and Ichimura, 1993).

Finally, the asymptotic theory for the above estimators requires trimming those observations arbitrarily close to the boundary of their observed supports. We did not address this in the above discussion, partly because of the lack of guidance on how to select trimming parameters with fixed sample sizes, and partly because no trimming amounts to assuming that the actual support of the variables involved is larger than that observed in the data.

15.5 Modeling heterogeneity

In the introductory section we noted that heterogeneity is a pervasive feature in microeconometrics. The most tractable way of handling observed heterogeneity is to control for it by including sociodemographic variables such as family composition, age, gender, location, etc. The potential of this approach is limited by the scope of the available data. There still remains variation that is induced by unobserved factors, referred to in econometrics as unobserved heterogeneity.

Neglecting individual-level unobserved heterogeneity can have potentially serious consequences, analogous to those of omitted regressors. Even when heterogeneity is explicitly accommodated, the precise manner and assumptions under which it enters the model can have important consequences. Hence, not surprisingly, every proposed econometric specification is routinely scrutinized for the manner in which it accommodates heterogeneous behavior.

Not only are models with heterogeneity more flexible, and hence generally fit the data better, but they also lead to relaxation of strong constraints. For example, the multinomial logit (MNL) discrete choice model is subject to the strong restriction of independence of irrelevant alternatives (IIA), whereas the random parameter version of the MNL does not have the IIA restriction.

There are a number of distinctive ways of allowing for unobserved heterogeneity.

1. Treat heterogeneity either as an additive or a multiplicative random effect (uncorrelated with included regressors) or as a fixed effect (potentially correlated with included regressors). Within the class of random effects models, heterogeneity distributions may be treated as continuous or discrete. Examples include a random intercept in linear regression and linear panel models, fixed effects in linear and nonlinear panels, and multiplicative heterogeneity in models of counts and durations.
2. Allow both intercept and slope parameters to vary randomly and parametrically. Examples include random parameter discrete choice and outcome models and finite mixture models.
3. Model heterogeneity explicitly in terms of both observed and unobserved variables using mixed models, hierarchical models and/or models of clustering.

Which approach one takes to modeling heterogeneity and how it is combined with other assumptions, e.g., functional forms, has important consequences for computation. One researcher may impose strong functional forms but achieve modeling flexibility by allowing for behavior heterogeneity. Another may make very flexible functional form assumptions but not allow explicitly for unobserved heterogeneity. Currently both strategies coexist in the literature.

We now consider computational aspects of the different modeling strategies.

1. Under the fixed effects specification, the most popular approach is to treat heterogeneity in the nuisance parameter framework and eliminate it by a suitable transformation such as: within transformation; first-difference transformation; differences-in-differences transformation. In some parametric models with fixed effects, the nuisance parameters can be eliminated by applying the conditional likelihood approach that replaces the fixed effect by a sufficient statistic, but such a statistic is not always available.
2. Dummy variables can be introduced to capture individual-specific heterogeneity. This approach is familiar in linear panel models, but due to the incidental parameter problem, this formulation may not lead to consistent estimates. In panel models with a large cross-section dimension (n), the estimation dimension also increases and in nonlinear models this may lead to computational challenges, though there are examples where ingenious algorithms can address the issues (e.g., Greene, 2004a, 2004b).
3. In random effects models the standard and time-honored approach involves integrating out the distribution of unobserved heterogeneity, as was discussed in section 15.3.3. Such integration is often implemented numerically, leading to nontrivial computational challenges, especially if parameter dimension is large. Random parameter multinomial logit and multinomial probit models are two outstanding examples of this approach (see Train, 2003).

All the foregoing discussion has been carried out by reference to individual level heterogeneity. Heterogeneity may also exist at the level of groups, which leads to issues of clustering and interdependence that create additional computational challenges. A group can be a geographical, social, ethnic, or merely a sampling unit that exhibits some form of interdependent behavior induced by common environment or culture. Group membership may be modeled as an observable or a latent variable, analogous to fixed and random effects formulations in panel data.

In the remainder of this section we illustrate, using two data-based examples, how modeling heterogeneity can be computationally demanding but empirically informative.

15.5.1 Example: quantile regression

Whereas the standard linear regression is a useful tool for summarizing the average relationship between the outcome variable of interest and a set of regressors, i.e., the conditional mean function, $E[y|\mathbf{x}]$, QR can provide a more complete picture

of the relationship between outcome y and regressors $\mathbf{x}$ at different points in the distribution of y.

As stated in section 15.3.2, the objective function for QR is in the L_1-norm. Unlike the squared error loss function of the OLS framework, in the case of QR the loss is expressed through an asymmetric absolute loss function. The special case of median (LAD) regression corresponds to $q = 0.5$.

QRs have a certain robustness property and they also permit more informative modeling of the data. Specifically, the median regression is more robust to outliers compared with the mean regression. QR facilitates a richer interpretation of the data because it permits the study of the impact of regressors on both the location and scale parameters of the model, while avoiding parametric assumptions about data.

Other attractive properties of QR are as follows: (i) it is consistent under weaker stochastic assumptions than least squares estimation; (ii) it is based on weaker distributional assumptions; (iii) it has an equivariance to monotone transformations property, which implies that it does not run into the retransformation problem. The quantiles of a transformed variable y, denoted $h(y)$, where h is a monotonic function, equal the transforms of the quantiles of $y : Q_{h(y)}(\tau) = h(Q_y(\tau))$. Hence, if the quantile model is expressed in terms of $h(y)$, e.g., $\ln(y)$, then one can use the inverse transformation to translate the results back to y. This is not possible for the least squares estimator, i.e., if $E[h(y)] = \mathbf{x}^\top \boldsymbol{\beta}$, then $E[y|\mathbf{x}] \neq h^{-1}(\mathbf{x}^\top \boldsymbol{\beta})$.

Impediments to the use of QR are twofold. First, there are computational hurdles. Because the objective function is not differentiable, the gradient optimization methods mentioned in section 15.3 cannot be used and, instead, linear programming methods are applied. There is no closed-form solution for $\widehat{\boldsymbol{\beta}}_q$ and hence the asymptotic distribution of $\widehat{\boldsymbol{\beta}}_q$ cannot be obtained using standard methods. An analytical expression for the asymptotic variance of $\widehat{\boldsymbol{\beta}}_q$ comes from the result that:

$$\sqrt{n}(\widehat{\boldsymbol{\beta}}_q - \boldsymbol{\beta}_q) \xrightarrow{d} \mathcal{N}\left[\mathbf{0}, q(1-q)\mathbf{A}^{-1}\mathbf{B}\mathbf{A}^{-1}\right], \tag{15.32}$$

where $n^{-1}\sum_{i=1}^{n} \mathbf{x}_i\mathbf{x}_i^\top \xrightarrow{p} \mathbf{A}$, $n^{-1}\sum_{i=1}^{n} f_{u_q}(\xi(q)|\mathbf{x}_i)\mathbf{x}_i\mathbf{x}_i^\top \xrightarrow{p} \mathbf{B}$, $\xrightarrow{p}$ represents convergence in probability, and $f_{u_q}(\xi(q)|\mathbf{x})$ is the conditional density of the error term $u_q = y - \mathbf{x}^\top \boldsymbol{\beta}_q$ evaluated at $\xi(q)$, i.e., the q-quantile of u_q. Estimation of the variance of $\widehat{\boldsymbol{\beta}}_q$ is complicated by the need to estimate $f_{u_q}(\xi(q)|\mathbf{x})$. It is easier to obtain standard errors for $\widehat{\boldsymbol{\beta}}_q$ using the computationally more intensive bootstrap method, as is done in the example that follows.

Buchinsky (1995) evaluated a number of variance estimators for the QR in a Monte Carlo setting and recommended the use of a "design matrix" (or paired) bootstrap estimator. Application of the bootstrap variance is shown in algorithm 15.5.1.0.1.

Computational advances have made the application of QR more accessible to users and many popular packages include it. As an illustration we report a regression analysis of total medical expenditure (TOTEXP) by the Medicare elderly. The data

Algorithm 15.5.1.0.1 QR–bootstrap standard errors

1. Draw $(y_i^b, \mathbf{x}_i^{\top b})$, $b = 1, \ldots, B$, $i = 1, \ldots, n$, a (paired) bootstrap sample drawn from the empirical distribution of $(y_i, \mathbf{x}_i^{\top})$.
2. Estimate the conditional quantile function $\mathbf{x}_i^{\top b} \widehat{\boldsymbol{\beta}}_q^b$, where $\widehat{\boldsymbol{\beta}}_q^b$ is the bootstrap estimate of $\boldsymbol{\beta}_q$.
3. The bootstrap estimate of the variance, $\text{var}(\widehat{\boldsymbol{\beta}}_q)$, is given by:

$$\widehat{\text{var}}[\widehat{\boldsymbol{\beta}}_q] = \frac{n}{B} \sum (\widehat{\boldsymbol{\beta}}_q^b - \overline{\boldsymbol{\beta}}_q^b)(\widehat{\boldsymbol{\beta}}_q^b - \overline{\boldsymbol{\beta}}_q^b)^{\top},$$

where $\overline{\boldsymbol{\beta}}_q^b = B^{-1} \sum \widehat{\boldsymbol{\beta}}_q^b$.

are derived from the Medical Expenditure Panel Survey, and consists of 2,873 observations. The dependent variable is log(TOTEXP), so that zero values are omitted. The explanatory variables are supplementary private insurance (SUPPINS), which is a dummy variable, the number of chronic conditions (TOTCHR) as a measure of health status, and two demographic variables (AGE, FEMALE), and log(income) (LINC).

The numerical results are displayed in Table 15.4, which reports the OLS results with Eicker–White heteroskedasticity robust standard errors, and QR estimates for three values of q, 0.25, 0.50, 0.75. The OLS results in column 1 can be compared with the median regression results in column 3; the two should not be too different if the conditional distribution of the dependent variable is symmetric. The standard errors were computed using a paired bootstrap with 499 bootstrap replications. Because of the relatively small number of regressors in the model, this computation is manageable even on a desktop PC. Figure 15.4 displays the graphs of the quantile regression coefficients at different values of q. Such a visual representation is potentially very informative as it reveals the heterogeneity in response to variables at different quantiles of expenditure. For example, the impact of SUPPINS at $q = 0.25$ is nearly three times as large as at $q = 0.75$. The graphs also include the constant least squares coefficient as a benchmark.

Table 15.4 OLS and bootstrapped quantile regressions

15.5.2 Example: finite mixture model

Fully parametric models are popular in microeconometrics even though a parametric distributional assumption is an important simplification. There are many ways of replacing or relaxing this assumption, which may lead to additional computation. Replacing the assumption of a given parametric distribution by the assumption that the data distribution is a discrete mixture, also called a finite mixture (FM), of two or more distributions, not necessarily from the same family, can provide additional flexibility (Frühwirth-Schnatter, 2006). The FM representation is an intuitively attractive representation of heterogeneity in terms of a number of latent classes, each of which may be regarded as a "type" or a "group." It has found numerous applications in health and labor economics and in models of discrete choice. The FM model is related to latent class analysis (Aitken and Rubin, 1985; McLachlan and Peel, 2000).

In an FM model a random variable is a draw from an additive mixture of C distinct populations in proportions $\pi_1, \ldots, \pi_C$, where $\sum_{j=1}^{C} \pi_j = 1$, $\pi_j \geqslant 0$ $(j = 1, \ldots, C)$, denoted as:

$$f(y_i|\Theta) = \sum_{j=1}^{C-1} \pi_j f_j(y_i|\boldsymbol{\theta}_j) + \pi_C f_C(y_i|\boldsymbol{\theta}_C), \tag{15.33}$$

where each term in the sum on the right-hand side is the product of the mixing probability π_j and the component (sub-population) density $f_j(y_i|\boldsymbol{\theta}_j)$. Sometimes such models are referred to as models of permanent unobserved heterogeneity. In general the π_j are unknown and hence need to be estimated along with all the other parameters, denoted Θ. Also $\pi_C = (1 - \sum_{j=1}^{C-1} \pi_j)$. For identifiability the (label switching) restriction $\pi_1 \geq \pi_2 \geq \cdots \geq \pi_C$ is imposed; this can always be satisfied by rearrangement, post-estimation. Therefore, it plays no role in estimation. The parameter π_j may be further parameterized in terms of observed covariates using, e.g., the logit function.

For given C, maximum likelihood is a natural estimator for the FM model (see McLachlan and Peel, 2000, Ch. 2). Lindsay (1983) showed that finding the MLE involved a standard convex maximization problem in which a concave function is maximized over a convex set. An implication that follows is that if the likelihood is bounded, there exists a distribution, in the class of discrete distribution functions G with n or fewer points of support, that maximizes the likelihood.

There are two commonly used computational approaches – direct gradient-based optimization based on the roots of the likelihood equations, or the expectation maximization (EM) algorithm described below (see McLachlan and Peel, 2000). If the likelihood is bounded, then under correct specification of the model it has a global maximum. But it may be difficult to locate the global maximum if the component distributions are not well separated, or the convergence may be sensitive to the starting values. One way to guard against such a possibility is to check for robustness of convergence from different starting values. In some cases, such as the mixture of normals, the likelihood is unbounded and no global maximizer exists, so convergence will be to a local maximum. In practice, especially when the sample is small, the presence of local maxima cannot be ruled out.

In practice C is unknown. For a given sample size n, the standard way of selecting C is to treat this as a model selection problem and to use information criteria such as Akaike information criterion (AIC) or Bayesian information criterion (BIC) (see Deb and Trivedi, 2002, for a detailed application).

15.5.2.1 EM algorithm for model estimation

If C is given, the problem is to maximize the log-likelihood $\mathcal{L}(\pi, \Theta|C, \mathbf{y})$. Let $\mathbf{d}_i = (d_{i1}, \ldots, d_{iC})^\top$ define an indicator (dummy) variable such that $d_{ij} = 1$, $\sum_j d_{ij} = 1$, indicating that y_i was drawn from the jth (latent) group or class for $i = 1, \ldots, n$. That is, each observation may be regarded as a draw from one of the C latent classes or "types," each with its own distribution. The FM model specifies that $(y_i|\mathbf{d}_i, \boldsymbol{\theta}, \boldsymbol{\pi})$ are independently distributed with densities $\prod_{j=1}^{C} f(y_i|\boldsymbol{\theta}_j)^{d_{ij}}$, and $(d_{ij}|\ \boldsymbol{\theta}, \boldsymbol{\pi})$ are independent and identically distributed (i.i.d.) with multinomial distribution $\prod_{j=1}^{C} \pi_j^{d_{ij}}$, $0 < \pi_j < 1$, $\sum_{j=1}^{C} \pi_j = 1$. Hence the likelihood

function is:

$$\mathrm{L}(\boldsymbol{\theta}, \boldsymbol{\pi}|\mathbf{y}) = \prod_{i=1}^{n} \sum_{j=1}^{C} \pi_j^{d_{ij}} [f_j(\mathbf{y}; \boldsymbol{\theta}_j)]^{d_{ij}}, \quad 0 < \pi_j < 1, \quad \sum_{j=1}^{C} \pi_j = 1. \tag{15.34}$$

If π_j, $j = 1, \ldots, C$, is given, the posterior probability that observation y_i belongs to the population j, $j = 1, 2, \ldots, C$, is denoted z_{ij}, and $E\left[z_{ij}\right] = \pi_j$.

Estimation is implemented using the EM algorithm explained below. This may be slow to converge, especially if the starting values are not good. Gradient-based methods, such as Newton–Raphson or BFGS, are also used (see Böhning, 1995). The application reported below uses Newton–Raphson with gradients estimated using analytical formulae.

The EM algorithm is structured as in algorithm 15.5.2.1.1.

Algorithm 15.5.2.1.1 EM – implementation

---

1. Given an initial estimate $[\boldsymbol{\pi}^{(0)}, \boldsymbol{\theta}^{(0)}]$, the likelihood function (15.34) may be maximized using the EM algorithm in which the variable d_{ij} is replaced by its expected value, $E\left[d_{ij}\right] = \widehat{z}_{ij}$, yielding the expected log-likelihood:

$$E[\mathcal{L}(\Theta|\mathbf{y}, \boldsymbol{\pi})] = \sum_{i=1}^{n} \sum_{j=1}^{C} \widehat{z}_{ij} \left[\ln f_j(y_i; \boldsymbol{\theta}_j) + \ln \pi_j\right]. \tag{15.35}$$

2. The M-step of the EM algorithm maximizes (15.35) by solving the first-order conditions:

$$\widehat{\pi}_j - n^{-1} \sum_{i=1}^{n} \widehat{z}_{ij} = 0, \quad j = 1, \ldots, C$$

$$\sum_{i=1}^{n} \sum_{j=1}^{C} \widehat{z}_{ij} \frac{\partial \ln f_j(y_i; \boldsymbol{\theta}_j)}{\partial \theta_j} = 0.$$

3. Evaluate the marginal posterior probability $z_{ij}|\widehat{\pi}_j, \widehat{\theta}_j$, $j = 1, \ldots, C$,

$$z_{ij} \equiv \Pr[y_i \in \text{population } j] = \frac{\pi_j f_j(y_i|\mathbf{x}_i, \boldsymbol{\theta}_j)}{\sum_{j=1}^{C} \pi_j f_j(y_i|\mathbf{x}_i, \boldsymbol{\theta}_j)}.$$

   The E-step of the EM procedure obtains new values of $E[d_{ij}]$ using $E\left[z_{ij}\right] = \pi_j$.
4. Repeat steps 1–3 until $|\mathcal{L}(\widehat{\Theta}(k+1)) - \mathcal{L}(\widehat{\Theta}(k))| <$ tol, where tol denotes the selected tolerance level.

For estimating $\mathrm{var}(\widehat{\Theta})$, one can use either the observed information matrix or the robust Eicker–White sandwich formula. Though asymptotically valid given

regularity conditions, in practice such an application is subject to qualifications, especially in small samples or if the model is overfitted, so that one or more mixture components are small. This increases the appeal of variance calculation using the bootstrap (see McLachlan and Peel, 2000, Ch. 2.16).

15.5.2.2 FM of count models

Finite mixtures can be applied to continuous, discrete, or censored data (see McLachlan and Peel, 2000). Although the methods have not yet become common in widely used econometrics software, there are many examples in the literature. In the remainder of this section, we illustrate the potential richness of this modeling approach using an application to a count data regression (see Deb and Trivedi, 1997, 2002).

The dataset consists of 3,064 observations, where the dependent variable is number of doctor visits (DOCVIS). The predictors are age (AGE), squared age (AGE2), years of education (EDUC), a dichotomous indicator of activity limitation (ACTLIM), total number of chronic conditions (TOTCHR), and a dichotomous indicator of private health insurance status (PRIVATE). Table 15.5 shows results obtained using standard gradient methods of maximizing the likelihood. Poisson regression results appear in the first column. Typically this model gives a poor fit to the data because it imposes the assumption of equidispersion ($E[y|\mathbf{x}] = \text{var}(y|\mathbf{x})$),

which is usually inconsistent with the data. The negative binomial regression is often the next step because it can accommodate overdispersion in the data. As a common and plausible explanation of overdispersion comes from the presence of heterogeneity in the data, another approach to the problem is to allow for the possibility that a better specification is a two-component Poisson mixture, with each component corresponding to one type of individual. The results for this specification are presented in the next two columns. A further generalization is to allow for the possibility that the distribution is a two-component mixture of negative binomial (NB2) distributions with a quadratic variance function. The advantage here is that the NB2 specification allows for within-group heterogeneity as well. Thus each component represents the behavior of one group of individuals, but also allows for within-group heterogeneity.

Because the three models are nested, the log-likelihoods are comparable and the likelihood ratio can be used to test the restrictive models against the general 2-component mixture of NB2 distributions. Clearly, the FM2 specification of the NB2 distribution is the best-fitting model. The two components correspond to low users (around 40.5% of the population) and high users (around 59.5% of the population) of doctor visits. Evaluating the conditional means of distributions at the sample average of the predictors, the average is 3.92 for the first group and 8.62 for the second group. The groups also differ in their sensitivity to variations in the predictors. Of course, we have deliberately used a very simple specification so the exact numbers are only illustrative. The important point is that, although the mixture models are harder to estimate, especially when the number of components is increased, they are much more informative about the heterogeneity in the population.

15.6 Simulation-based maximum likelihood

In this section we consider an application of the MSL estimator to a nonlinear model with discrete outcomes and endogenous dummy regressors. There are two well-established approaches, limited information and full information, for handling endogeneity in linear models. Implementation of full information methods, based on the joint distribution of all endogenous variables, is often harder to implement because closed-form expressions for the joint distribution are rarely available. Thus there is strong motivation for limited-information methods based on instrumental variables, such as the GMM and two-stage sequential estimation. These have been extended to nonlinear models in a number of special cases, sometimes on an *ad hoc* computationally feasible basis, though not always with supporting formal justification. However, the consistency property of the two-step estimator may depend on particular assumptions about the structure of dependence. For example, in discrete outcome models sequential two-step estimation, based on the replacement of an endogenous variable by a fitted value, yields a consistent estimator only if the causal structure is recursive (Blundell and Powell, 2004; Chesher, 2005).

We consider computational issues of full information estimation in a model where the outcome of interest is a non-negative count which depends on a set of variables that includes dummy variables generated by a multinomial choice model (see Deb and Trivedi, 2006a, 2006b). The following section formally describes the nature of dependence.

15.6.1 Model specification

Consider a selectivity model in which individual i chooses a treatment from a set of three or more choices. This implies a multinomial choice model with a benchmark choice. $E[\mathrm{V}_{ij}^*]$ denotes the indirect utility of selecting the jth treatment, $j = 0, 1, 2, \ldots, J$, and:

$$E[\mathrm{V}_{ij}^*] = \mathbf{z}_i^\top \boldsymbol{\alpha}_j + \delta_j l_{ij} + \eta_{ij}, \tag{15.36}$$

where $\mathbf{z}_i$ denotes exogenous covariates, with associated parameters $\boldsymbol{\alpha}_j$, and η_{ij} are i.i.d. error terms. In addition, $E[\mathrm{V}_{ij}^*]$ includes a latent factor l_{ij} which incorporates unobserved characteristics common to individual i's treatment choice and outcome. The l_{ij} are assumed to be independent of η_{ij}. Without loss of generality, let $j = 0$ denote the control group and $E[\mathrm{V}_{i0}^*] = 0$.

Let d_j be binary (dummy) variables representing the observed treatment choice and $\mathbf{d}_i = (d_{i1}, d_{i2}, \ldots, d_{iJ})^\top$. In addition, let $\mathbf{l}_i = (l_{i1}, l_{i2}, \ldots, l_{iJ})^\top$. Then the probability of treatment can be represented as:

$$\Pr(\mathbf{d}_i|\mathbf{z}_i, \mathbf{l}_i) = \mathbf{g}(\mathbf{z}_i^\top \boldsymbol{\alpha}_1 + \delta_1 l_{i1}, \mathbf{z}_i^\top \boldsymbol{\alpha}_2 + \delta_2 l_{i2}, \ldots, \mathbf{z}_i^\top \boldsymbol{\alpha}_J + \delta_J l_{iJ}), \tag{15.37}$$

where $\mathbf{g}$ is an appropriate multinomial probability distribution. Specifically, we specify a mixed multinomial logit structure (MMNL) defined as:

$$\Pr(\mathbf{d}_i|\mathbf{z}_i, \mathbf{l}_i) = \frac{\exp(\mathbf{z}_i^\top \boldsymbol{\alpha}_j + \delta_j l_{ij})}{1 + \sum_{k=1}^{J} \exp(\mathbf{z}_i^\top \boldsymbol{\alpha}_k + \delta_k l_{ik})}. \tag{15.38}$$

For the count variable the expected outcome equation is:

$$E(y_i|\mathbf{d}_i, \mathbf{x}_i, \mathbf{l}_i) = \mathbf{x}_i^\top \boldsymbol{\beta} + \sum_{j=1}^{J} \gamma_j d_{ij} + \sum_{j=1}^{J} \lambda_j l_{ij}, \tag{15.39}$$

where $\mathbf{x}_i$ is a set of exogenous covariates with associated parameter vector $\boldsymbol{\beta}$ and the γ_j denote the treatment effects relative to the control. $E(y_i|\mathbf{d}_i, \mathbf{x}_i, \mathbf{l}_i)$ also depends on latent factors l_{ij}, i.e., the outcome is affected by unobserved characteristics that also affect selection into treatment. When λ_j, the factor loading parameter, is positive (negative), treatment and outcome are positively (negatively) correlated through unobserved characteristics, i.e., there is positive (negative) selection, with $\boldsymbol{\gamma}$ and $\boldsymbol{\lambda}$ the associated parameter vectors respectively.

Assume that f is the negative binomial-2 density:

$$f(y_i|\mathbf{d}_i, \mathbf{x}_i, \mathbf{l}_i) = \frac{\Gamma(y_i + \psi)}{\Gamma(\psi)\Gamma(y_i + 1)} \left(\frac{\psi}{\mu_i + \psi}\right)^{\psi} \left(\frac{\mu_i}{\mu_i + \psi}\right)^{y_i}, \tag{15.40}$$

where $\mu_i = E(y_i|\ \mathbf{d}_i, \mathbf{x}_i, \mathbf{l}_i) = \exp(\mathbf{x}_i^\top \boldsymbol{\beta} + \mathbf{d}_i^\top \boldsymbol{\gamma} + \mathbf{l}_i^\top \boldsymbol{\lambda})$ and $\psi \equiv 1/\alpha$ ($\alpha > 0$) is the overdispersion parameter.

As in the standard MNL model, the parameters in the MMNL are only identified up to a scale. Therefore, a normalization for the scale of the latent factors is required. We assume $\delta_j = 1$ for each j, without loss of generality. Although the model is identified when $\mathbf{z}_i = \mathbf{x}_i$, for robust identification it would be preferable to include some variables in $\mathbf{z}_i$ that are not included $\mathbf{x}_i$, i.e., identification via exclusion restrictions is the preferred approach.

15.6.2 Estimation algorithm

The joint distribution of treatment and outcome variables, conditional on the common latent factors, can be written as the product of the marginal density of treatment and the conditional density:

$$\begin{aligned} \Pr(y_i, \mathbf{d}_i|\mathbf{x}_i, \mathbf{z}_i, \mathbf{l}_i) &= f(y_i|\mathbf{d}_i, \mathbf{x}_i, \mathbf{l}_i) \times \Pr(\mathbf{d}_i|\mathbf{z}_i, \mathbf{l}_i) \\ &= f(\mathbf{x}_i^\top \boldsymbol{\beta} + \mathbf{d}_i^\top \boldsymbol{\gamma} + \mathbf{l}_i^\top \boldsymbol{\lambda}) \\ &\quad \times \mathbf{g}(\mathbf{z}_i^\top \boldsymbol{\alpha}_1 + \delta_1 l_{i1}, \ldots, \mathbf{z}_i^\top \boldsymbol{\alpha}_J + \delta_J l_{iJ}). \end{aligned} \tag{15.41}$$

The problem in estimation arises because the l_{ij} are unknown. Assume that the l_{ij} are i.i.d. draws from a standard normal distribution so their joint distribution $\mathbf{h}$ can be integrated out of the joint density, i.e.:

$$\begin{aligned} \Pr(y_i, \mathbf{d}_i|\mathbf{x}_i, \mathbf{z}_i) &= \int \Big[f(\mathbf{x}_i^\top \boldsymbol{\beta} + \mathbf{d}_i^\top \boldsymbol{\gamma} + \mathbf{l}_i^\top \boldsymbol{\lambda}) \\ &\quad \times \mathbf{g}(\mathbf{z}_i^\top \boldsymbol{\alpha}_1 + \delta_1 l_{i1}, \ldots, \mathbf{z}_i^\top \boldsymbol{\alpha}_J + \delta_J l_{iJ}) \Big] \mathbf{h}(\mathbf{l}_i) d\mathbf{l}_i. \end{aligned} \tag{15.42}$$

The main computational problem, given suitable specifications for $\mathbf{f}$, $\mathbf{g}$ and $\mathbf{h}_j$, is that the integral (15.42) does not have, in general, a closed-form solution. As was explained in section 15.3.3, this difficulty can be tackled using simulation-based estimation (Gouriéroux and Monfort, 1996). Note that:

$$\begin{aligned} \Pr(y_i, \mathbf{d}_i|\mathbf{x}_i, \mathbf{z}_i) &= E\Big[f(\mathbf{x}_i^\top \boldsymbol{\beta} + \mathbf{d}_i^\top \boldsymbol{\gamma} + \mathbf{l}_i^\top \boldsymbol{\lambda}) \\ &\quad \times \mathbf{g}(\mathbf{z}_i^\top \boldsymbol{\alpha}_1 + \delta_1 l_{i1}, \ldots, \mathbf{z}_i^\top \boldsymbol{\alpha}_J + \delta_J l_{iJ}) \Big] \\ &\approx \frac{1}{S} \sum_{s=1}^{S} \Big[f(\mathbf{x}_i^\top \boldsymbol{\beta} + \mathbf{d}_i^\top \boldsymbol{\gamma} + \tilde{\mathbf{l}}_{is}^\top \boldsymbol{\lambda}) \ , \\ &\quad \times \mathbf{g}(\mathbf{z}_i^\top \boldsymbol{\alpha}_1 + \delta_1 \tilde{l}_{i1s}, \ldots, \mathbf{z}_i^\top \boldsymbol{\alpha}_J + \delta_J \tilde{l}_{iJs}) \Big], \end{aligned} \tag{15.43}$$

where $\tilde{\mathbf{l}}_{is}$ is the sth draw (from a total of S draws) of a pseudo-random number from the density $\mathbf{h}$. The simulated log-likelihood function for the data is given by:

$$\begin{aligned} \ln l(y_i, \mathbf{d}_i|\mathbf{x}_i, \mathbf{z}_i) &\approx \sum_{i=1}^{N} \ln \left(\frac{1}{S} \sum_{s=1}^{S} \Big[f(\mathbf{x}_i^\top \boldsymbol{\beta} + \mathbf{d}_i^\top \boldsymbol{\gamma} + \tilde{\mathbf{l}}_{is}^\top \boldsymbol{\lambda}) \tilde{l}_{is} \ , \right. \\ &\quad \left. \times \mathbf{g}(\mathbf{z}_i^\top \boldsymbol{\alpha}_1 + \delta_1 \tilde{l}_{i1s}, \ldots, \mathbf{z}_i^\top \boldsymbol{\alpha}_J + \delta_J \tilde{l}_{iJs}) \Big] \right). \end{aligned} \tag{15.44}$$

Provided that S is sufficiently large, maximization of the simulated log-likelihood is equivalent to maximizing the log-likelihood. The covariance of the MSL estimates may be obtained using the robust Eicker–White formula.

15.6.3 Example: MSL estimation

To illustrate the method, we use pooled data from the Medical Expenditure Panel Surveys 1996–2003. The sample consists of 13,469 observations on persons between the ages of 19 and 64. The outcome variable is the number of doctor visits in a year (DOCVIS) and the multinomial treatment variable describes the type of health insurance plan (INSTYPE) and takes three values: (i) fee-for-service (FFS)–the control; (ii) health maintenance organizations (HMO); (iii) other managed care organizations (OMC). Exogenous covariates are AGE and FIRMSIZE; the latter serves as an exclusion restriction, i.e., as an instrument. The specification is deliberately (over)simplified by excluding many variables that would appear both in the choice and outcome models. Our objective is to demonstrate the feasibility of computation. MSL estimates, obtained using Halton sequences with $S = 50$ and 100, are given in Table 15.6.

The results show that even for such a simplified example the computational time is nontrivial. The sample size in this example is fairly large, which is expected to improve the precision of the estimation. Although the log-likelihood values are similar for $S = 50$ and $S = 100$, we see some differences in the coefficient estimates.

Train (2003, Ch. 9) gives examples in which 100 Halton draws have efficiency that exceeds that of 1,000 random draws. However, even $S = 100$ may not be high enough. The penalty for setting S too low is potential bias of the estimator, but having to determine the appropriate value of S by trial and error is a disadvantage. One expects longer computational time when additional regressors appear in the model, as would be the case with a more realistic model that adds further sociodemographic and health status factors. In this example, one factor-loading coefficient is estimated to be significantly different from zero, which confirms that endogeneity of the HMO variable is an empirically important consideration.

15.7 Concluding remarks

In applied microeconometrics computational matters have always featured prominently, and computational convenience has often been a criterion for choosing a methodology. Historically, advances in the quality and scope of research have moved in tandem with computational advances. During the 1960s and 1970s, the computational treatment of sample selection, discrete choice, nonlinearities, and limited dependent variable models remained central to the research agenda in microeconometrics. For example, in his 1976 survey paper on quantal choice analysis, McFadden mentioned computation of the multinomial probit model as an important unsolved problem, and remarked that "It would be particularly useful to achieve a computational breakthrough on the multinomial normal model." This remained an important research topic for close to two decades. Although such topics have not disappeared altogether, their importance is now smaller. Taking advantage of raw computing power, simulation-based estimation and inference methods based on resampling have emerged as feasible and practical approaches to many computational problems. Although this chapter did not survey the Bayesian approaches, the advances in this area have also been revolutionary; indeed, there are numerous cases in which the Bayesian MCMC computational approaches have proved more attractive than their frequentist counterparts. However, a major persistent computational challenge remains. It arises from the goal of constructing empirical models that can address important and detailed issues of public policy without resorting to excessive use of parametric restrictions. Such models are inherently structural, dynamic and high dimensional, and they often attempt to accommodate the heterogeneity in tastes, constraints and objectives of decision makers. These models face both the conceptual problems of identification and computational problems of implementation. It seems safe to predict that such challenges will remain with us for the foreseeable future.

Notes

1. Notable exceptions are source codes written in GAUSS, MATLAB and S-PLUS® that can be often interpreted by OxGAUSS, Octave and R respectively. The latter are non-proprietary languages.

2. A direct application of this capability is in storing a *sparse* matrix (a matrix populated primarily with zeros). By only storing the non-zero entries as opposed to storing all entries, it can yield huge savings in memory that can potentially speed up running time.
3. *NIX is often used to describe UNIX and other UNIX-like platforms, i.e., UNIX, BSD, and GNU/Linux distributions.
4. For example, if a local installation of R exists, then a C program has access to all R's pseudo-random number generators via the inclusion of `#include<R.h>` at the beginning of the C pseudo-code.
5. A cluster is a group of servers and other resources that act like a single system.
6. An implementation in Stata is described in Drukker and Gates (2006).
7. We would like to thank Jeffrey S. Racine for providing us with the necessary software to run these experiments at Indiana University's High Performance Clusters.

The Econometrics of Monetary Policy: An Overview

Carlo A. Favero

Abstract

This chapter concentrates on the econometrics of monetary policy. We describe the evolution of models estimated to evaluate the macroeconomic impact of monetary policy. We argue that the main challenge for the econometrics of monetary policy is in combining theoretical models and information from the data to construct empirical models. The failure of the large econometric models at the beginning of the 1970s might be explained by their incapability of taking proper account of both these aspects. The critiques by Lucas and Sims have generated an alternative approach which, at least initially, has been almost entirely dominated by theory. The LSE approach has instead concentrated on the properties of the statistical models and on the best way of incorporating information from the data into the empirical models, paying little attention to the economic foundation of the adopted specification. The realization that the solution of a DSGE model can be approximated by a restricted VAR, which is also a statistical model, has generated a potential link between the two approaches. The open question is which type of VARs are most appropriate for the econometric analysis of monetary policy.

16.1 The econometrics of monetary policy: what have we learnt?

Econometric evaluation of monetary policy started with large simultaneous equation models, in the tradition of the Cowles Commission. This first generation of models was largely driven by the IS/LM framework, in which the supply side was

left virtually unmodeled and relative price movements were not considered (see Fukac and Pagan, 2006). Large-scale models were obtained by specifying equations that described the determinants of variables in the national accounting identity for gross domestic product (GDP), for example, investment and consumption. This approach was aimed at the quantitative evaluation of the effects of modification in the variables controlled by the monetary policy maker (the instruments of monetary policy) on the macroeconomic variables which represent the final goals of the policy maker. The analysis was performed in three stages: *specification and identification* of the theoretical model, *estimation* of the relevant parameters and assessment of the dynamic properties of the model, with particular emphasis on the long-run properties, and *simulation* of the effects of monetary policies.

The crucial feature of the identification-specification stage was that the specified empirical model was usually loosely related to theoretical models and that identification was achieved by imposing numerous a priori restrictions attributing exogeneity status to a number of variables. As a consequence, identification was usually achieved within Cowles Commission models with a large number of overidentifying restrictions.

Interestingly, traditional modeling was aware of the presence of some misspecification in the estimated equations. This resulted in a departure from the conditions which warrant that ordinary least squares (OLS) estimators are best linear unbiased estimators (BLUE). The solution proposed was not re-specification but, instead, a modification of the estimation techniques. This is well reflected in the structure of the traditional textbooks (see, for example, Goldberger, 1991, where the OLS estimator is introduced first and then different estimators are considered as solutions to different pathologies in the model residuals). Pathologies are identified as departures from the assumptions which guarantee that OLS estimators are BLUE.

Stagflation condemned the first-generation models in the late 1970s, as they "did not represent the data, . . . did not represent the theory . . . [and] were ineffective for practical purposes of forecasting and policy evaluation" (Pesaran and Smith, 1995). Different explanations of the failure of these models were proposed. We classify them into diagnoses related to the solution of the structural identification problem and diagnoses related to the (lack of a) solution of the statistical identification problem.

The distinction between structural and statistical identification has been introduced by Spanos (1990). Structural models can be viewed statistically as a reparameterization, possibly (in the case of overidentified models) with restrictions, of the reduced form. Structural identification refers to the uniqueness of the structural parameters, as defined by the reparameterization and restriction mapping from the statistical parameters in the reduced form, while statistical identification refers to the choice of a well-defined statistical model as the reduced form.

The Lucas (1976) and Sims (1980) critiques are the diagnoses related to the solution of the identification problem. Lucas questions the superexogeneity status of the policy variables. and criticizes the identification scheme proposed by the Cowles Commission by pointing out that these models do not take expectations into account explicitly. Therefore, the identified parameters within the Cowles

Commission approach are a mixture of "deep parameters," describing preference and technology in the economy, and expectational parameters which, by their nature, are not stable across different policy regimes. The main consequence of such instability is that traditional structural macro-models are useless for the purpose of policy simulation.

Sims reinforced Lucas' point by labeling the Cowles Commission restrictions as "incredible"; in fact, no variable can be deemed as exogenous in a world of forward-looking agents whose behavior depends on the solution of an intertemporal optimization model. Optimality of monetary policy requires its endogeneity. Note also that, by invalidly imposing exogeneity of monetary policy, the model might induce a spuriously significant effectiveness of policy in the determination of macroeconomic variables. Endogeneity of policy does generate correlations between macroeconomic and policy variables, which, by invalidly assuming policy as exogenous, can be interpreted as a causal relation running from policy to the macroeconomic variables.

The diagnosis related to the specification of the statistical model explains the ineffectiveness of the Cowles Commission models for the practical purposes of forecasting and policy as being due to their incapability of representing the data. The root of the failure of the traditional approach lies in the inadequate attention paid to the statistical model implicit in the estimated structure. The diagnosis related to the specification of the statistical model gave rise to the LSE approach to macroeconometric modeling[1] and to the "structural cointegrating VAR" approach. The LSE approach has greatly emphasized the importance of a correct dynamic specification of the reduced form model and has placed very little emphasis on the explicit modeling of the economy based on intertemporal optimization. Recently the link between theory and dynamic specification has been re-established by a research approach based on the belief that economic theory is most informative about the long-run relationships between the relevant variables, proposed by Hashem Pesaran and a number of co-authors (see, for example, Pesaran and Shin, 2002; Garratt *et al*., 2006) in the so-called "structural cointegrating VAR approach." This approach is based on testing theory-based overidentifying restrictions on the long-run relations to provide a statistically coherent framework for the analysis of the short run.

The Lucas and Sims critiques have instead generated a totally new approach to econometric policy evaluation. These great critiques made clear that questions like "How should a central bank respond to shocks in macroeconomic variables?" are to be answered within the framework of quantitative monetary general equilibrium models of the business cycle. So the answer should rely on a theoretical model rather than on an empirical *ad hoc* macroeconometric model. Initially, this approach led to the construction of real business cycle (RBC) models where monetary policy played no role in explaining macroeconomic fluctuations. Moreover, these models depended on a limited numbers of structural parameters that were not estimated but calibrated. This period has been labeled by John Taylor (2005) as the "dark age" of the econometrics of monetary policy. This "dark age" came to an end

as a consequence of developments in macroeconomic theory and empirical modeling. On the theory side, the realization of the importance of price stickiness and of slow adjustment to the forward-looking rational expectations equilibria led to the "renaissance" of the role of monetary policy in understanding macroeconomic fluctuations. At the same time a new role was attributed to empirical analysis of providing evidence on the stylized facts to include in the theoretical model adopted for policy analysis and deciding between competing general equilibrium monetary models. This new role emerged with the realization that the solution of a dynamic stochastic general equilibrium (DSGE) model can be well approximated by a vector autoregressive (VAR) model, and VARs have become the natural tool for model evaluation.

The use of VARs led to the establishment of a number of facts and features to be included in models for monetary policy evaluation, well described by Christiano, Eichenbaum and Evans (2005) and Sims (2007).

1. Since VAR models are not estimated to yield advice on the best policy but rather to provide empirical evidence on the response of macroeconomic variables to policy impulses in order to discriminate between alternative theoretical models of the economy, it then becomes crucial to identify policy actions using restrictions independent from the theoretical models of the transmission mechanism under empirical investigation, taking into account the potential endogeneity of policy instruments.
2. Most of the monetary actions are systematic responses to the state of the economy, so there is very little in the way of random fluctuations in policy to produce business cycles.
3. Money supply is close to a random walk and monetary aggregate shocks do not look like monetary policy shocks in their effect. The foundation of the way people think about monetary policy is based on interest rate adjustments.

The main results of the VAR-based evaluation model is that, in order to match fluctuations in the data, any model must feature some attrition that causes temporary but rather persistent deviations from the long-run equilibrium defined by a frictionless neoclassical economy.

Adding frictions implies increasing the number of parameters, especially along the dimension of parameters little related to theory. As a consequence, calibration became impractical for attributing numerical values to the DSGE parameters and estimation came back into fashion. However, estimating DSGE models by classical maximum likelihood methods proved to be very hard, as the convergence of the estimates to values that ensure a unique stable solution turned out to be practically impossible to achieve when implementing unconstrained maximum likelihood estimation. Note that three types of solution are possible for a DSGE model, depending on its parameterization: no stable rational expectations solution exists, the stable solution is unique (determinacy), or there are multiple stable solutions (indeterminacy). Determinacy is a prerequisite in order to use a model to simulate the effects of economic policy.[2]

The practical impossibility of applying the classical maximum likelihood principle to estimate DSGE models paved the way for Bayesian methods. These methods have been used both for parameter estimation (see, for example, Smets and Wouters, 2003) and model evaluation (Del Negro and Schorfheide, 2004). As clearly pointed out by Sims (2007), this practice leads to a new interaction between theory and empirical analysis where the theoretical DSGE model should not be considered as a model for the data but as a generator of a prior distribution for the empirical model.

16.2 The econometrics of monetary policy in large econometric models

Consider a model designed to evaluate the effect of monetary policy. A first-generation structural model can be represented as follows:

$$\mathbf{A}\begin{pmatrix}\mathbf{Y}_t\\ \mathbf{M}_t\end{pmatrix} = \mathbf{C}_1(L)\begin{pmatrix}\mathbf{Y}_{t-1}\\ \mathbf{M}_{t-1}\end{pmatrix} + \mathbf{B}\begin{pmatrix}\boldsymbol{\nu}_t^Y\\ \boldsymbol{\nu}_t^M\end{pmatrix}, \tag{16.1}$$

$$\begin{pmatrix}\boldsymbol{\nu}_t^Y\\ \boldsymbol{\nu}_t^M\end{pmatrix} | I_{t-1}\Bigg) \sim (\mathbf{0}, \mathbf{I}).$$

The vector of n variables of interest is partitioned into two sub-sets: $\mathbf{Y}$, which represents the vector of macroeconomic variables of interest, and $\mathbf{M}$, the vector of monetary policy variables determined by the interaction between the policy maker and the economy.

The probabilistic structure for the variables of interest is determined by the implied reduced form. This statistical model has the following representation:

$$\begin{pmatrix}\mathbf{Y}_t\\ \mathbf{M}_t\end{pmatrix} = D_1(L)\begin{pmatrix}\mathbf{Y}_{t-1}\\ \mathbf{M}_{t-1}\end{pmatrix} + \mathbf{u}_t, \tag{16.2}$$

$$\mathbf{u}_t = \begin{pmatrix}\mathbf{u}_t^Y\\ \mathbf{u}_t^M\end{pmatrix},$$

$$u_t \mid I_{t-1} \sim n.i.d.\left(\mathbf{0}, \sum\right),$$

$$\begin{pmatrix}\mathbf{Y}_t\\ \mathbf{M}_t\end{pmatrix} | I_{t-1}\Bigg) \sim \left(D_1(L)\begin{pmatrix}\mathbf{Y}_{t-1}\\ \mathbf{M}_{t-1}\end{pmatrix}, \sum\right).$$

This system specifies the statistical distribution for the vector of variables of interest conditional upon the information set available at time $t-1$.[3] In relating the structure of interest to the statistical model a crucial identification problem has to be solved, since there is more than one structure of economic interest which can give rise to the same statistical model for our vector of variables.

Any given structure (16.1) will give rise to the observed reduced form (16.2) when the following restrictions are satisfied:

$$\mathbf{A}^{-1}\mathbf{C}_1(L) = D_1(L), \quad \mathbf{A}\begin{pmatrix} \mathbf{u}_t^Y \\ \mathbf{u}_t^M \end{pmatrix} = \mathbf{B}\begin{pmatrix} \boldsymbol{\nu}_t^Y \\ \boldsymbol{\nu}_t^M \end{pmatrix}.$$

There exists a whole class of structures which produce the same statistical model (16.2) under the same class of restrictions:

$$F\mathbf{A}\begin{pmatrix} \mathbf{Y}_t \\ \mathbf{M}_t \end{pmatrix} = F\mathbf{C}_1(L)\begin{pmatrix} \mathbf{Y}_{t-1} \\ \mathbf{M}_{t-1} \end{pmatrix} + F\mathbf{B}\begin{pmatrix} \boldsymbol{\nu}_t^Y \\ \boldsymbol{\nu}_t^M \end{pmatrix}, \tag{16.3}$$

where F is an admissible matrix, that is, it is conformable by product with $\mathbf{A}$, $\mathbf{C}_1(L)$, and $\mathbf{B}$, and $F\mathbf{A}$, $F\mathbf{C}_1(L)$, $F\mathbf{B}$ feature the same restrictions as $\mathbf{A}$, $\mathbf{C}_1(L)$, $\mathbf{B}$.

The identification problem is solved in the Cowles Commission approach by imposing restrictions on the $\mathbf{A}$, $\mathbf{C}_1(L)$ and $\mathbf{B}$ matrices so that the only admissible F matrix is the identity matrix. This is typically achieved by attributing an exogeneity status to the policy variables. Engle, Hendry and Richard (1983) illustrate that estimation requires weak exogeneity ($\mathbf{A}$ and $\mathbf{B}$ lower triangular), forecasting requires strong exogeneity ($\mathbf{A}$, $\mathbf{C}_1(L)$ and $\mathbf{B}$ lower triangular), while policy simulation requires superexogeneity, that is, strong exogeneity plus invariance of the parameters of interest to changes in the distribution of the policy variables.

Having identified the model and estimated the parameters of interest, the effect of monetary policy can be simulated. For given values of the parameters and the exogenous variables, values for the endogenous variables are recovered by finding the dynamic solution of the model.

Dynamic simulation is used to evaluate the effect of different policies, defined by specifying different patterns for the exogenous variables. Policy evaluation is implemented by examining how the predicted values of the endogenous variables change after some exogenous variables are modified. This implies simulating the model twice. First, a baseline, *control*, simulation is run. Such simulations can be run within the sample, in which case observed data are available for the exogenous variables, or outside the available sample, and values are assigned to the exogenous variables. The results of the baseline simulations are then compared with those obtained from an alternative, *disturbed*, simulation, based on the modification of the relevant exogenous variables. Policy evaluation was usually based on *dynamic multipliers,* which show the effect over time of the modification in the exogenous variables.

The construction of diagnostics for model evaluation is related to the solution of the identification problem. In fact, in the (very common) case of overidentified models, a test of the validity of the overidentifying restrictions can be constructed by comparing the restricted reduced form implied by the structural model with the reduced form implied by the just-identified model in which each endogenous variable depends on all exogenous variables with unrestricted coefficients. The statistics are derived in Anderson and Rubin (1949) and Basmann (1960). The logic of the test attributes a central role to the structural model. The statistical model of

reference for the evaluation of the structural model is derived from the structural model itself.

16.3 The different diagnoses of the failure of large econometric models

The monetary policies based on first generation models failed to prevent stagflation in the late 1970s. There are different explanations of this failure, which focused either on structural identification or on statistical identification.

16.3.1 Diagnoses related to structural identification

Lucas (1976) questions the superexogeneity status of the policy variables. He attacks the identification scheme proposed by the Cowles Commission by pointing out that these models do not take expectations explicitly into account and, therefore, the identified parameters within the Cowles Commission approach are a mixture of "deep parameters," describing preferences and technology in the economy, and expectational parameters which, by their nature, are not stable across different policy regimes. The main consequence of such instability is that traditional structural macro-models are useless for the purpose of policy simulation. To illustrate the point, assume the following data-generating process (DGP), in which expected monetary policy matters for the determination of macroeconomic variables in the economy:

$$\begin{pmatrix} \mathbf{Y}_t \\ \mathbf{M}_t \end{pmatrix} = \begin{pmatrix} c_{01} \\ c_{02} \end{pmatrix} + \begin{pmatrix} c_{11} & c_{12} \\ 0 & c_{22} \end{pmatrix} \begin{pmatrix} \mathbf{Y}_{t-1} \\ \mathbf{M}_{t-1} \end{pmatrix} + \begin{pmatrix} \gamma \\ 0 \end{pmatrix} \left(\mathbf{M}^e_{t+1}\right) + \begin{pmatrix} \mathbf{u}^Y_t \\ \mathbf{u}^M_t \end{pmatrix}. \quad (16.4)$$

A Cowles Commission model is estimated without explicitly including expectations and it will have the following specification:

$$\begin{pmatrix} 1 & a_{12} \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \mathbf{Y}_t \\ \mathbf{M}_t \end{pmatrix} = \begin{pmatrix} d_{01} \\ c_{02} \end{pmatrix} + \begin{pmatrix} d_{11} & d_{12} \\ 0 & c_{22} \end{pmatrix} \begin{pmatrix} \mathbf{Y}_{t-1} \\ \mathbf{M}_{t-1} \end{pmatrix} + \begin{pmatrix} \mathbf{u}^Y_t \\ \mathbf{u}^M_t \end{pmatrix}. \quad (16.5)$$

Under the assumed DGP the restrictions $a_{12} = \gamma c_{22}$ and $d_{01} = \gamma c_{02}$ apply and simulation of alternative policy regimes, that is, alternative values of c_{02} and c_{22}, cannot be implemented by keeping the estimated parameters constant.

Sims (1980) reinforced the Lucas critique by emphasizing a point originally made by Liu (1960), labeling the traditional restrictions as "incredible." In fact, no variable can be deemed exogenous in a world of forward-looking agents whose behaviour depends on the solution of an intertemporal optimization model. Optimality of policy cannot be consistent with the restrictions that $\mathbf{A}$, $\mathbf{C}_1(L)$, and $\mathbf{B}$ are lower triangular. Note also that, by invalidly imposing such restrictions, the model might induce a spurious statistical effectiveness of policy in the determination of macroeconomic variables. Endogeneity of policy does generate correlations between macroeconomic and policy variables, which, by invalidly assuming policy as exogenous, can be wrongly interpreted as a causal relation running from policy to the macroeconomic variables.

16.3.2 Diagnoses related to statistical identification

The diagnosis related to the specification of the statistical model explains the ineffectiveness of the first-generation models for the practical purposes of forecasting and policy as due to their incapability of representing the data. The root of the failure of the traditional approach lies in the lack of attention paid to the statistical model implicit in the estimated structure. Any identified structure is bound to fail if the implied reduced form, that is, the statistical model, is not an accurate description of the data. The accuracy of the description of the data is to be measured by evaluating the properties of the residuals of the statistical model: "congruent" models should feature residuals that are normally distributed, free of autocorrelation and homoskedastic. Spanos (1990) considers the case of a simple demand and supply model to show how the reduced form is ignored in the traditional approach. The example is based on the market for commercial loans discussed in Maddala (1988). Most of the widely used estimators allow the derivation of numerical values for the structural parameters without even seeing the statistical models represented by the reduced form. Following this tradition, the estimated (by two-stage least squares (2SLS)) structural model is a static model that relates the demand for loans to the average prime rate, to the Aaa corporate bond rate and to the industrial production index, while the supply of loans depends on the average prime rate, the three-month bill rate and total bank deposits. The quantity of commercial loans and the average prime rate are considered as endogenous while all other variables are taken as, at least, weakly exogenous variables and no equation for them is explicitly estimated. Given that there are two omitted instruments in each equation, one overidentifying restriction is imposed in both the demand and supply equations. The validity of the restrictions is tested via the Anderson–Rubin (1949) tests, and leads to the rejection of the restrictions at the 5% level in both equations, although in the second equation the restrictions cannot be rejected at the 1% level. Estimation of the statistical model, that is, the reduced form implied by the adopted identifying restrictions, yields a model for which the underlying statistical assumptions of linearity, homoskedasticity, absence of autocorrelation and normality of residuals are all strongly rejected. On the basis of this evidence the adopted statistical model is not considered as appropriate. An alternative model is then considered which allows for a richer dynamic structure (two lags) in the reduced form. Such dynamic specification is shown to provide a much better statistical model for the data than the static reduced from. Of course, the adopted structural model implies many more overidentifying restrictions than the initial one. When tested, the validity of these restrictions is overwhelmingly rejected for both the demand and supply equations. This evidence leads Spanos to conclude that statistical identification should be distinguished from structural identification. Statistical identification refers to the choice of a well-defined statistical model, structural identification refers to the uniqueness of the structural parameters as defined by the reparameterization and restriction mapping from the statistical parameters. Lucas and Sims concentrate on model failure related to structural identification problems, but models can fail

independently from structural identification problems as a consequence of lack of statistical identification.

16.4 Model specification and model diagnostics when statistical identification matters

The diagnosis related to the specification of the statistical model gave rise to the LSE approach to macroeconometric modeling and to the "structural cointegrating VAR" approach.

There are several possible causes for the inadequacy of the statistical models implicit in structural econometric models: omission of relevant variables, or of the relevant dynamics for the included variables, or invalid assumptions of exogeneity. The LSE solution to the specification problem is the theory of reduction. Any econometric model is interpreted as a simplified representation of the unobservable DGP. For the representation to be valid or "congruent," to use Hendry's own terminology, the information lost in reducing the DGP to its adopted representation, given by the reduced form, must be irrelevant to the problem at hand. Adequacy of the statistical model is evaluated by analyzing the reduced form, that is, by checking statistical identification. Therefore, the prominence of the structural model, with respect to the reduced form representation, is reversed. The LSE approach starts its specification and identification procedure with a general dynamic reduced form model. The congruency of such a model cannot be directly assessed against the true DGP, which is unobservable. However, model evaluation is made possible by applying the general principle that congruent models should feature truly random residuals; hence, any departure of the vector of residuals from a random normal multivariate distribution should signal a misspecification. Stationarity of the statistical model is a crucial feature when the model has to be simulated. Nonstationarity in macroeconomic time series is treated in the LSE methodology by reparameterizing the reduced form VAR as a cointegrated VAR. This is achieved by imposing rank reduction restrictions on the matrix determining the long-run equilibria of the system and by solving the identification problem of cointegrating vectors (see Johansen, 1995). Once the baseline model has been validated, the reduction process begins by simplifying the dynamics and reducing the dimensionality of the model by omitting the equations for those variables for which the null hypothesis of exogeneity is not rejected. Different tests are proposed for the different concepts of exogeneity by Engle, Hendry and Richard (1983) and even the validity of the Lucas critique becomes a testable concept (Engle and Hendry, 1993; Hendry, 1988). The product of the process of reduction is a statistical model for the data, possibly discriminating between short-run dynamics and long-run equilibria. Only after this validation procedure can the structural model be identified and estimated. A just-identified specification does not require any further testing, as its implicit reduced form does not impose any further restrictions on the baseline statistical model. The validity of the overidentified specification is, instead, tested by evaluating the restrictions implicitly imposed on the general reduced form. The most popular applications of the general-to-specific specification strategy are in the

area of money demand (Baba, Hendry and Starr, 1992) and aggregate consumption expenditure (see, for example, Hendry, Muellbauer and Murphy, 1990). As is well discussed in Fukac and Pagan (2006), the LSE approach was influential in the development of a second generation of large equation models, such as the Canadian model RDX2 (Helliwell *et al.* 1991) and the MPS model at the Fed (Gramlich, 2004), which, apart from introducing much stronger supply-side features with respect to traditional IS/LM models, paid considerable attention to dynamic specification and to the implementation of error correction models. In this type of specification the static solution represented a target to which the decision variable adjusted.

In practice, the LSE approach has almost exclusively concentrated on the statistical diagnosis of the failure of large structural models and has brought more attention to the dynamic specification and the long-run properties of models built in the Cowles Commission tradition and used by policy makers. It has paid much less attention to the possibility of specifying a forward-looking microeconomically founded model consistent with the theory-based diagnosis for the failure of traditional Cowles Commission models (an interesting example of this approach can be found in Juselius and Johansen, 1999). In a recent paper, Juselius and Franchi (2007) propose formulating all the basic assumptions underlying a theoretical model as a set of hypotheses on the long-run structure of a cointegrated VAR. They also argue in favor of using an identified cointegrated VAR as a way of structuring the data that offers a number a "sophisticated" stylized facts to be matched by empirically relevant theoretical models.

The idea of constructing empirical models based on the belief that economic theory is most informative about the long-run relationships between the relevant variables has been further developed by Hashem Pesaran and a number of co-authors (see, for example, Pesaran and Shin, 2002; Garratt *et al.,* 2006) in the so-called "structural cointegrating VAR approach." This approach is based on testing theory based overidentifying restrictions on the long-run relations to provide a statistically coherent framework for the analysis of the short-run. In practice, the implementation is based on a log-linear VARX model, where the baseline VAR model is augmented with weakly exogenous variables, such as oil prices or country specific foreign variables. Theory-based cointegrating relationships are tested and, whenever not rejected, imposed on the specification. No restrictions are imposed on the short-run dynamics of the model except for the, inevitable, choice of lag length for the VARX. Models are then used to evaluate the effect of policies via generalized impulse response functions (see Pesaran and Shin, 1998) and for forecasting.

16.5 Model specification and model diagnostics when structural identification matters

The great critiques made clear that questions like "How should a central bank respond to shocks in macroeconomic variables?" are to be answered within the framework of a quantitative monetary general equilibrium model of the business cycle, a DSGE model. The general linear (or linearized around equilibrium) DSGE model takes the following form (see Sims, 2002):

$$\mathbf{\Gamma}_0\mathbf{Z}_t = \mathbf{\Gamma}_1\mathbf{Z}_{t-1} + C + \Psi\epsilon_t + \Pi\eta_t, \tag{16.6}$$

where C is a vector of constants, ϵ_t is an exogenously evolving random disturbance, and η_t is a vector of expectations errors, $\left(E_t\left(\eta_{t+1}\right) = \mathbf{0}\right)$, not given exogenously but to be treated as part of the model solution. The forcing processes here are the elements of the vector ϵ_t, which contains processes like total factor productivity or policy variables that are not determined by an optimization process. Policy variables set by optimization, typically included in $\mathbf{Z}_t$, are naturally endogenous as optimal policy requires some response to current and expected developments of the economy.[4] Expectations at time t for some of the variables of the system at time $t+1$ are also included in the vector $\mathbf{Z}_t$ whenever the model is forward-looking. Models like (16.6) can be solved using standard numerical techniques (see, for example, Sims, 2002), and the solution can be expressed as:

$$\mathbf{Z}_t = \mathbf{A}_0 + \mathbf{A}_1\mathbf{Z}_{\mathbf{t-1}} + \mathbf{R}\epsilon_t,$$

where the matrices $\mathbf{A}_0$, $\mathbf{A}_1$,and $\mathbf{R}$ contain convolutions of the underlying structural model parameters. Note that the solution is naturally represented as a VAR. In fact, it is a VAR potentially with stochastic singularity, as the dimension of the vector of shocks is typically smaller than that of the vector of variables included in the VAR. However, this problem is promptly solved by adding the appropriate number of measurement errors.[5] Canonical RBC models (see, for example, Kydland and Prescott, 1982; King, Plosser and Rebelo, 1988) contain a limited number of parameters, and within this class of models the role of estimation was clearly de-emphasized and parameters have often been calibrated rather than estimated.

Calibration is extensively described in Cooley (1997). The aim of calibration is not to provide a congruent representation of the data, but simply to find values for the structural parameters of the model that are jointly compatible with the theory and the data in particular well-specified dimensions. The main difference between calibration and standard econometrics lies in the bidirectional relationship between theory and measurement that characterizes the former (see Favero, 2001). Cooley (1995, p. 60) states very clearly that in the calibration approach, data and measurement are concepts determined by the features of the theory. The empirics of calibration proceeds in several stages.

First, a preliminary, non-theoretical inspection of the data identifies some general stylized facts that any economic model should internalize. The theoretical framework at hand, then, integrated by these observed stylized facts, generates the parametric class of models to be evaluated. Once a particular model has been developed, it precisely defines the quantities of interest to be measured, and suggests how available measurements have to be reorganized if they are inconsistent with the theory.

Then, measurements are used to give empirical content to the theory, and in particular to provide empirically based values for the unknown parameters. They are chosen, according to Cooley (1997, p. 58), by specifying first some features of the data for the model to reproduce[6] and then by finding some one-to-one relationship

between these features and the deep parameters of the model. Finally, this relationship is inverted to determine the parameter values that make the model match the observed features.

From this point of view, calibration can be interpreted as a method of moments estimation procedure that focuses on a limited parameter sub-set, setting only the discrepancy between some simulated and observed moments to zero. Christiano and Eichenbaum (1992) generalize this idea and propose a variant of Hansen's (1982) generalized method of moments (GMM) procedure to estimate and assess stochastic general equilibrium models using specific moments of the actual data. These procedures are formal developments of the basic methodological approach, and share with standard calibration the focus on a limited set of previously selected moments, while standard econometric methods use, in principle, the whole available information set, weighting different moments exclusively according to how much information on them is contained in the actual data, as, for example, in maximum likelihood methods.

Generally, not all parameters can be calibrated, simply because there are more unknown parameters than invertible relationships. A sub-set of them has to be left to more standard econometric techniques.

Once a parameterization is available, the model is simulated and different kinds of numerical exercises are performed. At this stage model evaluation can also be implemented. Model evaluation was initially conducted by assessing the ability of the model to reproduce some particular features (of course, ones that are different from those used to calibrate it) of the data. The metric chosen to compare the observed properties and the simulated ones is a critical issue. In the traditional calibration procedure, an informal, "aesthetic" metric is used, based on the comparison between simulated and observed moments of the relevant variables (see, for example, Kydland and Prescott, 1996, p. 75). Moreover, as DSGE models are usually solved by linearizing them around equilibrium, raw data cannot be used to generate the set of statistics relevant for model evaluation. Raw data contain trends, so they are usually detrended using filtering techniques before using them to generate the relevant statistics.[7]

Model evaluation in DSGE models became much more sophisticated when the practice started to exploit the fact that a solved DSGE model is a VAR.

If we repartition the vector of variables included in the VAR into macroeconomic and policy variables $[\mathbf{Y}_t \mathbf{M}_t]$, the solved DSGE model could be represented as a structural VAR (SVAR):

$$\mathbf{A} \begin{pmatrix} \mathbf{Y}_t \\ \mathbf{M}_t \end{pmatrix} = \mathbf{C}(L) \begin{pmatrix} \mathbf{Y}_{t-1} \\ \mathbf{M}_{t-1} \end{pmatrix} + \mathbf{B} \begin{pmatrix} \boldsymbol{\nu}_t^Y \\ \boldsymbol{\nu}_t^M \end{pmatrix}. \tag{16.7}$$

Within this framework a new role for empirical analysis emerges: to provide evidence on the stylized facts to include in the theoretical model adopted for policy analysis and to decide between competing DSGE models. The operationalization of this research program in the analysis of monetary policy is very well described

in a paper by Christiano, Eichenbaum and Evans (1998). There are three relevant steps:

1. monetary policy shocks are identified in actual economies, that is, in a VAR without theoretical restrictions;
2. the response of relevant economic variables to monetary shocks is then described;
3. finally, the same experiment is performed in the model economies to compare actual and model-based responses as an evaluation tool and a selection criterion for theoretical models.

The identification of the shocks of interest is the first and most relevant step in VAR-based model evaluation. VAR modeling recognizes that identification and estimation of structural parameters is impossible without explicitly modeling expectations. Therefore, a structure like (16.7) can only be used to run special experiments that do not involve simulating different scenarios for the parameters of interest. A natural way to achieve these results is to experiment with the shocks $\boldsymbol{\nu}_t^M$. *Facts* are then provided by looking at impulse response analysis, variance decompositions and historical decompositions. Impulse response analysis describes the effect over time of a policy shock on the variables of interest, variance decomposition illustrates how much of the variance of the forecasting errors for macroeconomic variables at different horizons can be attributed to policy shocks, and historical decomposition allows the researcher to evaluate the effect of zeroing policy shocks on the variables of interest. All these experiments are run by keeping estimated parameters unaltered. Importantly, running these experiments is easier if shocks to the different variables included in the VAR are orthogonal to each other, otherwise it would not be possible to simulate a policy shock by maintaining all the other shocks at zero. As a consequence, VAR models need a structure because orthogonal shocks are normally not a feature of the statistical model. This fact generates an identification problem. In the reduced form we have:

$$\begin{pmatrix} \mathbf{Y}_t \\ \mathbf{M}_t \end{pmatrix} = \mathbf{A}^{-1}\mathbf{C}(L)\begin{pmatrix} \mathbf{Y}_{t-1} \\ \mathbf{M}_{t-1} \end{pmatrix} + \begin{pmatrix} \mathbf{u}_t^Y \\ \mathbf{u}_t^M \end{pmatrix},$$

where $\mathbf{u}$ denotes the VAR residual vector, normally and independently distributed with full variance-covariance matrix $\boldsymbol{\Sigma}$. The relation between the residuals in $\mathbf{u}$ and the structural disturbances in $\boldsymbol{\nu}$ is therefore:

$$\mathbf{A}\begin{pmatrix} \mathbf{u}_t^Y \\ \mathbf{u}_t^M \end{pmatrix} = \mathbf{B}\begin{pmatrix} \boldsymbol{\nu}_t^Y \\ \boldsymbol{\nu}_t^M \end{pmatrix}. \tag{16.8}$$

Undoing the partitioning, we have:

$$\mathbf{u}_t = \mathbf{A}^{-1}\mathbf{B}\boldsymbol{\nu}_t,$$

from which we can derive the relation between the variance-covariance matrices of $\mathbf{u}_t$ (observed) and $\boldsymbol{v}_t$ (unobserved) as follows:

$$E\left(\mathbf{u}_t\mathbf{u}_t'\right) = \mathbf{A}^{-1}\mathbf{B}E\left(\boldsymbol{v}_t\boldsymbol{v}_t'\right)\mathbf{B}'\mathbf{A}^{-1}.$$

Substituting population moments with sample moments we have:

$$\widehat{\sum} = \widehat{\mathbf{A}}^{-1}\widehat{\mathbf{B}}\mathbf{I}\widehat{\mathbf{B}}'\widehat{\mathbf{A}}^{-1}, \tag{16.9}$$

$\widehat{\sum}$ contains $n(n+1)/2$ different elements, so this is the maximum number of identifiable parameters in matrices **A** and **B**. Therefore, a necessary condition for identification is that the maximum number of parameters contained in the two matrices equals $n(n+1)/2$, and such a condition makes the number of equations equal to the number of unknowns in system (16.9). As usual, for such a condition also to be sufficient for identification, no equation in (16.9) should be a linear combination of the other equations in the system (see Amisano and Giannini, 1996; Hamilton, 1994). As for traditional models, we have the three possible cases of underidentification, just-identification and overidentification. The validity of overidentifying restrictions can be tested via a statistic distributed as a χ^2 with the number of degrees of freedom equal to the number of overidentifying restrictions. Once identification has been achieved, the estimation problem is solved by applying generalized method of moments estimation.

Since VAR models are used to discriminate between alternative theoretical models of the economy, it then becomes crucial to identify policy actions using restrictions independent from the theoretical models of the transmission mechanism under empirical investigation, taking into account the potential endogeneity of policy instruments. Restrictions based on the theoretical predictions of models are clearly inappropriate, and so are the Cowles Commission type of restrictions, as they do not acknowledge the endogeneity of systematic policy. The recent literature on the monetary transmission mechanism (see Bernanke and Mihov, 1998; Christiano, Eichenbaum and Evans, 1996a; Leeper, Sims and Zha, 1996) offers good examples on how these kind of restrictions can be derived. VARs of the monetary transmission mechanism are specified on six variables, with the vector of macroeconomic non-policy variables including GDP, the consumer price index (P) and the commodity price level (Pcm), while the vector of policy variables includes the federal funds rate (FF), the quantity of total bank reserves (TR) and the amount of non-borrowed reserves (NBR). Given the estimation of the reduced form VAR for the six macro and monetary variables, a structural model is identified by: (i) assuming orthogonality of the structural disturbances; (ii) requiring that macroeconomic variables do not simultaneously react to monetary variables, while simultaneous feedback in the other direction is allowed, and (iii) imposing restrictions on the monetary block of the model reflecting the operational procedures implemented by the monetary policy maker. All identifying restrictions satisfy the criterion of independence from specific theoretical models. In fact, within the class of models estimated on monthly data, restrictions (ii) are consistent with a wide spectrum

of alternative theoretical structures and imply a minimal assumption on the lag of the impact of monetary policy actions on macroeconomic variables, whereas restrictions (iii) are based on institutional analysis. Restrictions (ii) are made operational by setting to zero an appropriate block of elements of the **A** matrix. Note that restrictions on the contemporaneous feedbacks among variables is not the only way of imposing restrictions consistent with a wide spectrum of theoretical models. In fact, such an aim could be achieved by imposing restrictions on the long run effects of shocks (for example, there is a clear consensus among macroeconomists that demand shocks have zero effect on output in the long run) or on the shape of some impulse response functions. These types of restrictions are easily imposed on the SVAR (see, for example, Blanchard and Quah, 1989; Uhlig, 1999), although one must always be aware of the effect of imposing invalid restrictions on parameter estimates (Faust and Leeper, 1997). Finally, note that partial identification can easily be implemented in a VAR model. If the relevant dimension for model comparison is the response of the economy to monetary policy shocks, then there is no need to identify the non-monetary structural shocks in the model.

16.5.1 VAR-based model evaluation: an assessment

VAR-based model evaluation can be assessed by first discussing the results achieved and their impact on model building, and then offering some considerations on the specification of the VAR and on the evaluation of the statistical model adopted.

The main results of the VAR-based evaluation model is that, in order to match fluctuations in the data, any model must feature some attrition that causes temporary but rather persistent deviations from the long-run equilibrium defined by a frictionless neoclassical economy. In a series of recent papers, Christiano, Eichenbaum and Evans (1996a, 1996b) apply the VAR approach to derive "stylized facts" on the effect of a contractionary policy shock, and conclude that plausible models of the monetary transmission mechanism should be consistent at least with the following evidence on price, output and interest rates: (i) the aggregate price level initially responds very little; (ii) interest rates initially rise, and (iii) aggregate output initially falls, with a *j*-shaped response and a zero long-run effect of the monetary impulse. Such evidence leads to the dismissal of traditional RBC models, which are not compatible with the liquidity effect of monetary policy on interest rates, and of the Lucas (1972) model of money, in which the effect of monetary policy on output depends on price misperceptions. The evidence seems to be more in line with alternative interpretations of the monetary transmission mechanism based on sticky price models (Goodfriend and King, 1997), limited participation models (Christiano and Eichenbaum, 1992) or models with indeterminacy–sunspot equilibria (Farmer, 1997). When models are extended to analyze the components of output, more frictions need to be added to explain the dynamics of consumption and investment: typically, some habit persistence is needed to explain fluctuations in consumption and some adjustment costs are needed to match the dynamics of investment and the stock of capital in the data.

Specification of the VAR and its statistical adequacy is an issue that has not received much explicit attention in the literature. It seems that the choice of the

variables included in the VAR is driven by the theoretical model. This is natural: if the theoretical model is a restricted VAR, the natural benchmark is the same VAR without restrictions. But what about potential misspecification of the statistical model?

Statistical analysis of the unrestricted VAR is rather rare, although some implicit consideration has clearly been devoted to this issue. Think, for example, of the "liquidity puzzle" and the "price puzzle" for models of the monetary transmission mechanism.

VAR models of the monetary transmission mechanism were initially estimated on a rather limited set of variables, that is, prices, money and output, and identified by imposing a diagonal form on the matrix **B** and a lower triangular form on the matrix **A**, with money coming last in the ordering of the variables included in the VAR (Choleski identification). The typical impulse responses obtained within this type of model show that prices slowly react to monetary policy, output responds in the short run, in the long run (from two years after the shock onwards) prices start adjusting and the significant effect on output vanishes. There is no strong evidence for the endogeneity of money. Macroeconomic variables play a very limited role in explaining the variance of the forecasting error of money, while money instead plays an important role in explaining fluctuations of both the macroeconomic variables.

Sims (1980) extended the VAR to include the interest rate on federal funds, ordered just before money as a penultimate variable in the Choleski identification. The idea was to assess the robustness of the above results after identifying the part of money which is endogenous to the interest rate. Impulse response functions and forecast error variance decomposition (FEVD) raise a number of issues.

1. Though little of the variation in money is predictable from past output and prices, a considerable amount becomes predictable when past short-term interest rates are included in the information set.
2. It is difficult to interpret the behavior of money as driven by money supply shocks. The response to money innovations gives rise to the "liquidity puzzle": the interest rate initially declines very slightly in response to a money shock and then starts increasing afterwards.
3. There are also difficulties with interpreting shocks to interest rates as monetary policy shocks. The response of prices to an innovation in interest rates gives rise to the "price puzzle": prices increase significantly after an interest rate hike. An accepted interpretation of the liquidity puzzle relies on the argument that the money stock is dominated by demand rather than supply shocks. Moreover, the interpretation of money as demand shocks driven is consistent with the impulse response of money to interest rates. Note also that, even if the money stock were to be dominated by supply shocks, it would reflect both the behavior of central banks and the banking system. For both these reasons the broad monetary aggregate has been substituted by narrower aggregates, bank reserves, on which it is easier to identify shocks mainly driven by the behavior

> of the monetary policy maker. The "price puzzle" has been attributed to the misspecification of the four-variables VAR used by Sims. Suppose that there exists a leading indicator for inflation to which the Fed reacts. If such a leading indicator is omitted from the VAR, then we have an omitted variable positively correlated with inflation and interest rates. Such omission makes the VAR misspecified and explains the positive relation between prices and interest rates observed in the impulse response functions. It has been observed (see Christiano, Eichenbaum and Evans, 1996b; Sims and Zha, 1996) that the inclusion of a Commodity Price Index in the VAR solves the "price puzzle."

As a result of these developments, a consensus was reached on the specification of the VAR to provide facts on the monetary transmission mechanism (MTM) as a model including prices, output, a commodity price index, the policy rate and the narrow money indicators necessary to model the market for bank reserves.

Note that the final specification is very different from the initial one and the modifications in the specification are driven by a number of puzzles found in the impulse responses of discarded VARs. One can, of course, interpret these puzzles as signals of misspecification of the VAR, but it is not clear that puzzles are the best way to diagnose misspecification of the statistical model. Think, for example, of the recent practice of identifying shocks by imposing constraints on the shape of the impulse response functions. It might well be regarded as reasonable to assume that a monetary policy restriction has a non-positive effect on inflation. Obviously, if VARs of the MTM would have always been identified by imposing this restriction, then the price puzzle would never have been observed and one is left to wonder if the consensus specification of the VAR to analyze the MTM would have evolved differently from what it did.

Another issue of crucial importance is structural stability of the parameters estimated in the VAR. If the VAR is a reduced form of a forward-looking model it is of crucial importance to estimate its parameters on a single regime. Although this issue has been explicitly recognized in some papers, (for example, Bernanke and Mihov, 1998), the consensus VAR is normally estimated on a sample including different monetary regimes. The main justification for this practice is that monetary policy shocks are robust to the different identifications generated by the different monetary policy regimes. Some authors have been left skeptical by such robustness and some criticisms have been made of VAR-based monetary policy shocks. Rudebusch (1998) argues that VAR-based monetary shocks do not make sense as they are very weakly correlated with monetary policy shocks directly derived from asset prices (the Federal Fund future). The mainstream reaction to this criticism is that, even if the two types of shocks are very weakly correlated, the impulses responses of macroeconomic variables to VAR based and financial market-based monetary policy shocks are not significantly different from each other. Rudebusch's criticism has shared the same fate as other criticisms of the VAR approach. Lippi and Reichlin (1993) pointed out that a crucial assumption in structural VAR modeling is that structural shocks are linear combinations of the residuals in reduced form VAR models, so that modern macroeconomic models which are linearized

into dynamic systems tend to include noninvertible moving average components and structural shocks are therefore not identifiable. In fact, the linearized modern macroeconomic models of the monetary transmission mechanism deliver short VARs. In such models structural shocks are combinations of the residuals in the reduced form VARs (the Wold innovations) and the Lippi–Reichlin critique does not seem to be applicable (for a further discussion of this point see Amisano and Giannini, 1996).

To sum up, although the original idea of the Cowles Commission to use the implied unrestricted reduced form as a benchmark to evaluate the structural model is clearly reflected in the VAR-based evaluation of DSGE models, the potential importance of the formal evaluation of the adequacy of the statistical model adopted has certainly not received the same attention. However, in the practice of VAR specification some attention to the issue of potential misspecification has clearly been paid, although such attention has been more related to the economic interpretation of results than to the implementation of formal statistical criteria for model evaluation.

16.6 From VAR-based model evaluation to Bayesian analysis of DSGE models

VAR-based evaluation of early DSGE models made clear that a large number of nominal and real frictions should be added to the traditional new-classical RBC models to replicate relevant features in observed data (see, for example, Christiano, Eichenbaum and Evans, 2005). Adding frictions implies increasing the number of parameters, especially along the dimension of parameters little related to theory. As a consequence, calibration became impractical for attributing numerical values to the DSGE parameters and estimation came back into fashion. However, estimating DSGE models by classical maximum likelihood methods proved to be very hard, as the convergence of the estimates to values that ensure a unique stable solution turned out to be practically impossible to achieve when implementing unconstrained maximum likelihood estimation. A paper by Ireland (2004) was an exception and obtained convergence of numerical estimates of parameters of a DSGE model to values that allow economic policy simulation. In fact, the Ireland method consists of penalizing the likelihood function along some dimension so that the range of variation of many parameters is limited (for an interesting discussion of the estimation implemented in Ireland, see Johansen, 2004).

In practice, one can think of Ireland's method as a naive Bayesian one in which some form of (very tight) prior is imposed on (at least a sub-set of) the parameters. A natural development of Ireland's proposal was to extend the naive Bayesian framework to a proper Bayesian framework. This is what happened as soon as the use of MCMC methods to derive the relevant posterior distribution of parameters became widespread (see An and Schorfeide, 2006; Del Negro *et al.*, 2006; Ruge-Murcia, 2003, for surveys and applications).

Once adopted, the Bayesian framework naturally offered some new possibilities of integrating theoretical and empirical models. Originally this interaction

was proposed as a set of modern model evaluation tools. These were generated by pairing the tradition of model evaluation in the Bayesian approach to macroeconometrics with the VAR nature of a solved DSGE model.

The Bayesian approach made its way into applied macroeconometrics to solve the problem of the lack of parsimony of VARs. In practice, data availability from a single regime poses a binding constraint on the number of variables and the number of lags that can be included in a VAR without overfitting the data. A solution to the problem of over-parameterization is to constrain the parameters by shrinking them toward some specific point in the parameter space. The Minnesota prior, proposed by Doan, Litterman and Sims (1984), uses the Bayesian approach to shrink the estimates toward the univariate random walk representation for all variables included in the VAR. Within this framework, Bayesian methods are used to save degrees of freedom on the basis of the well established statistical evidence that no-change forecasts are known to be very hard to beat for many macroeconomic variables. DeJong, Ingram and Whiteman (1996, 2000) and Ingram and Whiteman (1994) proposed evaluating RBC models by comparing the forecasting performance of a Bayesian VAR estimated via the Minnesota prior with that of a VAR in which the atheoretical prior information in the Minnesota prior was supplanted by the information in an RBC model.

In a series of papers, Del Negro and Schorfeide (2004, 2006) and Del Negro *et al.* (2006) use this approach to develop a model evaluation method that tilts coefficient estimates of an unrestricted VAR toward the restriction implied by a DSGE model. The weight placed on the DSGE model is controlled by a hyperparameter called λ. This parameter takes values ranging from 0 (no-weight on the DSGE model) to ∞ (no weight on the unrestricted VAR). Therefore, the posterior distribution of λ provides an overall assessment of the validity of the DSGE model restrictions. To see how the approach is implemented, consider that the solved DSGE model generates a restricted moving average (MA) representation for the vector of n variables of interest, $\mathbf{Z}_t = \begin{pmatrix} \mathbf{Y}_t & \mathbf{M}_t \end{pmatrix}$, that can be approximated by a VAR of order p:

$$\begin{aligned}
\mathbf{Z}_t &= \mathbf{\Phi}_0^*(\theta) + \mathbf{\Phi}_1^*(\theta)\mathbf{Z}_{t-1} + ... + \mathbf{\Phi}_p^*(\theta)\mathbf{Z}_{t-p} + \mathbf{u}_t^* \\
\mathbf{u}_t^* &\sim N\left(\mathbf{0}, \Sigma_u^*(\theta)\right) \\
\mathbf{Z}_t' &= \mathbf{X}_t'\mathbf{\Phi}^*(\theta) + \mathbf{u}_t', \\
\mathbf{X}_t &= \left[1, \mathbf{Z}_{t-1}', ..., \mathbf{Z}_{t-p}'\right] \\
\mathbf{\Phi}^*(\theta) &= \left[\mathbf{\Phi}_0^*(\theta), \mathbf{\Phi}_1^*(\theta), ..., \mathbf{\Phi}_p^*(\theta)\right]',
\end{aligned}$$

where all coefficients are convolutions of the structural parameters in the model included in the vector θ. The chosen benchmark to evaluate this model is the unrestricted VAR derived from the solved DSGE model:

$$\begin{aligned}
\mathbf{Z}_t' &= \mathbf{X}_t'\mathbf{\Phi} + \mathbf{u}_t', \\
\mathbf{\Phi} &= \left[\mathbf{\Phi}_0, \mathbf{\Phi}_1, ..., \mathbf{\Phi}_p\right],
\end{aligned}$$

where:

$$\mathbf{\Phi} = \mathbf{\Phi}^{*}(\theta) + \mathbf{\Phi}^{\Delta}$$
$$\Sigma_u = \Sigma_u^{*}(\theta) + \Sigma_u^{\Delta}.$$

The DSGE restrictions are imposed on the VAR by defining:

$$\Gamma_{XX}(\theta) = E_\theta^D\left[\mathbf{X}_t\mathbf{X}_t'\right]$$
$$\Gamma_{XZ}(\theta) = E_\theta^D\left[\mathbf{X}_t\mathbf{Z}_t'\right],$$

where E_θ^D defines the expectation with respect to the distribution generated by the DSGE model. Such a distribution needs to be well defined. We then have:

$$\mathbf{\Phi}^{*}(\theta) = \Gamma_{XX}(\theta)^{-1}\Gamma_{XZ}(\theta).$$

Beliefs about the DSGE model parameters θ and model misspecification matrices $\mathbf{\Phi}^{\Delta}$ and Σ_u^{Δ} are summarized in prior distributions, that, as shown in Del Negro *et al.* (2006), can be transformed into priors for the VAR parameters $\mathbf{\Phi}$ and Σ_u. In particular we have:

$$\Sigma_u|\theta \sim IW\left(\lambda T\Sigma_u^{*}(\theta), \lambda T - k, n\right)$$
$$\mathbf{\Phi}|\Sigma_u, \theta \sim N\left(\Phi^{*}(\theta), \frac{1}{\lambda T}\left[\Sigma_u^{-1}\otimes\Gamma_{XX}(\theta)\right]^{-1}\right),$$

where the parameter λ controls the degree of model misspecification with respect to the VAR: for small values of λ the discrepancy between the VAR and the DSGE-VAR is large and a sizeable distance is generated between unrestricted VAR and DSGE estimators, large values of λ correspond to small model misspecification and, for $\lambda = \infty$, beliefs about DSGE misspecification degenerate to a point mass at zero. Bayesian estimation could be interpreted as estimation based on a sample in which data are augmented by a hypothetical sample in which observations are generated by the DSGE model; within this framework λ determines the length of the hypothetical sample.

Given the prior distribution, posteriors are derived by Bayes' theorem:

$$\Sigma_u|\theta, Z \sim IW\left((\lambda+1)T\hat{\Sigma}_{u,b}(\theta), (\lambda+1)T - k, n\right)$$
$$\mathbf{\Phi}|\Sigma_u, \theta, Z \sim N\left(\hat{\mathbf{\Phi}}_b(\theta), \Sigma_u\otimes\left[\lambda T\Gamma_{XX}(\theta) + \mathbf{X}'\mathbf{X}\right]^{-1}\right)$$
$$\hat{\mathbf{\Phi}}_b(\theta) = \left(\lambda T\Gamma_{XX}(\theta) + \mathbf{X}'\mathbf{X}\right)^{-1}\left(\lambda T\Gamma_{XZ}(\theta) + \mathbf{X}'\mathbf{Z}\right)$$
$$\hat{\Sigma}_{u,b}(\theta) = \frac{1}{(\lambda+1)T}\left[\left(\lambda T\Gamma_{ZZ}(\theta) + \mathbf{Z}'\mathbf{Z}\right) - \left(\lambda T\Gamma_{XZ}(\theta) + \mathbf{X}'\mathbf{Z}\right)\hat{\mathbf{\Phi}}_b(\theta)\right],$$

which shows that the smaller λ, the closer the estimates are to the OLS estimates of an unrestricted VAR, the higher λ the closer the estimates are to the values implied by the DSGE model parameters θ.

In practice, a grid search is conducted on a range of values for λ to choose that value which maximizes the marginal data density. The typical result obtained when using DSGE-VECM(λ) to evaluate models with frictions is that "the degree of misspecification in large-scale DSGE models is no longer so large as to prevent their use in day-to-day policy analysis, yet is not small enough that it can be ignored."

16.6.1 DSGE-VAR analysis: an assessment

If we consider the DSGE-VAR approach to be a model evaluation tool, we observe that it takes the Lucas and Sims critique very seriously but it ignores the issue of specification of the statistical model. The VAR used as a benchmark is the solved DSGE model that is generalized only by relaxing restrictions on parameters. The validity of the statistical model underlying the empirical specification is never questioned. Although the models are different, the evaluation strategy in the DSGE-VAR approach is very similar to the approach of evaluating models by testing overidentifying restrictions without assessing the statistical model, as implemented in Cowles Commission models. In fact, the DSGE-VAR approach is looser than that of the Cowles Commission approach as model-based restrictions are not imposed and tested but a different question is asked: restrictions are made fuzzy by imposing a distribution on them. Within this approach the relevant question becomes "What is the amount of uncertainty that we have to add to model based restrictions in order to make them compatible not with the data but with a model-derived unrestricted VAR representation of the data?" The natural question here is "How well does this procedure do in rejecting false models?" Spanos (1990) has clearly shown that modification of the structure of the statistical model could lead to dramatic changes in the outcome of tests for overidentifying restrictions. Why is this worry so strongly de-emphasized in the DSGE-VAR literature?

What are the potential sources of model-derived VAR misspecification? An obvious candidate are all those variables that are related to the misspecification of the theoretical model, but there are also all those variables that are not theory-related but are important for modeling the actual behavior of policy makers. Think, for example, of the commodity price index and the modeling of the behavior of the monetary policy authority. We have discussed in the previous section how the inclusion of this variable in a VAR to identify monetary policy shocks has been deemed important to model correctly the information set of the monetary policy maker when forecasting inflation and then to fix the "price puzzle." DSGE models do not typically include the commodity price index in their specification, and, as a consequence, the VAR derived by relaxing the theoretical restrictions in a DSGE model is misspecified. Thus the evaluation of the effects of conducting model misspecification with a "wrong" benchmark is a practically relevant one.

As a matter of fact, DSGE models tend to produce a high number of very persistent shocks (see Smets and Wouters, 2003), and this would have certainly been taken as a signal of model misspecification by an LSE-type methodology. Still, the models

do not do too badly when judged by the metric of the λ test. It would be important to have some evaluation of phenomena like this.

Another dimension potentially relevant for evaluating the statistical model underlying the VAR-DSGE is the structural stability of the VAR parameters. If the DSGE restrictions are valid, then parameters in the VAR are convolutions of structural parameters that, by their nature, should be constant over time. It is well known that tests for structural stability have problems of power, especially in the presence of multiple breaks at unknown dates. Detecting structural breaks in parameters of interest becomes even harder when structural innovations in the DSGE are allowed to have volatilities that vary over time. Justiniano and Primiceri (2005) have extended the Bayesian framework to develop an algorithm for inferring DSGE model parameters and time-varying volatilities of structural shocks. Allowing for time-varying volatilities makes the DSGE model consistent with structural breaks while keeping the deep parameters constant. However, it is hard to distinguish empirically the case for genuine stochastic volatility against a situation in which allowing for stochastic volatility in the estimation picks up parameter instability in a VAR model with constant volatility of structural shocks (see Benati and Surico, 2007).

There are alternatives to the use of a VAR as a benchmark. The limited information problem of VARs could be solved by combining traditional VAR analysis with recent developments in factor analysis for large data sets and using a factor-augmented VAR (FAVAR) as the relevant statistical model to conduct model evaluation. A recent strand of the econometric literature (Stock and Watson, 2002; Forni and Reichlin, 1996, 1998; Forni *et al.*, 2000) has shown that very large macroeconomic datasets can be properly modeled using dynamic factor models, where the factors can be considered to be an exhaustive summary of the information in the data. This approach has been successfully employed to forecast macroeconomic time series and, in particular, inflation. As a natural extension of the forecasting literature, Bernanke and Boivin (2003), and Bernanke, Boivin and Eliasz (2005) proposed exploiting these factors in the estimation of VARs. A FAVAR benchmark for the evaluation of a DSGE model will take the following specification:

$$\begin{pmatrix} \mathbf{Z}_t \\ \mathbf{F}_t \end{pmatrix} = \begin{bmatrix} \mathbf{\Phi}_{11}(L) & \mathbf{\Phi}_{12}(L) \\ \mathbf{\Phi}_{21}(L) & \mathbf{\Phi}_{22}(L) \end{bmatrix} \begin{pmatrix} \mathbf{Z}_{t-1} \\ \mathbf{F}_{t-1} \end{pmatrix} + \begin{pmatrix} \mathbf{u}_t^Z \\ \mathbf{u}_t^F \end{pmatrix},$$

where $\mathbf{Z}_t$ are the variables included in the DSGE model and $\mathbf{F}_t$ is a small vector of unobserved factors extracted from a large dataset of macroeconomic time series that capture additional economic information relevant to model the dynamics of $\mathbf{Z}_t$. The system reduces to the standard VAR used to evaluate DSGE models if $\mathbf{\Phi}_{12}(L) = 0$. Therefore, within this context, the relevant λ test would add to the usual DSGE model-related restrictions on $\mathbf{\Phi}_{11}(L)$ the restrictions $\mathbf{\Phi}_{12}(L) = 0$.

Consolo, Favero and Paccagnini (2007) apply this idea to find that FAVAR models dominate VAR specifications generated by adopting unrestricted versions of the solution of DSGE models. Such dominance is clearly established by analysis of

residuals and evaluation of forecasting performance. However, when the Bayesian approach is applied to the DSGE-FAVAR instead of the DSGE-VAR, some support for the DSGE model is still found in the data (the optimal λ in the DSGE-FAVAR is different from zero). Moreover, the optimal combination of the DSGE model and the statistical model based on a larger information set (the FAVAR) delivers a forecasting model (the DSGE-FAVAR) that dominates all alternatives. This evidence leads to a new interaction between theory and empirical analysis, where the theoretical DSGE model should not be considered as a model for the data but as a generator of prior distributions for the empirical model. The use of the FAVAR as an empirical model allows including in the analysis the information that is not considered in the theoretical model.

Besides this application there has been no work using FAVAR to evaluate DSGE. Interestingly, what has instead happened is that FAVAR has been interpreted as the reduced form of a DSGE model. This result has been achieved by removing the assumption that economic variables included in a DSGE are properly measured by a single indicator: variables in the theoretical model are considered as unobservable and the information in the factors is used to map them (Boivin and Giannoni, 2006). This approach makes a FAVAR the reduced form of a DSGE model, although the restrictions implied by the DSGE model on a general FAVAR are very difficult to trace and model evaluation becomes even more difficult to implement. In fact, a very tightly parameterized theory model can have a very highly parameterized reduced form if one is prepared to accept that the relevant theoretical concepts in the model are combinations of many macroeconomic and financial variables. Identification of the relevant structural parameters, which is already very hard in DSGE model with observed variables (see Canova and Sala, 2005), becomes even harder. Natural advantages of this approach are increased efficiency in the estimation of the model and improved forecasting performance. However, model evaluation becomes almost impossible to pursue and a theoretical model can only by rejected by another theoretical model, while the implied statistical model is made so general that it becomes very hard to use theory as a generator of prior distributions and it becomes impossible to use the evidence from the data to reject theory.

16.7 What's next?

The main challenge for the econometrics of monetary policy is in combining of theoretical models and information from the data to construct empirical models. The failure of the large econometric models at the beginning of the 1970s might be explained by their incapability of taking proper account of both these aspects. The great critiques by Lucas and Sims have generated an alternative approach which, at least initially, has been almost entirely dominated by theory. The LSE approach has instead concentrated on the properties of the statistical models and on the best way of incorporating information from the data into the empirical models, paying little attention to the economic foundation of the adopted specification. The realization that the solution of a DSGE model can be approximated by a restricted VAR, which is also a statistical model, has generated a potential link between the

two approaches. The open question is which type of VARs are most appropriate for the econometric analysis of monetary policy.

At the moment there are a number of alternative answers to this question. A first approach looks at theoretical DSGE models as the natural way to generate prior distributions for the empirical model, which should be an (optimal) combination of a tightly parameterized theoretical model and of a more general empirical model. This approach requires the application of Bayesian methods. A second approach looks at theory as informative only for the long-run relations between economic variables, so theory should be used to specify a cointegrated VAR in which the short-run dynamics are determined by the data but the long-run properties of the model depend on testable (and tested) theoretical assumptions. Importantly, both these answers recognize the importance of both the theoretical and the statistical model, although the relative weights can be very different. Within this framework, modeling nonlinearity and structural breaks could be an important development.

The econometrics of monetary policy is now based on models that incorporate a large number of nominal and real frictions added to the traditional neoclassical RBC models to replicate relevant features in observed data. These models typically incorporate the labour market, consumers and producers behavior and monetary and fiscal policies, so the next step is probably more accurate and explicit modeling of the interaction between financial markets and product markets.

16.8 Appendix: The Sims (2002) representation of a small macroeconomic model

Consider a small New Keynesian DSGE model of the economy which features a representative household optimizing over consumption, real money holdings and leisure, a continuum of monopolistically competitive firms with price adjustment costs and a monetary policy authority which sets the interest rate. The model is driven by three exogenous processes which determine government spending, g_t, the stationary component of technology, z_t, and the policy shock, $\epsilon_{R,t}$. A full description of the model can be found in Woodford (2003). For the purpose at hand we focus on its log-linear representation, which takes each variable as deviations from its trend. The model has a deterministic steady state with respect to the detrended variables: the common component is generated by a stochastic trend in the exogenous process for technology. The specification follows Del Negro and Schorfheide (2004)(DS) and reads:

$$\tilde{x}_t = E_t\tilde{x}_{t+1} - \frac{1}{\tau}(\tilde{R}_t - E_t\tilde{\pi}_{t+1}) + (1-\rho_G)\tilde{g}_t + \rho_z\frac{1}{\tau}\tilde{z}_t \tag{16.10}$$

$$\tilde{\pi}_t = \beta E_t\tilde{\pi}_{t+1} + \kappa\left(\tilde{x}_t - \tilde{g}_t\right) \tag{16.11}$$

$$\tilde{R}_t = \rho_R\tilde{R}_{t-1} + (1-\rho_R)(\psi_1\tilde{\pi}_t + \psi_2\tilde{x}_t) + \epsilon_{R,t} \tag{16.12}$$

$$\tilde{g}_t = \rho_g\tilde{g}_{t-1} + \epsilon_{g,t} \tag{16.13}$$

$$\tilde{z}_t = \rho_z\tilde{z}_{t-1} + \epsilon_{z,t}, \tag{16.14}$$

where $\tilde{x}_t$ is the output gap, $\tilde{\pi}_t$ is the inflation rate, $\tilde{R}_t$ is the short-term interest rate and $\tilde{g}_t$ and $\tilde{z}_t$ are two stationary AR(1) processes for government and technology, respectively.

The first equation is an intertemporal Euler equation obtained from the household's optimal choice of consumption and bond holdings. There is no investment in the model and so output is proportional to consumption up to an exogenous process that describes fiscal policy. The net effects of these exogenous shifts on the Euler equation are captured in the process $\tilde{g}_t$. The parameter $0 < \beta < 1$ is the household's discount factor and $\tau > 0$ is the inverse of the elasticity of intertemporal substitution. The second equation is the forward-looking Phillips curve, which describes the dynamics of inflation and where κ determines the degree of the short-run trade-off between output and inflation. The third equation is the monetary policy reaction function. The central bank follows a nominal interest rate rule by adjusting its instrument to deviations of inflation and output from their respective target levels. The shock $\epsilon_{R,t}$ can be interpreted as an unanticipated deviation from the policy rule or as policy implementation error. Fiscal policy is simply described by an autoregressive process. The set of structural shocks is thus $\epsilon_t = \left(\epsilon_{R,t}, \epsilon_{g,t}, \epsilon_{z,t}\right)'$, which collects technology, government and monetary shocks.

To cast the model in the form of:

$$\Gamma_0 \widetilde{\mathbf{Z}}_t = \Gamma_1 \widetilde{\mathbf{Z}}_{t-1} + C + \Psi \epsilon_t + \Pi \eta_t, \tag{16.15}$$

specify the relevant matrices as follows:

$$\widetilde{\mathbf{Z}}_t = \begin{bmatrix} \widetilde{x_t} \\ \widetilde{\pi_t} \\ \widetilde{R_t} \\ \widetilde{R_t^*} \\ \widetilde{g_t} \\ \widetilde{z_t} \\ \widetilde{E_t x_{t+1}} \\ \widetilde{E_t \pi_{t+1}} \end{bmatrix} \quad \epsilon_t = \begin{bmatrix} \epsilon_t^R \\ \epsilon_t^G \\ \epsilon_t^Z \end{bmatrix} \quad \eta_t = \begin{bmatrix} \eta_t^x = x_t - E_{t-1}(x_t) \\ \eta_t^\pi = \pi_t - E_{t-1}(\pi_t) \end{bmatrix}$$

$$\Gamma_0 = \begin{bmatrix} 1 & 0 & \frac{1}{\tau} & 0 & -(1-\rho_g) & -\frac{\rho_z}{\tau} & -1 & -\frac{1}{\tau} \\ -\kappa & 1 & 0 & 0 & \kappa & 0 & 0 & -\beta \\ 0 & 0 & 1 & -(1-\rho_R) & 0 & 0 & 0 & 0 \\ -\psi_2 & -\psi_1 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}$$

$$\Gamma_1 = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & \rho_R & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \rho_G & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & \rho_Z & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

$$\Psi = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \qquad \Pi = \begin{bmatrix} 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}.$$

As a solution to (16.15), we obtain the following policy function:

$$\tilde{Z}_t = T(\theta)\,\tilde{Z}_{t-1} + R(\theta)\,\epsilon_t. \tag{16.16}$$

To provide the mapping between the observable data and those computed as deviations from the steady-state of the model, we set the following measurement equations, as in DS:

$$\Delta \ln x_t = \ln \gamma + \Delta \tilde{x}_t + \tilde{z}_t \tag{16.17}$$

$$\Delta \ln P_t = \ln \pi^* + \tilde{\pi}_t \tag{16.18}$$

$$\ln R_t = 4[(\ln R^* + \ln \pi^*) + \tilde{R}_t], \tag{16.19}$$

which can also be cast into matrices as:

$$Y_t = \Lambda_0(\theta) + \Lambda_1(\theta)\,\tilde{Z}_t + \nu_t, \tag{16.20}$$

where $Y_t = \left(\Delta \ln x_t, \Delta \ln P_t, \ln R_t\right)'$, $\nu_t = 0$ and Λ_0 and Λ_1 are defined accordingly. For completeness, we write the matrices T, R, Λ_0 and Λ_1 as a function of the structural parameters in the model, $\theta = \left(\ln \gamma, \ln \pi^*, \ln r^*, \kappa, \tau, \psi_1, \psi_2, \rho_R, \rho_g, \rho_Z, \sigma_R, \sigma_g, \sigma_Z\right)'$: such a formulation derives from the rational expectations solution.

The evolution of the variables of interest, Y_t, is therefore determined by (16.15) and (16.20), which impose a set of restrictions across the parameters of the MA representation. Finally, the MA representation is approximated by a finite-order VAR representation.

Notes

1. The LSE approach was initiated by Denis Sargan but owes its diffusion to a number of Sargan's students and is extremely well described in the book by David Hendry (1995).

2. Importantly, the analysis of determinacy of the equilibria led to the discovery that a central bank can need fiscal backing; in fact, there is a class of equilibria for the economy that are invisible if one focuses entirely on money demand. These are equilibria in which the monetary authority is completely passive: it picks a nominal interest rate and agrees to accommodate any amount of debt issue by monetizing it. In conventional models this leads to an indeterminate price level, but in a model in which the fiscal authority is committed to a fixed level of primary surpluses there is a unique price level. So inflation cannot be controlled by only controlling the stock of money (see Leeper, 1991; Sims, 2007).
3. The statistical model is a VAR. When variables included in the VAR are non-stationary, the model can be reparameterized as a vector error correction model (VECM). In this case, after the solution of the identification problems of cointegrating vectors, the information set available at $t-1$ contains n lagged endogenous variables and r cointegrating vectors.
4. See the appendix for an example of this representation applied to a simple macroeconomic model.
5. Expressing the solution of a DSGE as a VAR might also involve solving some noninvertibility problems of the matrix governing the simultaneous relation among variables originally considered in the theoretical model. This problem is carefully discussed by Fabio Canova in Chapter 2 of this volume.
6. Importantly, these features ought to be different from those under examination.
7. Some abuses of this practice are present in the literature; the most common one is to compare the properties of filtered raw data with those of filtered model-generated data. Filtering model-generated data is clearly hard to justify given that model-generated data are stationary by their nature.

Macroeconometric Modeling for Policy

Gunnar Bårdsen and Ragnar Nymoen

Abstract

The first part of this chapter sets out a coherent approach to dynamic macroeconometric model-building; the second part demonstrates the approach through building and evaluating a small econometric model; the final part demonstrates various usages of the model for policy.

> "I think it should be generally agreed that a model that does not generate many properties of actual data cannot be claimed to have any 'policy implications' ..." (Clive W.J. Granger (1992, p. 4))

17.1 Introduction

Depending upon its properties, a macroeconometric model can highlight various aspects of economic policy: communication of policy actions, structuring of economic debate, policy simulations, testing of competing theories, forecasting, stress testing, etc. From an academic perspective, the desired properties of a model are also legion, but the end result will depend upon the preferences for coherence along dimensions such as: theory foundations (microfoundations/aggregation/general/partial), econometric methods (Bayesian/frequentist), and model properties (size/robustness/nonlinearities/transparency/dynamics).

Satisfying the different needs and desires of policy making could therefore entail a collection of models. Such a model collection could include more or less calibrated theory models, structural and Bayesian vector autoregressions (VARs), simultaneous equation models (SEMs), and dynamic stochastic general equilibrium (DSGE) models (see Pagan, 2003, for an overview). A choice of model(s) for the event at hand could then be made on the basis of strengths and weaknesses of the various candidates. The inherent weaknesses of the main candidates are well known. If one were to follow Ambrose Bierce, and write a "Devil's Dictionary" of macroeconometrics, some of the entries could read: Structural VARs: how to estimate models inefficiently; SEMs: estimates of something; Bayesian estimation: *see* calibration; DSGEs: sophisticated naivety. Therefore, a choice of model(s) for the event at hand should be made on the basis of strengths and weaknesses of the various model classes.

The profession's collective understanding of the causes and possible remedies of model limitations, both in forecasting and in policy analysis, has improved

markedly over the last decades. The Lucas (1976) critique and the Clements and Hendry (1999) analysis of the sources of forecast failures with macroeconometric models are milestones in that process. Interestingly, the methodological ramifications of those two critiques are different: the Lucas critique has led to the current dominance of representative agent-based macroeconomic models. Hendry (2001a), on the other hand, concludes that macroeconometric systems of equations, despite their vulnerability to regime shifts, but because of their potential adaptability to breaks, remain the best long-run hope for progress in macroeconomic forecasting. Since monetary policy can be a function of the forecasts, as with inflation forecast targeting (cf. Svensson, 1997), the choice of forecasting model(s) is important.

The class of macroeconometric models we present in this chapter requires coherent use of economic theory, data, and mathematical and statistical techniques. This approach, of course, has a long history in econometrics, going back to Tinbergen's first macroeconometric models, and has enjoyed renewed interest in the last decades. Recent advances in econometrics and in computing mean that we now have much better tools than, say, 20 years ago for developing and maintaining macroeconometric models in this tradition (see Garratt *et al.*, 2006, for one recent approach).

Regardless of underlying theory, a common aim of macroeconometric model-building is identification of invariant relationships, if they exist at all (see Haavelmo, 1944, Ch. II). A well-specified macroeconometric model is a good starting point for such a quest, since it provides an ideal test-bed for further over-identifying restrictions of microeconomic behavior. Such a strategy is, in particular, relevant to the challenges from behavioral economics, with implications for time inconsistency (hyperbolic discounting), changing expectations (learning), asset bubbles (herd behavior), etc.

Macroeconomic models of the representative agent, intertemporal optimizing, type are said to have structural interpretations, with "deep structural parameters" that are immune to the Lucas critique. However, when the model's purpose is to describe observed macroeconomic behavior, its structural properties are conceptually different. Heuristically, we take a model to have structural properties if it is invariant and interpretable (see Hendry, 1995b). Structural properties are nevertheless relative to the history, nature and significance of regime shifts. There is always the possibility that the next shocks to the system may incur real damage to a model with hitherto high structural content. The approach implies that a model's structural properties must be evaluated along several dimensions, and the following seem particularly relevant:

1. theoretical interpretation
2. ability to explain the data
3. ability to explain earlier findings, i.e., encompass the properties of existing models
4. robustness to new evidence in the form of updated/extended data series and new economic analysis suggesting, e.g., new explanatory variables.

Economic analysis (1) is an indispensable guidance in the formulation of econometric models. Clear interpretation also helps communication of ideas and results among researchers, in addition to structuring debate. However, since economic theories are necessarily simplifying abstractions, translations of theoretical to econometric models must lead to problems such as biased coefficient estimates, wrong signs of coefficients, and/or residual properties that hamper valid inference. The main distinction seems to be between seeing theory as representing *the* correct specification (leaving parameter estimation to the econometrician) and viewing theory as a guideline in the specification of a model which also accommodates institutional features, attempts to accommodate heterogeneity among agents, addresses the temporal aspects for the dataset, etc. (see Granger, 1999).

Arguments against "largely empirical models" include sample dependency, lack of invariance, unnecessary complexity (in order to fit the data) and chance findings of "significant" variables. Yet the ability to characterize the data (2) remains an essential quality of useful econometric models and, given the absence of theoretical truisms, the implications of economic theory have to be confronted with the data in a systematic way.

We use cointegration methods on linearized and discretized dynamic systems to estimate theory-interpretable and identified steady-state relationships, imposed in the form of equilibrium correction models. We also make use of an automated model selection approach to sift out the best theory-interpretable and identified dynamic specifications. Hoover and Perez (1999), Hendry and Krolzig (1999) and Doornik (2008) have shown that automated model selection methods have a good chance of finding a close approximation to the data-generating process (DGP), and that the danger of overfitting is, in fact, (surprisingly) low. Conversely, acting *as if* the specification is given by theory alone, with only coefficient estimates left to "fill in," is bound to result in the econometric problems noted above, and to a lower degree of relevance of the model for the economy it claims to represent.

In order to develop a scientific basis for policy modeling in macroeconometrics, a new model's capability of encompassing earlier findings should be regarded as an important aspect of structure (3). There are many reasons for the coexistence of contested models for the same phenomena, some of which may be viewed as inherent (limited number of data observations, measurement problems, controversy about operational definitions, new theories). Nevertheless, the continued use of corroborative evaluation (i.e., only addressing goodness-of-fit or predicting the stylized fact correctly) may inadvertently hinder the accumulation of evidence. One suspects that there would be huge gains from a breakthrough in new standards of methodology and practice for the profession.

Ideally, empirical modeling is a cumulative process whereby models continuously become overtaken by new and more useful ones. By "useful," we mean models that are relatively invariant to changes elsewhere in the economy, i.e., they contain autonomous parameters (see Haavelmo, 1944; Johansen, 1977; Aldrich, 1989; Hendry, 1995b). Models with a high degree of autonomy represent structural properties: they remain invariant to changes in economic policies and other

shocks to the economic system, as implied by (4) above.[1] However, structure is partial in two respects. First, autonomy is a relative concept, since an econometric model cannot be invariant to every imaginable shock. Second, all parameters of an econometric model are unlikely to be equally invariant, and only the parameters with the highest degree of autonomy represent structure. Since elements of structure typically will be grafted into equations that also contain parameters with a lower degree of autonomy, forecast breakdown may frequently be caused by shifts in these non-structural parameters.[2]

A strategy for model evaluation that puts emphasis on forecast behavior, without a careful evaluation of the causes of forecast failure *ex post*, runs a risk of discarding models that actually contain important elements of structure. Hence, e.g., Doornik and Hendry (1997) and Clements and Hendry (1999, Ch. 3) show that the main source of forecast failure is location shifts (shifts in means of levels, changes, etc.), and not shifts in such coefficients that are of primary concern in policy analysis, i.e., the derivative coefficients of behavioral equations. Therefore, a rough spell in terms of forecasting performance does not, by itself, disqualify the model's relevance for policy analysis. If the cause of the forecast failure is location shifts, they can be attenuated *ex post* by intercept correction or additional differencing "within" the model (Hendry, 2004). With these add-ons, and once the break period is in the information set, the model forecast will adapt to the new regime and improve again. Failure to adapt to the new regime may then be a sign of a deeper source of forecast failure, in the form of non-constant derivative coefficients, which also undermines the models relevance for policy analysis.[3] In general, without adaptive measures, models with high structural content will lose regularly to simple forecasting rules (see, e.g., Clements and Hendry, 1999; Eitrheim, Husebø and Nymoen, 1999). Hence different models may be optimal for forecasting and for policy analysis, which fits well with the often heard recommendations of a suite of monetary policy models.

Structural breaks are always a main concern in econometric modeling but, like any hypothesis or theory, the only way to judge the significance of a hypothesized break is by confrontation with the evidence in the data. Moreover, given that an encompassing approach is followed, a forecast failure is not only destructive but represents potential for improvement, if successful respecification follows in its wake (cf. Eitrheim, Jansen and Nymoen, 2002). In the same vein, one important intellectual rationale for DSGE models is the Lucas critique. If the Lucas critique holds, any "reduced-form" equation in a model is liable to be unstable over the historical sample, due to regime shifts and policy changes that have taken place in the economy. Hence, according to the Lucas critique, parameter instability may be endemic in any model that fails to obey the rational expectations hypothesis (REH), with the possible consequence that without integration of the REH, the model is unsuited for policy analysis. However, as stated by Ericsson and Irons (1995), the Lucas critique is only a possibility theorem, not a truism, and the implications of the Lucas critique can be tested (see also, e.g., Hendry, 1988; Engle and Hendry, 1993; Ericsson and Hendry, 1999). In Bårdsen, Jansen and Nymoen

(2003) we have shown, by extensive testing of a previous version of our model, that the Lucas critique has little force for our system of equations. This finding is consistent with the international evidence presented in Ericsson and Irons (1995) and Stanley (2000). On the basis of these results, our model is more consistent with agents adopting robust forecasting rules, in line with the analysis and suggestions of Hendry and Mizon (2000). In that case the Lucas critique does not apply, although the degree of autonomy remains an issue that needs to be evaluated as fully as possible, given the information available to us.

This chapter documents the approach we use to dynamic macroeconometric model-building and policy analysis. To make the analysis applied, the approach is illustrated through a model of the Norwegian economy. Our approach is, of course, applicable to other economies, but we know more about market characteristics, policy changes and institutional development in Norway than in any other country or economic area. And since such factual knowledge is an indispensable and complementary aid to formal econometrics in the building of an empirical model, we prefer to work with the economy we have most knowledge about.

The rest of the chapter consists of three main sections. Section 17.2 sets out a coherent approach to dynamic macroeconometric model building; section 17.3 demonstrates the approach through building and evaluating a small econometric model; section 17.4 demonstrates various tools for policy analysis using the model. Section 17.2 involves three steps in going from general to specific. The first step is theoretical and establishes a framework for linearizing and discretizing an approximation to a general theory model with constant steady-state values. The second step is to estimate, and solve, the steady-state model in the form of overidentifying cointegrating relationships and common trends. The third step is to identify and estimate the dynamic structure of the model.

Section 17.3 illustrates the approach set out in section 17.2 by the construction and evaluation of a small open-economy model.

Section 17.4 demonstrates five tools for policy using the model: tractability, simulations of policy responses, optimal policy considerations, theory evaluation, and forecasting. The first use is illustrated by introducing a method to construct stylized versions of complex models. The second use is illustrated by evaluating responses to monetary policy shocks. The third use shows how important model specification is for the derivation of optimal monetary policy. The fourth use is illustrated by testing the New Keynesian Phillips curve. The final use evaluates possible sources affecting forecast performance.

17.2 A modeling framework

As the values of all major economic variables are announced regularly, it is easy to believe that a local approximation to a DGP can exist. It is an interesting philosophical question whether the true generating mechanism can (ever) be completely described, but the usefulness of the concept does not hinge on the answer to that question. The main point is that once the real economic world, in its enormous, ever-changing complexity, is accepted as a premise for macroeconomic modeling,

it follows that the main problems of macroeconometrics are model specification and model evaluation, rather than finding the best estimator under the assumption that the model is identical to the DGP.

The local DGP is changing with the evolution of the real world economy–through technical progress, changing patterns of family composition and behavior, and political reform. Sometimes society evolves gradually and econometric models are then usually able to adapt to the underlying real-life changes, i.e., without any noticeable loss in "usefulness." Often, however, society evolves so quickly that estimated economic relationships break down and cease to be of any aid in understanding the current macroeconomy and in forecasting its development even over the first couple of years. In this case we speak of a changing local approximation in the form of a regime shift in the generating process, and a structural break in the econometric model. Since the complexity of the true macroeconomic mechanism, and the regime shifts also contained in the mechanism, lead us to conclude that any model will at best be a local approximation to the DGP, judging the quality of, and choosing between, the approximations becomes central.

In the rest of this section we present our approach to finding a local approximation useful for policy.[4]

17.2.1 Linearization

Consider a very simple example of an economic model in the form of the differential equation:

$$\frac{dy}{dt} = f(y, x), \quad x = x(t), \tag{17.1}$$

in which a constant input $x = \bar{x}$ induces $y(t)$ to approach asymptotically a constant state $\bar{y}$ as $t \to \infty$. Clearly $\bar{x}$ and $\bar{y}$ satisfy $f(\bar{y}, \bar{x}) = 0$. For example, standard DSGE models usually take this form, with the models having deterministic steady-state values. The usual procedure then is to expand the differential (or difference) equation about this steady-state solution (see, e.g., Campbell, 1994; Uhlig, 1999). Employing this procedure yields:

$$f(y, x) = f(\bar{y}, \bar{x}) + \frac{\partial f(\bar{y}, \bar{x})}{\partial y}(y - \bar{y}) + \frac{\partial f(\bar{y}, \bar{x})}{\partial x}(x - \bar{x}) + R, \tag{17.2}$$

where:

$$R = \frac{1}{2!}\left(\frac{\partial^2 f(\xi, \eta)}{\partial x^2}(x - \bar{x})^2 + 2\frac{\partial^2 f(\xi, \eta)}{\partial x \partial y}(x - \bar{x})(y - \bar{y}) + \frac{\partial^2 f(\xi, \eta)}{\partial y^2}(y - \bar{y})^2\right),$$

and (ξ, η) is a point such that ξ lies between y and $\bar{y}$ while η lies between x and $\bar{x}$. Since $\bar{y}$ and $\bar{x}$ are the steady-state values for y and x respectively, then the expression for $f(y, x)$ takes the simplified form:

$$f(y, x) = a\,(y - \bar{y}) + \delta\,(x - \bar{x}) + R, \tag{17.3}$$

where $a = \partial f(\bar{y}, \bar{x})/\partial y$ and $\delta = \partial f(\bar{y}, \bar{x})/\partial x$ are constants.

If f is a linear function of y and x then $R = 0$ and so:

$$f(x, y) = a\left(y - \bar{y} + \frac{\delta}{a}(x - \bar{x})\right) = a\,(y - bx - c), \tag{17.4}$$

in which $b = -\delta/a$ and $c = \bar{y} + (\delta/a)\bar{x}$.

17.2.2 Discretization

For a macroeconometric model, a discrete representation is usually practical, and it can be worked out as follows. Let $t_1,\ t_2,\ \cdots,\ t_k,\ \cdots$ be a sequence of times spaced h apart and let $y_1,\ y_2,\ \cdots,\ y_k,\ \cdots$ be the values of a continuous real variable $y(t)$ at these times. The backward-difference operator $\triangle$ is defined by the rule:

$$\triangle y_k = y_k - y_{k-1}, \quad k \geq 1. \tag{17.5}$$

By observing that $y_k = (1 - \triangle)^0 y_k$ and $y_{k-1} = (1 - \triangle)^1 y_k$, the value of y at the intermediate point $t = t_k - sh$ $(0 < s < 1)$ may be estimated by the interpolation formula:

$$y(t_k - sh) = y_{k-s} = (1 - \triangle)^s y_k, \quad s \in [0, 1]. \tag{17.6}$$

When s is not an integer, $(1 - \triangle)^s$ should be interpreted as the power series in the backward-difference operator obtained from the binomial expansion of $(1 - x)^s$. This is an infinite series of differences. Specifically:

$$(1 - \triangle)^s = 1 - s\triangle - \frac{s(1-s)}{2!}\triangle^2 - \frac{s(1-s)(2-s)}{3!}\triangle^3 - \cdots. \tag{17.7}$$

With this preliminary background, the differential equation:

$$\frac{dy}{dt} = f(y, x), \quad x = x(t), \tag{17.8}$$

may be integrated over the time interval $[t_k, t_{k+1}]$ to obtain:

$$y(t_{k+1}) - y(t_k) = \triangle y_{k+1} = \int_{t_k}^{t_{k+1}} f(y(t), x(t))\,dt, \tag{17.9}$$

in which the integral on the right-hand side of this equation is to be estimated by using the backward-difference interpolation formula given in equation (17.7). The substitution $t = t_k + sh$ is now used to change the variable of this integral from $t \in [t_k, t_{k+1}]$ to $s \in [0, 1]$. The details of this change of variable are:

$$\int_{t_k}^{t_{k+1}} f(y(t), x(t))\,dt = \int_0^1 f(y(t_k + sh), x(t_k + sh))\,(h\,ds) = h\int_0^1 f_{k+s}\,ds,$$

where $f_{k+s} = f(y(t_k+sh), x(t_k+sh))$. The value of this latter integral is now computed using the interpolation formula based on (17.7). Thus:

$$\begin{aligned}\int_0^1 f_{k+s}\,ds &= \int_0^1 (1-\triangle)^{-s} f_k\,ds \\ &= \int_0^1 \left(f_k + s\triangle f_k + \frac{s(1+s)}{2!}\triangle^2 f_k + \frac{s(1+s)(2+s)}{3!}\triangle^3 f_k + \cdots\right) ds \\ &= f_k + \frac{1}{2}\triangle f_k + \frac{5}{12}\triangle^2 f_k + \frac{3}{8}\triangle^3 f_k + \cdots .\end{aligned}$$

The final form for the backward-difference approximation to the solution of this differential equation is therefore

$$\triangle y_{k+1} = hf_k + \frac{h}{2}\triangle f_k + \frac{5h}{12}\triangle^2 f_k + \frac{3h}{8}\triangle^3 f_k + \cdots . \tag{17.10}$$

17.2.3 Equilibrium correction representations and cointegration

The discretization scheme (17.10) applied to the linearized model (17.3), with $k = t-1$ and $h = 1$, gives the equilibrium correction model, EqCM, representation

$$\begin{aligned}\triangle y_t = a\,(y - bx - c)_{t-1} + R_{t-1} + \frac{1}{2}a(\triangle y_{t-1} - b\triangle x_{t-1}) + \frac{1}{2}\triangle R_{t-1} \\ + \frac{5}{12}a(\triangle^2 y_{t-1} - b\triangle^2 x_{t-1}) + \frac{5}{12}\triangle^2 R_{t-1} + \cdots .\end{aligned}$$

At this point two comments are in place. The first is that an econometric specification will mean a truncation of the polynomial both in terms of powers and lags. Diagnostic testing is therefore imperative to ensure a valid local approximation, and indeed to test that the statistical model is valid (see Hendry, 1995a, p. 15.1; Spanos, 2008). The second is that the framework allows for flexibility regarding the form of the steady state. The standard approach in DSGE modeling has been to filter the data, typically using the so-called Hodrick–Prescott filter, to remove trends, hopefully achieving stationary series with constant means, and then work with the filtered series. Another approach, popular at present, is to impose the theoretical balanced growth path of the model on the data, expressing all series in terms of growth corrected values. However, an alternative approach is to estimate the balanced growth paths in terms of finding the number of common trends and identifying and estimating cointegrating relationships. The present approach allows for all of these interpretations.

To illustrate the approach in terms of cointegration, consider real wages to be influenced by productivity, as in many theories.[5] Assume that the logs of the real wage rw_t and productivity z_t are each integrated of order one, but found to be cointegrated, so:

$$rw_t \sim I(1)\,,\ \triangle rw_t \sim I(0) \tag{17.11}$$

$$z_t \sim I(1)\,,\ \triangle z_t \sim I(0) \tag{17.12}$$

$$(rw - \beta z)_t \sim I(0)\,. \tag{17.13}$$

Letting $y_t \equiv (rw - \beta z)_t$ and $x_t \equiv \Delta z_t$ then gives:

$$\Delta rw_t = -ac + a(rw - \beta z)_{t-1} + \frac{a}{2}\Delta\,(rw - \beta z)_{t-1} + \beta\Delta z_t - ab\Delta z_{t-1} - \frac{ab}{2}\,\Delta^2 z_{t-1} + \cdots.$$

17.2.4 System representations

The approach easily generalizes to a system representation. For ease of exposition, we illustrate the two-dimensional case for which $y_1 \to \bar{y}_1$ and $y_2 \to \bar{y}_2$ as $t \to \infty$. Expanding with respect to y_1 and y_2 about their steady-state values yields:

$$\begin{bmatrix} f_1\,(y_1, y_2) \\ \\ f_2\,(y_1, y_2) \end{bmatrix} = \begin{bmatrix} f_1\,(\bar{y}_1, \bar{y}_2) \\ \\ f_2\,(\bar{y}_1, \bar{y}_2) \end{bmatrix} + \begin{bmatrix} \dfrac{\partial f_1(\bar{y}_1, \bar{y}_2)}{\partial y_1} & \dfrac{\partial f_1(\bar{y}_1, \bar{y}_2)}{\partial y_2} \\ \dfrac{\partial f_2(\bar{y}_1, \bar{y}_2)}{\partial y_1} & \dfrac{\partial f_2(\bar{y}_1, \bar{y}_2)}{\partial y_2} \end{bmatrix} \begin{bmatrix} y_1 - \bar{y}_1 \\ \\ y_2 - \bar{y}_2 \end{bmatrix} + \begin{bmatrix} R_1 \\ \\ R_2 \end{bmatrix},$$

where $[R_1, R_2]'$ denotes the vector:

$$\frac{1}{2!}\begin{bmatrix} \dfrac{\partial^2 f_1(\zeta, \eta)}{\partial y_1^2}\,(y_1 - \bar{y}_1)^2 + 2\dfrac{\partial^2 f_1(\zeta, \eta)}{\partial y_1 \partial y_2}\,(y_1 - \bar{y}_1)\,(y_2 - \bar{y}_2) + \dfrac{\partial^2 f_1\,(\zeta, \eta)}{\partial y_2^2}\,(y_2 - \bar{y}_2)^2 \\ \dfrac{\partial^2 f_2\,(\zeta, \eta)}{\partial y_1^2}\,(y_1 - \bar{y}_1)^2 + 2\dfrac{\partial^2 f_2\,(\zeta, \eta)}{\partial y_1 \partial y_2}\,(y_1 - \bar{y}_1)\,(y_2 - \bar{y}_2) + \dfrac{\partial^2 f_2\,(\zeta, \eta)}{\partial y_2^2}\,(y_2 - \bar{y}_2)^2 \end{bmatrix},$$

so that:

$$\begin{bmatrix} \dfrac{\partial y_1}{\partial t} \\ \dfrac{\partial y_2}{\partial t} \end{bmatrix} = \begin{bmatrix} \alpha_{11} & \alpha_{12} \\ \\ \alpha_{21} & \alpha_{22} \end{bmatrix} \begin{bmatrix} y_1 - \bar{y}_1 \\ \\ y_2 - \bar{y}_2 \end{bmatrix} + \begin{bmatrix} R_1 \\ \\ R_2 \end{bmatrix}.$$

The backward-difference approximation to the solution of the system of differential equations gives the system in EqCM form (see Bårdsen, Hurn and Lindsay, 2004, for details), namely:

$$\begin{aligned} \begin{bmatrix} \Delta y_1 \\ \Delta y_2 \end{bmatrix}_t &= \begin{bmatrix} -\alpha_{11} c_1 \\ -\alpha_{22} c_2 \end{bmatrix} + \begin{bmatrix} \alpha_{11} & 0 \\ 0 & \alpha_{22} \end{bmatrix} \begin{bmatrix} y_1 - \delta_1 y_2 \\ y_2 - \delta_2 y_1 \end{bmatrix}_{t-1} + \begin{bmatrix} R_1 \\ \\ R_2 \end{bmatrix}_{t-1} \\ &+ \frac{1}{2}\begin{bmatrix} \alpha_{11} & \alpha_{12} \\ \alpha_{21} & \alpha_{22} \end{bmatrix} \begin{bmatrix} \Delta y_1 \\ \Delta y_2 \end{bmatrix}_{t-1} + \begin{bmatrix} \Delta R_1 \\ \\ \Delta R_2 \end{bmatrix}_{t-1} \\ &+ \frac{5}{12}\begin{bmatrix} \alpha_{11} & \alpha_{12} \\ \alpha_{21} & \alpha_{22} \end{bmatrix} \begin{bmatrix} \Delta^2 y_1 \\ \Delta^2 y_2 \end{bmatrix}_{t-1} + \begin{bmatrix} \Delta^2 R_1 \\ \\ \Delta^2 R_2 \end{bmatrix}_{t-1} \\ &+ \frac{3}{8}\begin{bmatrix} \alpha_{11} & \alpha_{12} \\ \alpha_{21} & \alpha_{22} \end{bmatrix} \begin{bmatrix} \Delta^3 y_1 \\ \Delta^3 y_2 \end{bmatrix}_{t-1} + \begin{bmatrix} \Delta^3 R_1 \\ \\ \Delta^3 R_2 \end{bmatrix}_{t-1} + \cdots, \end{aligned}$$

with:

$$c_1 = \left(\bar{y}_1 + \delta_1 \bar{y}_2\right), \quad \delta_1 = \frac{\alpha_{12}}{\alpha_{11}}$$
$$c_2 = \left(\bar{y}_2 + \delta_2 \bar{y}_1\right), \quad \delta_2 = \frac{\alpha_{21}}{\alpha_{22}}.$$

As before, the variables y_1 and y_2 can be considered as stationary functions of non-stationary components – cointegration is imposed upon the system. Consider the previous example, assuming linearity so $R_i = 0$, and ignoring higher-order dynamics for ease of exposition:

$$\begin{bmatrix} \triangle y_1 \\ \triangle y_2 \end{bmatrix}_t = \begin{bmatrix} -\alpha_{11} c_1 \\ -\alpha_{22} c_2 \end{bmatrix} + \begin{bmatrix} \alpha_{11} & 0 \\ 0 & \alpha_{22} \end{bmatrix} \begin{bmatrix} y_1 - \delta_1 y_2 \\ y_2 - \delta_2 y_1 \end{bmatrix}_{t-1}$$
$$\begin{bmatrix} \triangle(rw - \beta z) \\ \Delta^2 z \end{bmatrix}_t = \begin{bmatrix} -\alpha_{11} c_1 \\ -\alpha_{22} c_2 \end{bmatrix} + \begin{bmatrix} \alpha_{11} & 0 \\ 0 & \alpha_{22} \end{bmatrix} \begin{bmatrix} (rw - \beta z) - \delta_1 \Delta z \\ \Delta z - \delta_2 (rw - \beta z) \end{bmatrix}_{t-1},$$

or multiplied out:

$$\triangle rw_t = -\alpha_{11} c_1 + \alpha_{11} (rw - \beta z)_{t-1} + \beta \Delta z_t - \alpha_{12} \Delta z_{t-1}$$
$$\Delta z_t = -\alpha_{22} \left(\bar{y}_2 + \frac{\alpha_{21}}{\alpha_{22}} \bar{y}_1\right) + \left(\alpha_{22} - 1\right) \Delta z_{t-1} - \alpha_{21} (rw - \beta z)_{t-1}.$$

If $\alpha_{21} = 0$ and $\left|\alpha_{22} - 1\right| < 1$ the system simplifies to the familiar exposition of a bivariate cointegrated system with z being weakly exogenous for β:

$$\triangle rw_t = -\alpha_{11} c_1 + \alpha_{11} (rw - \beta z)_{t-1} + \beta \Delta z_t - \alpha_{12} \Delta z_{t-1}$$
$$\Delta z_t = -\alpha_{22} \bar{z} + \left(\alpha_{22} - 1\right) \Delta z_{t-1},$$

where the common trend is a productivity trend.

17.2.5 From a discretized and linearized cointegrated VAR representation to a dynamic SEM in three steps

We will keep this section brief, as comprehensive treatments can be found in many places – e.g., Hendry (1995a), Johansen (1995, 2006), Juselius (2007), Garratt *et al.* (2006), and Lütkepohl (2006) – and only make some comments on issues in each step in the modelling process we believe merit further attention.

17.2.5.1 First step: the statistical system

Our starting point for identifying and building a macroeconometric model is to find a linearized and discretized approximation as a data-coherent statistical system representation in the form of a cointegrated VAR:

$$\Delta \mathbf{y}_t = \mathbf{c} + \Pi \mathbf{y}_{t-1} + \sum_{i=1}^{k} \Gamma_{t-i} \Delta \mathbf{y}_{t-i} + \mathbf{u}_t, \tag{17.14}$$

with independent Gaussian errors $\mathbf{u}_t$, as a basis for valid statistical inference about economic theoretical hypotheses.

The purpose of the statistical model (17.14) is to provide the framework for hypothesis testing, the inferential aspect of macroeconometric modeling. However, it cannot be postulated directly, since the cointegrated VAR itself rests on assumptions. Hence, validation of the statistical model is an essential step: is a model which is linear in the parameters flexible enough to describe the fluctuations of the data? What about the assumed constancy of parameters, does it hold over the sample that we have at hand? The assumption of Gaussian distributed error terms also needs validation, since that assumption underlies the use of (17.14) for statistical inference. The main intellectual rationale for the model validation aspect of macroeconometrics is exactly that the assumptions of the statistical model requires separate attention (Johansen, 2006; Spanos, 2006). In practice, one important step in model validation is to make the hypothesized statistical model subject to a battery of misspecification tests using the ordinary least squares (OLS) residuals $\hat{\mathbf{u}}_t$ as data.[6]

As pointed out by Garratt *et al.* (2006), the representation (17.14) does not preclude forward-looking behavior in the underlying model, as rational expectations models have backward-looking solutions. The coefficients of the solution will be defined in specific ways though, and this entails restrictions on the VAR which can be utilized for testing rational expectations (see Johansen and Swensen, 1999, 2004).

Even with a model which, for many practical purposes, is small scale, it is usually too big to be formulated in "one go" within a cointegrated VAR framework. Hence, model (17.14) is not interpretable as a rather high-dimensional VAR, with the (incredible) long lags which would be needed to capture the complicated dynamic interlinkages of a real economy. Instead, as explained in Bårdsen *et al.* (2003), our operational procedure is to partition the (big) simultaneous distribution function of markets and variables (prices, wages, output, interest rates, the exchange rate, foreign prices, and unemployment, etc.) into a (much smaller) simultaneous model of wage- and price-setting – the labor market – and several sub-models of the rest of the macro-economy. The econometric rationale for specification and estimation of single equations, or of markets, subject to exogeneity conditions, before joining them up in a complete model, is discussed in Bårdsen, Jansen and Nymoen (2003) and also in Bårdsen *et al.* (2005, Ch. 2).

17.2.5.2 Second step: the overidentified steady state

The second step of the model-building exercise will then be to identify the steady state, by testing and imposing overidentifying restrictions on the cointegration space:

$$\Delta \mathbf{y}_t = \mathbf{c} + \alpha \beta^{'} \mathbf{y}_{t-1} + \sum_{i=1}^{k} \Gamma_{t-i} \Delta \mathbf{y}_{t-i} + \mathbf{u}_t,$$

thereby identifying both the exogenous common trends, or permanent shocks, and the steady state of the model.

Even though there now exists a literature on identification of cointegration vectors, it is worthwhile to reiterate that identification of cointegrating vectors cannot be databased. Identifying restrictions have to be imposed *a priori*. It is therefore of crucial importance to have a specification of the economic model and its derived steady-state before estimation. Otherwise we will not know what model and hypotheses we are testing and, in particular, we could not be certain that it was identifiable from the available dataset.

17.2.5.3 Third step: the dynamic SEM

The final step is to identify the dynamic structure:

$$\mathbf{A}_0 \Delta \mathbf{y}_t = \mathbf{A}_0 \mathbf{c} + \mathbf{A}_0 \alpha \beta^{'} \mathbf{y}_{t-1} + \sum_{i=1}^{k} \mathbf{A}_0 \Gamma_{t-i} \Delta \mathbf{y}_{t-i} + \mathbf{A}_0 \mathbf{u}_t,$$

by testing and imposing overidentifying restrictions on the dynamic part – including the forward-looking part – of the statistical system.

The estimated parameters and, therefore, the interpretation of the model dynamics are dependent upon the dating of the steady-state solution. However, the steady-state multipliers are not. The economic interpretations of the derived paths of adjustment are not invariant to the identification of the dynamic part of the model, whereas the steady-state parts of the model are (see Bårdsen and Fisher, 1993, 1999).

17.2.6 Example: the supply side of a medium-term macroeconomic model

One main focus of an empirical macro-model is always going to be the supply side. We end the section on methodology by giving an extended example of the theoretical and econometric specification of a labor market model that we later include in a macro-model, intended for medium-term analysis and forecasting. The first step is the specification of the relevant economic theory to test. We next develop the theoretical relationships into hypotheses about cointegration that can be tested in a statistical model and identified as steady-state relationships, Steps 1 and 2 above. We also go through Step 3 in detail. Throughout the rest of the chapter we let lower-case letters denote natural logarithms of the corresponding upper-case variable names, so $x_t \equiv \ln(X_t)$.

17.2.6.1 Economic theory

A main advance in the modeling of labor markets rests on the perception that firms and their workers are engaged in a partly cooperative and partly conflicting sharing of the rents generated by the operation of the firm. In line with this assumption, *nominal wages* are modeled in a game theoretic framework which fits the comparatively high level of centralization and coordination in Norwegian wage-setting (see, e.g., Nymoen and Rødseth, 2003; Barkbu, Nymoen and Røed, 2003, for a discussion of the degree of coordination).

The modeling of nominal wage-setting in a game theoretic framework is a theoretical advance with several implications. Linked with an assumption of monopolistically competitive firms, it represents an incomplete competition model of the

supply side, which we refer to as ICM in the following (see Bårdsen *et al.*, 2005, Chs. 5 and 6). In applications, the gap between the formal relationships of the theory and the empirical relationships that may be present in the data must be closed. The modeling assumption about $I(1)$-ness introduced above is an important part of the bridge between theory and data. This is because $I(1)$-ness allows us to interpret the theoretical wage and price equations as hypothesized cointegration relationships. From that premise, a dynamic model of the supply side in equilibrium-correction form follows logically.

There is a number of specialized models of "non-competitive" wage-setting. Our aim here is to represent the common features of these approaches by extending the model in Nymoen and Rødseth (2003) with monopolistic competition among firms.

We start with the assumption of a large number of firms, each facing downward-sloping demand functions. The firms are price-setters and equate marginal revenue to marginal costs. With labor being the only variable factor of production (and constant returns to scale), we have the price-setting relationship:

$$Q_i = \frac{El_Q Y}{El_Q Y - 1} \frac{W_i(1 + T1_i)}{Z_i},$$

where $Z_i = Y_i/N_i$ is average labor productivity, Y_i is output and N_i is labor input. W_i is the wage rate in the firm, and $T1_i$ is a payroll tax rate. $El_Q Y > 1$ denotes the absolute value of the elasticity of demand facing each firm i with respect to the firm's own price. In general, $El_Q Y$ is a function of relative prices, which provides a rationale for the inclusion of, e.g., the real exchange rate in aggregate price equations. However, it is a common simplification to assume that the elasticity is independent of other firms prices and is identical for all firms. With constant returns technology, aggregation is no problem, but for simplicity we assume that average labor productivity is the same for all firms and that the aggregate price equation is given by:

$$Q = \frac{El_Q Y}{El_Q Y - 1} \frac{W(1 + T1)}{Z}. \tag{17.15}$$

The expression for real profits (Π) is therefore

$$\Pi = Y - \frac{W(1 + T1)}{Q} N = \left(1 - \frac{W(1 + T1)}{Q} \frac{1}{Z}\right) Y.$$

We assume that the wage W is set in accordance with the principle of maximizing the Nash product:

$$(V - V_0)^{\upsilon} \Pi^{1-\upsilon}, \tag{17.16}$$

where V denotes union utility and V_0 denotes the fallback utility or reference utility. The corresponding break-point utility for the firms has already been set to zero in (17.16), but for unions the utility during a conflict (e.g., strike or work-to-rule) is non-zero because of compensation from strike funds. Finally, υ represents the relative bargaining power of unions.

Union utility depends on the consumer real wage of an unemployed worker and the aggregate rate of unemployment, thus $V(\frac{W}{P}, U, A_v)$ where P denotes the consumer price index.[7] The partial derivative with respect to wages is positive, and negative with respect to unemployment ($V'_W > 0$ and $V'_U \leq 0$). A_v represents other factors in union preferences. The fallback or reference utility of the union depends on the overall real wage level and the rate of unemployment, hence $V_0 = V_0(\frac{\bar{W}}{P}, U)$ where $\bar{W}$ is the average level of nominal wages, which is one of the factors determining the size of strike funds. If the aggregate rate of unemployment is high, strike funds may run low, in which case the partial derivative of V_0 with respect to U is negative ($V'_{0U} < 0$). However, there are other factors working in the other direction, for example that the probability of entering a labor market program, which gives laid-off workers higher utility than open unemployment, is positively related to U.

With these specifications of utility and break-points, the Nash product, denoted $\mathcal{N}$, can be written as:

$$\mathcal{N} = \left\{ V\left(\frac{W}{P}, U, A_v\right) - V_0\left(\frac{\bar{W}}{P}, U\right) \right\}^{\upsilon} \left\{ \left(1 - \frac{W(1+T1)}{Q}\frac{1}{Z}\right) Y \right\}^{1-\upsilon},$$

or:

$$\mathcal{N} = \left\{ V\left(\frac{RW}{P_q(1+T1)}, U, A_v\right) - V_0\left(\frac{\bar{W}}{P}, U\right) \right\}^{\upsilon} \left\{ \left(1 - RW\frac{1}{Z}\right) Y \right\}^{1-\upsilon},$$

where $RW = W(1+T1)/Q$ is the producer real wage, and $P_q(1+T1) = P(1+T1)/Q$ is the *wedge* between the consumer and producer real wage.

Note also that, unlike many expositions of the so-called "bargaining approach" to wage modeling (e.g., Layard, Nickell and Jackman, 1991, Ch. 7), there is no aggregate labor demand function – employment as a function of the real wage – subsumed in the Nash product. In this we follow Hahn and Solow (1997, Ch. 5.3), who point out that bargaining is usually over the nominal wage and not over employment.

The first-order condition for a maximum is given by $\mathcal{N}_{RW} = 0$, or:

$$\upsilon \frac{V'_W\left(\frac{RW}{P_q(1+T1)}, U, A_v\right)}{V\left(\frac{RW}{P_q(1+T1)}, U, A_v\right) - V_0\left(\frac{\bar{W}}{P}, U\right)} = (1-\upsilon)\frac{\frac{1}{Z}}{\left(1 - RW\frac{1}{Z}\right)}. \tag{17.17}$$

In a symmetric equilibrium, $W = \bar{W}$, leading to $\frac{RW}{P_q(1+T1)} = \frac{\bar{W}}{P}$ in equation (17.17). The aggregate bargained real wage RW^b is defined implicitly as:

$$RW^b = F(P_q(1+T1), Z, \upsilon, U), \tag{17.18}$$

or, using the definition:

$$RW^b \equiv W^b(1+T1)/Q,$$

we obtain the solution for the bargained nominal wage:

$$W^b = \frac{Q}{(1+T1)} F(P_q(1+T1), Z, \mho, U). \tag{17.19}$$

Letting lower-case letters denote logs of variables, a log-linearization of (17.19) gives:

$$w^b = m_w + q_t + (1-\delta_{12})(p-q) + \delta_{13} z - \delta_{15} u - \delta_{16} T1. \tag{17.20}$$
$$0 \le \delta_{12} \le 1,\ 0 < \delta_{13} \le 1,\ \delta_{15} \ge 0,\ \ 0 \le \delta_{16} \le 1.$$

The elasticity of the wedge variable $(p-q)$ is $(1-\delta_{12})$ in (17.20). In econometric models of wage-setting in manufacturing, the hypothesis of $\delta_{12} = 1$ is typically not rejected, meaning that the wedge variable drops out and the bargained nominal wage is linked one-to-one with the producer price q (see, e.g., Nymoen and Rødseth, 2003). However, at the aggregate level, a positive coefficient of the wedge is typically reported. This may be due to measurement problems: since gross domestic product (GDP) is an income variable, the price deflator q is not a good index of "producer prices." That said, the estimated importance of the wedge may also reflect that the economy-wide average wage is influenced by the service sector, where wage claims are linked to cost of living considerations, implying that $(1-\delta_{12})$ is different from zero.

Irrespective of the split between q and p, productivity z is found to be a main determinant of the secular growth in wages in bargaining-based systems, so we expect the elasticity δ_{13} to be close to one. The impact of the rate of unemployment on the bargained wage is given by the elasticity $-\delta_{15} \le 0$. Blanchflower and Oswald (1994) provide evidence for the existence of the empirical law that the value of $-\delta_{15}$ is 0.1, which is the slope coefficient of their *wage curve*. Other authors instead emphasize that the slope of the wage-curve is likely to depend on the level of aggregation and on institutional factors. For example, one influential view holds that economies with a high level of coordination and centralization are expected to be characterized by a higher responsiveness to unemployment (a higher $-\delta_{15}$) than uncoordinated systems that give little incentive to solidarity in wage-bargaining (Layard, Nickell and Jackman, 2005, Ch. 8). Finally, from the definition of the wedge, one could set $\delta_{16} = \delta_{12}$, but we keep δ_{16} as a separate coefficient to allow for separate effects of the payroll tax on wages.

Equation (17.20) is a general proposition about the bargaining outcome and its determinants, and can serve as a starting point for describing wage formation in any sector or level of aggregation of the economy. In the following we regard equation (17.20) as a model of the average wage in the total economy and, as explained above, we therefore expect $(1-\delta_{12}) > 0$, meaning that there is a wedge effect in the long-run wage equation.

Equation (17.15) already represents a price-setting rule based upon so-called normal cost pricing. Upon linearization we have:

$$q^f = m_q + (w + T1 - z), \tag{17.21}$$

where we use q^f as a reminder that this is a theoretical equation for firms' price-setting.

17.2.6.2 Cointegration and long-run identification

At this point we show how the two theoretical relationships (17.20) and (17.21) can be transformed into hypothesized relationships between observable time series. As explained in section 17.2.3, our maintained modeling assumption is that the real wage and productivity are $I(1)$ series. The rate of unemployment is assumed to be $I(0)$, possibly after removal of deterministic shifts in the mean.

Using subscript t to indicate period t variables, equation (17.20) defines w_t^b as an $I(1)$ variable. Next define:

$$ecm_t^b = rw_t - rw_t^b \equiv w_t - w_t^b.$$

Under the null hypothesis that the theory is correct, the "bargained wage" w_t^b cointegrates with the actual wage, hence $ecm_t^b \sim I(0)$, which is a testable hypothesis. We can write the long-run wage equation following from bargaining theory as:

$$w_t = m_w + q_t + (1 - \delta_{12})(p_t - q_t) + \delta_{13} z_t - \delta_{15} u_t - \delta_{16} T1_t + ecm_t^b. \qquad (17.22)$$

With reference to equation (17.21), a similar argument applies to price-setting. The "firm-side" real wage can be defined as:

$$rw_t^f \equiv w_t + T1_t - q_t^f = -m_q + z_t,$$

and the difference between the actual real wage and the real wage implied by price-setting becomes:

$$ecm_t^f = rw_t - rw_t^f = w_t + T1_t - q_t - \{-m_q + z_t\}.$$

Hence, the implied long-run price-setting equation becomes:

$$q_t = m_q + (w_t + T1_t - z_t) - ecm_t^f, \qquad (17.23)$$

where $ecm_t^f \sim I(0)$ for the equation to be consistent with the modeling assumptions.

The two cointegrating relationships (17.22) and (17.23) are not identified in general, but in several cases of relevance, identification is unproblematic (see Bårdsen *et al.*, 2005, p. 81). Here we consider a case which is relevant for an aggregate model of the supply side in an open economy. Equations (17.22) and (17.23) can then be combined with a definition of the consumer price index p_t,

$$p_t = (1 - \zeta) q_t + \zeta pi_t + \eta T3_t, \; 0 < \zeta < 1, \quad 0 < \eta \leq 1, \qquad (17.24)$$

where the import price index pi_t naturally enters. The parameter ζ reflects the openness of the economy.[8] Also, the size of the parameter η will depend on how much of the retail price basket is covered by the indirect tax-rate index $T3_t$. By substitution of (17.24) in (17.22), and of (17.23) in (17.24), the system can be

specified in terms of w_t and p_t:

$$w_t = m_w + \left\{1 + \zeta \frac{\delta_{12}}{(1-\zeta)}\right\} p_t \tag{17.25}$$
$$- \frac{\delta_{12}\zeta}{(1-\zeta)} pi_t - \frac{\delta_{12}\eta}{(1-\zeta)} T3_t + \delta_{13} z_t - \delta_{15} u_t - \delta_{16} T1_t + ecm_t^b$$

$$p_t = (1-\zeta) m_q + (1-\zeta)\left\{w_t + T1_t - z_t\right\} + \zeta pi_t + \eta T3_t - (1-\zeta) ecm_t^f. \tag{17.26}$$

By simply viewing (17.25) and (17.26) as a pair of simultaneous equations, it is clear that the system is unidentified in general. However, for the purpose of modeling the aggregate economy, we choose the consumer price index p_t as the representative domestic price index by setting $\delta_{12} = 0$. In this case, (17.26) is unaltered, while the wage equation becomes:

$$w_t = m_w + p_t + \delta_{13} z_t - \delta_{15} u_t - \delta_{16} T1_t + ecm_t^b. \tag{17.27}$$

The long-run price equation (17.26) and the long-run wage equation (17.27) are identified by the order condition.

17.2.6.3 VAR and identified equilibrium correction system

The third stage in the operationalization is the equilibrium-correction system, where we follow Bårdsen and Fisher (1999). In brief, we allow wage growth Δw_t to interact with current and past price inflation, changes in unemployment, changes in tax rates, and previous deviations from the desired wage level consistent with (17.27):

$$\begin{aligned} \Delta w_t - \alpha_{12,0} \Delta q_t = {} & c_1 + \alpha_{11}(L)\,\Delta w_t + \alpha_{12}(L)\,\Delta q_t + \beta_{12}(L)\,\Delta z_t \\ & - \beta_{14}(L)\,\Delta u_t - \beta_{15}(L)\,\Delta T1_t \\ & - \gamma_{11} ecm_{t-r}^b + \beta_{18}(L)\,\Delta p_t + \epsilon_{1t}, \end{aligned} \tag{17.28}$$

where Δ is the difference operator, and the $\alpha_{1j}(L)$ and $\beta_{1j}(L)$ are polynomials in the lag operator L:

$$\alpha_{1j}(L) = \alpha_{1j,1} L + \cdots + \alpha_{1j,(r-1)} L^{r-1},\ j = 1, 2,$$
$$\beta_{1j}(L) = \beta_{1j,0} + \beta_{1j,1} L + \cdots + \beta_{1j,(r-1)} L^{r-1},\ j = 2, 4, 5, 6.$$

The β-polynomials are defined so that they can contain contemporaneous effects. The order r of the lag polynomials may, of course, vary between variables and is to be determined empirically. This specification is a generalization of the typical European wage curve, where the American version is derived by setting $\gamma_{11} = 0$ (see Blanchard and Katz, 1999).

Any increase in output above the optimal trend exerts a (lagged) positive pressure on prices, measured by the output gap_t, as in Phillips curve inflation models (see Clarida, Gali and Gertler, 1999). In addition, product price inflation interacts with

wage growth and productivity gains and with changes in the payroll tax rate, as well as with corrections from an earlier period's deviation from the equilibrium price (as a consequence of, e.g., information lags; see Andersen, 1994, Ch. 6.3):

$$\Delta q_t - \alpha_{21,0}\Delta w_t = c_2 + \alpha_{22}(L)\,\Delta q_t + \alpha_{21}(L)\,\Delta w_t + \beta_{21}(L)\,gap_t - \beta_{22}(L)\,\Delta z_t + \beta_{25}(L)\,\Delta T1_t - \gamma_{22} ecm^f_{t-r} + \epsilon_{2t}, \tag{17.29}$$

where:

$$\alpha_{2j}(L) = \alpha_{2j,1}L + \cdots + \alpha_{2j,(r-1)}L^{r-1},\ j = 1, 2,$$

$$\beta_{2j}(L) = \beta_{2j,0} + \beta_{2j,1}L \cdots + \beta_{2j,(r-1)}L^{r-1}, j = 1, 2, 5.$$

Solving equation (17.24) for Δq_t (i.e., the equation is differenced first), and then substituting out in equations (17.28) and (17.29), the theoretical model condenses to a wage–price model suitable for estimation and similar to the early equilibrium-correction formulation of Sargan (1980):

$$\begin{aligned}
&\begin{bmatrix} 1 & -a_{12,0} \\ -a_{21,0} & 1 \end{bmatrix}\begin{bmatrix} \Delta w \\ \Delta p \end{bmatrix}_t \\
&= \begin{bmatrix} \alpha_{11}(L) & -a_{12}(L) \\ -a_{21}(L) & \alpha_{22}(L) \end{bmatrix}\begin{bmatrix} \Delta w \\ \Delta p \end{bmatrix}_t \\
&+ \begin{bmatrix} 0 & \beta_{12}(L) & -\zeta\dfrac{\alpha_{12}(L)}{1-\zeta} & -\beta_{14}(L) & -\beta_{15}(L) & -\eta\dfrac{\alpha_{12}(L)}{1-\zeta} \\ b_{21}(L) & -b_{22}(L) & \zeta\alpha_{22}(L) & 0 & b_{25}(L) & \eta\alpha_{22}(L) \end{bmatrix} \\
&\times \begin{bmatrix} gap \\ \Delta z \\ \Delta pi \\ \Delta u \\ \Delta T1 \\ \Delta T3 \end{bmatrix}_t - \begin{bmatrix} \gamma_{11} & 0 \\ 0 & \gamma_{22} \end{bmatrix} \\
&\times \begin{bmatrix} 1 & -(1+\zeta d_{12}) & -\delta_{13} & \zeta d_{12} & \delta_{15} & \delta_{16} & \eta d_{12} \\ -(1-\zeta) & 1 & (1-\zeta) & -\zeta & 0 & -(1-\zeta) & -\eta \end{bmatrix} \\
&\times \begin{bmatrix} w \\ p \\ z \\ pi \\ u \\ T1 \\ T3 \end{bmatrix}_{t-r} + \begin{bmatrix} e_1 \\ e_2 \end{bmatrix}_t,
\end{aligned} \tag{17.30}$$

where we have omitted the intercepts to save space, and have substituted the equilibrium-correction terms using (17.25) and (17.26) above. The mapping from the theoretical parameters in (17.28) and (17.29) to the coefficients of the model

(17.30) is given by:

$$
\begin{aligned}
a_{12,0} &= \frac{\alpha_{12,0}}{1-\zeta} + \beta_{18,0}, \\
a_{21,0} &= (1-\zeta)\,\alpha_{21,0}, \\
a_{12}(L) &= \frac{\alpha_{12}(L)}{1-\zeta} + \beta_{18}(L), \\
a_{21}(L) &= (1-\zeta)\,\alpha_{21}(L), \\
b_{2j}(L) &= (1-\zeta)\,\beta_{2j}(L), \; j = 1, 2, 5, \\
d_{12} &= \frac{\delta_{12}}{1-\zeta}, \\
e_1 &= \epsilon_1, \\
e_2 &= (1-\zeta)\,\epsilon_2.
\end{aligned}
\tag{17.31}
$$

The model (17.30) contains the different channels and sources of inflation discussed so far: imported inflation Δpi_t, and several relevant domestic variables – the output gap, and changes in the rate of unemployment, in productivity, and in tax rates. Finally, the model includes deviations from the two cointegration equations associated with wage-bargaining and price-setting, which have equilibrium-correction coefficients γ_{11} and γ_{22} respectively. Consistency with assumed cointegration implies that the joint hypothesis of $\gamma_{11} = \gamma_{22} = 0$ can be rejected.

17.2.6.4 Economic interpretation of the steady state

The dynamic model in (17.30) can be rewritten in terms of real wages $(w-p)_t$ and real exchange rates $(pi-p)_t$. Using a specification with first-order dynamics, Bårdsen *et al.* (2005, Ch. 6) discuss several different aspects of this model. Most importantly, the dynamic system is asymptotically stable under quite general assumptions about the parameters, including, e.g., dynamic homogeneity in the two equilibrium-correction equations. The steady state is conditional on any given rate of unemployment, which amounts to saying that our core supply-side model does not tie down an equilibrium rate of unemployment. Instead, there is a stalemate in the dynamic "tug-of-war" between workers and firms that occurs for, in principle, any given rate of unemployment (see Kolsrud and Nymoen, 1998; Bårdsen and Nymoen, 2003, for proofs). Since there are no new unit roots implied by the generalized dynamics in equation (17.30) above, asymptotic stability holds also for this, extended, version of the model. We therefore have the following important results: the dynamics of the supply side are asymptotically stable in the usual sense that, if all stochastic shocks are switched off, then $(pi_t - q_t) \to rex_{ss}(t)$, and $(w_t + T1_t - q_t) = wq_{ss}(t)$, where $rex_{ss}(t)$ and $wq_{ss}(t)$ represent deterministic steady-state growth paths of the real exchange rate and the producer real wage.

Generally, the steady-state growth paths depend on the steady-state growth rate of import prices, and of the mean of the logarithm of the rate of unemployment, denoted u_{ss}, and the expected growth path of productivity $z(t)$. However, under the

condition that $\delta_{13} = 1$, homogeneity of degree one with respect to productivity, which we have seen is implied theoretically by assuming bargaining power on the part of unions, $z(t)$ has a zero coefficient in the expression for rex_{ss}, which therefore is constant in the steady state. Moreover, assuming $\delta_{13} = 1$, the implied steady-state wage share, $wq_{ss}(t) - z(t) = ws_{ss}$, which is also a constant in steady state.

With $\delta_{13} = 1$, the implied steady-state inflation rate therefore follows immediately: since $\Delta(pi_t - q_t) = 0$ in steady state, and $\Delta p_t = (1-\zeta)\,\Delta q_t + \zeta\,\Delta pi_t$, domestic inflation is equal to the constant steady-state rate of imported inflation:

$$\Delta p_t = \Delta pi_t = \pi. \tag{17.32}$$

The above argument implicitly assumes an exogenous and, for simplicity, constant, nominal exchange rate. For the case of an endogenous nominal exchange rate, as with a floating exchange rate regime, it might be noted that, since:

$$pi_t = v_t + p_t^*,$$

where v_t is the nominal exchange rate and the index of import prices in foreign currency is denoted p_t^*, the stability of inflation requires stability of Δv_t. This condition can only be verified by the use of a more complete model representation of the economy, which is what we do when we consider the steady state of a complete econometric model in section 17.3.2 below. However, to anticipate events slightly, the complete model that we document below meets the requirement in the sense that $\Delta^2 v_t \to 0$ in the long run. But our results also indicate that π in (17.32) is affected by the rate of change in the nominal exchange rate, which might be non-zero in an asymptotically stable steady state.

The supply-side determined steady state has a wider relevance as well. For example, what does the model say about the dictum that the existence of a steady-state inflation rate requires that the rate of unemployment follows the law of the natural rate or non-accelerating inflation rate of unemployment (NAIRU)? The version of this natural rate/NAIRU view of the supply side that fits most easily into our framework is the one succinctly expressed by Layard, Nickell and Jackman (1994, p. 18; emphasis added): "Only if the real wage (W/P) desired by wage-setters is the same as that desired by price setters will inflation be stable. *And, the variable that brings about this consistency is the level of unemployment.*" Translated to our conceptual framework, this view corresponds to setting $ecm_t^b = ecm_t^f = 0$ in (17.22) and (17.23), with $\delta_{13} = 1$, and solving for the rate of unemployment that reconciles the two desired wage shares, call it u^w:[9]

$$u^w = \frac{m_w + m_q}{-\delta_{15}} + \frac{1-\delta_{12}}{-\delta_{15}}(p-q) + \frac{1-\delta_{16}}{-\delta_{15}}T1,$$

which can be expressed in terms of the real exchange rate $(p - pi)$, and the two tax rates as:

$$u^w = \frac{-(m_w + m_q)}{\delta_{15}} + \frac{1-\delta_{12}}{\delta_{15}(1-\zeta)}\zeta(p-pi) + \frac{1-\delta_{12}}{\delta_{15}(1-\zeta)}\eta T3 + \frac{1-\delta_{16}}{-\delta_{15}}T1. \tag{17.33}$$

This is one equation in two endogenous variables, u^w and the wedge $(p - pi)$, so it appears that there is a continuum of u^w values depending on the size of the wedge, in particular of the value of the real exchange rate. It is, however, customary to assume that the equilibrium value of the wedge is determined by the requirement that the current account is in balance in the long run. Having thus pinned down the long-run wedge as a constant equilibrium real exchange rate $(\overline{p - pi})$, it follows that NAIRU u^w is determined by (17.33). If the effect of the wedge on wage claims is not really a long-run phenomenon, then $\delta_{12} = 1$ and u^w is uniquely determined from (17.33), and there is no need for the extra condition about balanced trade in the long run (see Layard, Nickell and Jackman, 2005, p. 33).

Compare this to the asymptotically stable equilibrium consisting of $u_t = u_{ss}$, $\Delta p_t = \pi$ and $w_t + T1 - q_t - z_t = ws_{ss}$. Clearly, inflation is stable, even though u_{ss} is determined "from the outside" and is not determined by the wage- and price-setting equations of the model. Hence the (emphasized) second sentence in the above quotation has been disproved: it is not necessary that u_{ss} corresponds to the NAIRU u^w in equation (17.33) for inflation to be stable with a well-defined value in steady state.

Figure 17.1 illustrates the different equilibria. Wage-setting and price-setting curves correspond to (deterministic versions) of equations (17.22) and (17.23). The NAIRU u^w is given by the intersection of the curves, but the steady-state rate of unemployment u_{ss} may be lower than u^w, the case shown in the graph, or higher. The figure further indicates (by a •) that the steady-state wage share will reside at a point on the line segment A–B: heuristically, this is a point where price-setters

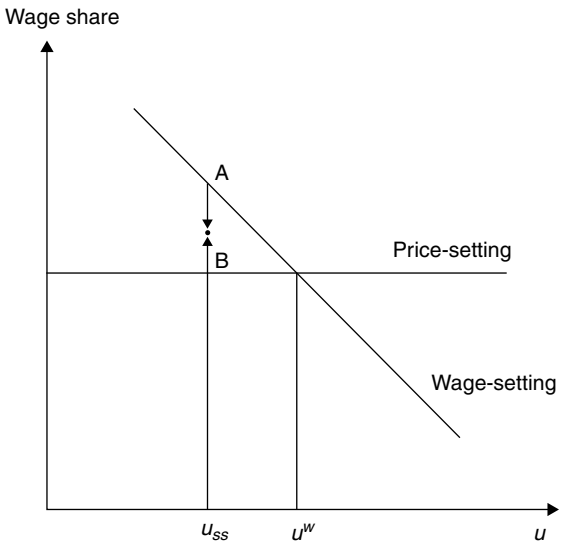

Figure 17.1 Real wage and unemployment determination, NAIRU and the steady-state rate of unemployment u_{ss}

are trying to attain a lower real wage by nominal price increases, at the same time as the wage bargain is delivering nominal wage increases that push the real wage upwards.

Bårdsen *et al.* (2005, Ch. 6) show which restrictions on the parameters of the system (17.30) are necessary for $u_t \to u_{ss} = u^w$ to be an implication, so that the NAIRU corresponds to the stable steady state. In brief, the model must be restricted in such a way that the nominal wage- and price-setting adjustment equations become two conflicting dynamic equations for the real wage. Because of the openness of the economy, this is not achieved by imposing dynamic homogeneity. What is required is to purge the model (17.30) of all nominal rigidity, which seems to be unrealistic on the basis of both macro- and micro-evidence.

We have seen that the Layard–Nickell version of the NAIRU concept corresponds to a set of restrictions on the dynamic model of wage- and price-setting. The same is true for the natural rate of unemployment associated with a vertical Phillips curve, which still represents the baseline model for the analyses of monetary policy. This is most easily seen by considering a version of (17.28) with first-order dynamics and where we simplify the equation by setting the short-run effects of productivity, unemployment and taxes equal to zero ($\beta_{12} = \beta_{14} = \beta_{15} = 0$). With first-order dynamics we have:

$$\Delta w_t - \alpha_{12,0}\Delta q_t = c_1 - \gamma_{11} ecm^b_{t-1} + \beta_{18}\Delta p_t + \epsilon_{1t},$$

and using (17.22) we can then write the wage equation as:

$$\begin{aligned}\Delta w_t = {} & k_w + \alpha_{12,0}\Delta q_t + \beta_{18}\Delta p_t - \mu_w u_{t-1} \\ & - \gamma_{11}(w_{t-1} - q_{t-1}) + \gamma_{11}(1-\delta_{12})(p_{t-1} - q_{t-1}) + \gamma_{11}\delta_{16} T1_{t-1} + \epsilon_{1t},\end{aligned} \tag{17.34}$$

where $k_w = c_1 + \gamma_{11} m_w$, and the parameter μ_w is defined in accordance with Kolsrud and Nymoen (1998) as:

$$\mu_w = \gamma_{11}\delta_{13} \text{ when } \gamma_{11} > 0 \text{ or } \mu_w = \varphi \text{ when } \gamma_{11} = 0. \tag{17.35}$$

The notation in (17.35) may seem cumbersome at first sight, but it is required to secure internal consistency: note that if the nominal wage rate is adjusting towards the long-run wage curve, $\gamma_{11} > 0$, the only logical value of φ in (17.35) is zero, since u_{t-1} is already contained in the equation, with coefficient $\gamma_{11}\delta_{15}$. Conversely, if $\gamma_{11} = 0$ so the model of collective wage-bargaining fails, it is nevertheless possible that there is a wage Phillips curve relationship consistent with the assumed $I(0)$-ness of the rate of unemployment, hence $\mu_w = \varphi \geq 0$ in this case.

Subject to the restriction $\gamma_{11} = 0$, and assuming an asymptotically stable steady-state inflation rate π, (17.34) can be solved for the Phillips curve NAIRU u^{phil}:

$$u^{phil} = \frac{k_w}{\varphi} + \frac{(\alpha_{12,0} + \beta_{18} - 1)}{\varphi}\pi,$$

which becomes a natural rate of unemployment, independent of inflation subject to dynamic homogeneity $\alpha_{12,0} + \beta_{18} = 1$.

However, the claim that u_t^{phil} represents an asymptotically stable solution must be stated with some care. As shown in, e.g., Bårdsen and Nymoen (2003), $\gamma_{11} = 0$ is a necessary but not a sufficient condition. The sufficient conditions include $\gamma_{22} = 0$ in addition to $\gamma_{11} = 0$ and, instead of equilibrium correction in wages and prices, dynamic stability requires equilibrium correction in the unemployment equation or in a functionally equivalent part of the model.

The result that the steady-state level of unemployment is generally undetermined by the wage–price sub-model is a strong case for building larger systems of equations, even if the main objective is to model inflation. Conversely, in general, no inconsistencies or issues about overdetermination arise from enlarging the wage/price-setting equations with a separate equation for the rate of unemployment, where demand-side variables may enter.

Looking ahead, in section 17.4.3 we show how the specification of the supply side, either as a Phillips curve model (PCM) or as an incomplete competition model (ICM) given by equations (17.28) and (17.29) above, gains economic significance though the implications of the chosen specification for optimal interest rate-setting.

17.2.6.5 Implementation in the Norwegian aggregate model

We have implemented the above model of the supply side in our quarterly model of the Norwegian economy, called the Norwegian aggregate model (NAM).[10]

The estimated versions of (17.30) are given in section 17.3.1, equations (17.38) and (17.39). The equilibrium correction terms are defined consistently with the two long-run equations (17.25) and (17.26). For example, $\delta_{12} = 0$, $\zeta = 0.7$, $\delta_{15} = 0.1$ and $\delta_{16} = 1$ are taken as known parameters from the cointegration analysis documented in Bårdsen *et al.* (2005, Ch. 9.2). With this parameterization, the estimated equilibrium correction coefficients $\hat{\gamma}_{11}$ and $\hat{\gamma}_{22}$ are jointly and individually significant (the t-values are 8.6 and 3.8).

The estimated short-run dynamics can also be interpreted in the light of the theoretical model (17.30). For example, the estimated wage equation (17.39) shows that $\hat{a}_{12}(1) = 1$, saying that dynamic homogeneity with respect to consumer price is a valid restriction on wage dynamics in the wage equation. Identification of the short-run wage price model is in terms of zero-restrictions on the GDP growth variable in the Δw_t equation, and on the change in the rate of unemployment in the Δp_t equation. There are overidentifying restrictions as well though.

17.3 Building a model for monetary policy analysis

Monetary policy now plays a dominant role in stabilization policy in general and in managing inflation in particular. As economists have recognized for a long time, inflation is a many-faceted phenomenon. In particular, in open economies, a proper understanding of the inflation mechanism requires the construction of a

model that separates the internal dynamics of the domestic wage price spiral from the factors that impinge upon it from outside. The complexity of the real-world inflation process also means that models which only include one or two dimensions typically fail to characterize the data. Our starting point is therefore that, at a minimum, foreign and domestic aspects of inflation have to be modeled jointly, and that the inflationary impetus from the labor market, the battle of markups between unions and monopolistic firms, needs to be represented in the model.

The last section ended with an example of the econometric specification of a model of wage- and price-setting that defines an integral part of the NAM model. Earlier versions of this model have been used to analyze the issues raised by the introduction of model-based monetary policy in Norway (see Bårdsen, Jansen and Nymoen, 2002, 2003; Bårdsen *et al.*, 2005). NAM is in use for forecasting as part of the Normetrics forecasting system.[11] A designated version is operational for stress testing by the financial stability division at the central bank of Norway.

17.3.1 The model and its transmission mechanisms

In the regime with inflation targeting, the policy instrument in the model is the money market interest rate, symbolized by R in Figure 17.2 (and throughout this chapter), with the estimated reaction function reported in equation (17.46).[12]

The qualitative transmission mechanisms of the model, from the perspective of monetary policy analysis, are shown in Figure 17.2. The corresponding quantitative approximate transmission mechanisms are easily worked out with the stylized

where $\pi_{Ct} \equiv 100\frac{\Delta_4 P_{C,t}}{P_{C,t-4}}$; $\bar{\pi}_U = 2.5$ (the inflation target); $\bar{U} = 3.4$ (average unemployment rate); $\bar{R}^* = 3.5$ (average foreign short-run interest rate).

Note: Standard errors are reported in parentheses below the coefficients. See the appendix to this chapter for information about the statistics reported below each equation.

model version in section 17.4.1. That simplified quantitative transmission mechanism is derived from the dynamic econometric model reported in Table 17.1. We report the estimated macroeconometric relationships in equilibrium-correction form, with cointegration coefficients imposed as known. The identities that complete the NAM model are not reported. To save space, seasonals and other dummies are also omitted from the equations in the table. The definitions of the variables in the equations are given in the appendix to this chapter.

Consider, for example, the analysis conducted in section 17.4.2.1 of an increase in the interest rate R. The immediate and direct effect is an appreciation of the krone, measured as an increase in the exchange rate v, defined as krone per unit foreign exchange. The multiplier is approximated in (17.60) as $\frac{\Delta v_t}{\Delta R_t} \approx -0.04$, while the complete equation is reported in (17.36).[13]

The decrease in v will affect domestic prices and wage-setting through decreased import prices pi, as reported in equations (17.37)–(17.39), which gives corresponding approximate partial multipliers as $\frac{\Delta pi_t}{\Delta v_t} \approx 0.9$ and $\frac{\Delta p_t}{\Delta pi_t} \approx 0.03$ from (17.61) and (17.62). Hence, at least for a period of time after the interest rate increase, the *exchange rate channel* will provide inflation dampening following an increase in the interest rate.

The exchange rate channel also affects wages and prices indirectly, through GDP y and unemployment u, reported in equations (17.44) and (17.41), respectively. The mechanisms are as follows. Due to nominal rigidity, the real exchange rate appreciates together with the nominal rate, causing decreased competitiveness, lower output, and higher unemployment. Together with the interaction with productivity z in equation (17.40), this constitutes the *labor market channel*. For example, the approximate partial real-wage response from a shock to unemployment is $\frac{\Delta(w-p)_t}{\Delta u_t} \approx -0.04$ from (17.63).

The interest rate effects on the real economy are first channeled through financial markets, where an increase in the money market rate leads to adjustment of the banks' interest rate R_L, and bond yield R_B (see (17.42)–(17.43)). A rise in R_L affects GDP through an increased real interest rate. This is the *demand channel* found in mainstream monetary policy models (see e.g., Ball, 1999). In the model, there is also a second, *credit channel*, whereby interest rates affect output: when interest rates are raised, the amount of available real credit is reduced, as documented in (17.45), which has a negative effect on output. The average partial multiplier is $\frac{\Delta y_t}{\Delta(l-p)_t} \approx 0.4$, using (17.68).

The transmission mechanism pictured in Figure 17.2 shows that the model contains both positive and negative feedback effects from wage and price adjustments, to GDP and unemployment. Higher inflation means that the real interest rate continues to fall in the first periods after the initial cut in the nominal rate (positive feedback). On the other hand, and again due to the raised rate of inflation, the real exchange rate will start to stabilize (negative feedback).

In the figure, the focus is on the transmission mechanisms, which may give the impression that the development of wages and prices is mainly "determined by" monetary policy. This is not the case since, e.g., the important trend component in wages is related to productivity growth through wage-bargaining – (see (17.38)–(17.40)). Having analyzed the transmission mechanism of the model, we now turn to the steady-state properties, pinned down by the overidentified cointegrated steady-state relationships of the model, which are discussed in the next section.

17.3.2 Steady state

Equations (17.47)–(17.56) represent the model's implied long-run relationships. Cointegrated combinations of non-stationary variables are on the left-hand sides of the equations, while stationary variables are evaluated at their mean values on the right.

$$\left(v + p^* - p\right)_t = -0.12\left[(R - \pi) - \left(R^* - \pi^*\right)\right] + \mu_v \tag{17.47}$$

$$\left(pi - v - pi^*\right)_t - 0.55\left(p - v - p^*\right)_t = \mu_{pi} \tag{17.48}$$

$$p_t - 0.7(w - z)_t - (1 - 0.7)\,pi_t = \mu_p \tag{17.49}$$

$$\left(w - p - z\right)_t = 0.1u + \mu_w \tag{17.50}$$

$$z_t - 0.47\left(w - p\right)_t - 0.0029Trend_t = 0.03u + \mu_z \tag{17.51}$$

$$0 = u - 7.7\Delta\left(w - p\right) - 4.5\left[0.01\,(RL - \pi) - \Delta_4 y\right] - \mu_u \tag{17.52}$$

$$0 = RL - 0.41RB - 0.76R - \mu_{RL} \tag{17.53}$$

$$0 = RB - 0.43R - 0.57RB^* - \mu_{RB} \tag{17.54}$$

$$y_t - 0.9g_t - 0.16(v + p^* - p)_t = -0.06\,(RL - \pi) + \mu_y \tag{17.55}$$

$$\left(l - p\right)_t - 2.65y_t + 0.04(RL - RB)_t = \mu_{l-p}. \tag{17.56}$$

Equation (17.47) represents the equilibrium in the market for foreign exchange in a floating exchange rate regime. The central bank's foreign currency reserves are exogenous in the floating exchange rate regime that we are modeling, and therefore are not specified in (17.47). The nominal exchange rate v equilibrates the market in each time period, specifically in the hypothetical steady state represented in (17.47). The relationship follows from the definition of the risk premium, *rp*:

$$rp_t = R_t - R_t^* - (v_{t+1}^e - v_t),$$

where $(v_{t+1}^e - v_t)$ denotes expected depreciation. In real terms, using the definition $rex = v + p^* - p$, the relationship can be written as:

$$\left(v_{t+1}^e + p_{t+1}^{*e} - p_{t+1}^e\right) - \left(v_t + p_t^* - p_t\right) = \left[R_t - \left(p_{t+1}^e - p_t\right)\right] - \left[R_t^* - \left(p_{t+1}^{*e} - p_t^*\right)\right] - rp_t$$

$$\Delta rex_t^e = \left(R_t - \pi_{t+1}^e\right) - \left(R_t^* - \pi_{t+1}^{*e}\right) - rp_t.$$

If expected depreciation of the real exchange rate is assumed to react to deviations from the equilibrium real exchange rate $\overline{rex}$,

$$\Delta rex_t^e = \alpha\left(rex_t - \overline{rex}\right),$$

the solution for the realized real exchange rate becomes:

$$rex_t = \frac{1}{\alpha}\left[\left(R_t - \pi_{t+1}^e\right) - \left(R_t^* - \pi_{t+1}^{*e}\right)\right] + \overline{rex} - \frac{1}{\alpha} rp_t.$$

Finally, replacing expected with realized inflation and assuming a constant risk premium, the steady-state real exchange rate relationship becomes:

$$rex = -.12\left[(R - \pi) - \left(R^* - \pi^*\right)\right] + \mu_v,$$

The sign of α shows whether expectations are regressive ($\alpha < 0$) or extrapolative ($\alpha > 0$), so in our case, since real interest rates are in percentage points, α is given as:

$$\frac{1}{\alpha} = -.12 \times 100,$$

implying that expected depreciation is regressive with approximately 8% adjustment per period:

$$\Delta rex_t^e = -0.083\left(rex_t - \overline{rex}\right).$$

The long-run pass-through from the exchange rate and foreign prices onto import prices in domestic currency *pi* is represented by equation (17.48). It is a homogeneous function of v and foreign producer prices pi^*, but the import price also increases if the real exchange rate (in terms of consumer prices) appreciates. This is due to pricing-to-markets in import price-setting. Equation (17.48) is written in a way that shows the long-run relationship between the two operational definitions

of the real exchange rate. Hence, a 1% real appreciation in terms of consumer prices is associated with only a 0.55% appreciation in terms of import prices.

The equations for wage formation and domestic price-setting, in steady-state form, are given by (17.49)–(17.50) and have already been discussed in section 17.2.6. Equation (17.51) models output per hour of labor input, or productivity z. Productivity is positively influenced by both the real wage $(w - p)$ and the unemployment rate u – corresponding to efficiency wage models – as well as neutral technological progress approximated by a linear trend.

The steady-state rate of unemployment in equation (17.52) is seen to depend on the growth of real wages (which is contant in the steady state), and the difference between the real interest rate and the real GDP growth rate (see also Hendry, 2001b), which can potentially change, and will then induce a change in the long-run mean of the rate of unemployment.

Equations (17.53)–(17.56) represent the steady-state relationships for the market interest rates for loans R_L and bonds R_B, (17.53) and (17.54), followed by the equations for GDP (17.55) and domestic credit (17.56). Government expenditure is seen to be important in the GDP equation, but aggegate demand is also influenced by the market for foreign exchange through the real exchange rate $(v + p^* - p)$ (dubbed *rex* above) and the domestic real interest rate. According to equations (17.55) and (17.56), secular growth in domestic real credit is conditioned by the growth of the real economy, not the other way around, but an exogenous drop in credit supply (i.e., reduced μ_{l-p}) will harm GDP growth in the short run.

From the set of long-run relationships, it is straightforward to derive the steady state of the model. Differentiation of (17.47) gives inflation as:

$$\Delta p = \Delta p^* + \Delta v, \tag{17.57}$$

and steady-state wage growth is then:

$$\Delta w = \Delta p^* + \Delta z + \Delta v, \tag{17.58}$$

while import inflation follows from the price equation (17.49) and becomes:

$$\Delta pi = \Delta p^* + \Delta v. \tag{17.59}$$

Note that these relationships represent the same qualitative conclusion that we obtained from analysis of the theoretical supply-side model; compare equation (17.32), e.g., which is therefore seen to generalize to the full set of economic steady state relationships.

In light of the above, it also becomes clear that the economic long-run relationship (17.48) represents no separate restriction on the long-run relationship between growth rates, as it is a relationship between the marginal means of the two real exchange rates. The rest of the model can be solved for the steady-state rate of productivity, and for the steady-state unemployment level using (17.58), (17.51) and (17.52). Finally, the GDP growth rate and rate of growth in credit then follow from (17.47) and (17.56).

The above steady-state properties are derived for an exogenous policy interest rate R. The nature of the solution is not changed if we instead specify either an estimated interest rate reaction function on the basis of the data, or a response function based on theories of optimal policy rules. But the behavior of the dynamics will be affected, and the policy analysis and the level of predicted long-run inflation will depend on how the interest rate is modeled.

We agree with Hendry and Mizon (2000) that there are reasons for being pragmatic about how the policy instrument is "treated" in a macroeconometric model. For some purposes it is relevant to treat the instrument as exogenous, like in the analysis of the steady state (this sub-section) and its stability (next sub-section). That analysis will answer whether there is a fundamental tendency of dynamic instability in the model that instrument use will have to counteract in order to avoid the economy taking an unstable course or, conversely, whether there is sufficient stability represented by the modeled relationships. In that case the challenges to instrument setting are more linked to timing and to meeting a specific inflation target than to "securing" overall nominal or real dynamic stability.

In the following sections we will use both the open and closed versions of the NAM model with respect to the policy instrument. In the next section, and the first section on policy use (section 17.4.2.1), we will use the open model with exogenous R_t. Later (e.g., when evaluating tracking performance in section 17.4.2.2), we will use a version with an econometrically modeled interest rate reaction function, which is documented in Table 17.1. In section 17.4.3, to discuss optimal policy we will use a version with a theoretically derived interest rate response function.

17.3.3 Stability of the steady state

In an important paper, Frisch (1936) anticipated the day when it would become common among economists to define (and measure) "normal" or natural values of economic variables by the values of the variables in a stationary state. The steady-state defined by the long-run model above corresponds to such natural values of the model's endogenous variables. But it is impractical to derive all the "natural values" using algebra, even in such a simple system as ours. Moreover, the question about the stability of the steady state, e.g., whether the steady state is globally asymptotically stable – or perhaps stability is only a saddle-path property – can only be addressed by numerical simulation of the dynamic system of equations.

We therefore follow Frisch's suggestion and simulate the dynamic NAM model. Figure 17.3 shows the "natural values" for inflation (Δp_t above), the rate of unemployment, wage inflation, GDP growth, growth in import prices and the rate of currency depreciation. The first solution period is 2007(4) and the last solution period is 2035(4). The simulation period is chosen to be so long because we want to get a clear impression about whether these variables approach constant ("natural") values or not, and whether the effect of initial conditions die out, as they should if the solution is globally asymptotically stable. The simulation is stochastic. The solid lines represent the mean of the 1,000 replications, and the 95% prediction intervals represented by the distance between the two dashed lines accommodate only residual uncertainty, not coefficient uncertainty.

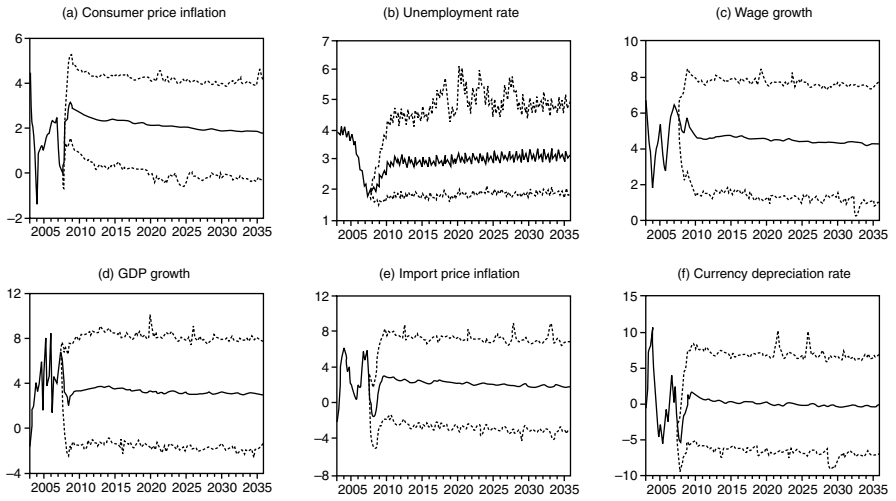

Figure 17.3 Stochastic dynamic simulation of NAM for the period 2007(4)–2035(4)
The money market interest rate is kept constant at the 2007(3) level for the length of the simulation period. The distance between the dotted lines indicates 95% prediction intervals.

In order to match the theoretical steady state above as closely as possible, the solution in Figure 17.3 is based on a constant domestic money market interest rate ($R_t = R_{2007(3)}$). The exogenous $I(1)$ variables have also been given constant growth rates for the length of the simulation period, e.g., foreign inflation is fixed at 2%. The impression is clearly that NAM has an asymptotically stable steady state, even under the assumption of a constant interest rate (the money market is in equilibrium by an endogenous money supply in the counterfactual "regime" defined by the constancy of the interest rate). The annual rate of inflation is seen to stabilize at a level just above 2.5%, and the natural rate of unemployment (in the Frisch sense) appears to be 3%. Clearly, in this scenario an inflation rate of 2.5% is attainable with very moderate instrument use. The seasonality of unemployment, modeled by dummies, is clearly visible and represents no problem in terms of stability.

17.4 Macroeconometric models as tools for policy analysis

In this last section we discuss several aspects of model usage that are of relevance for policy analysis. We begin with a practical problem, namely that congruent modeling, or a high degree of "data coherence" to cite the influential Pagan (2003) report on monetary policy modeling, gives rise to dynamic specifications that are too complicated to be of any help when the task is to explain the basic policy channels and lags between instruments and target. Nevertheless, section 17.4.1 shows that the need for simplicity in communication is not an argument for compromising empirical validity at the modeling stage, since it is always possible and convenient to work from the empirically valid and complicated model to a simple and stylized model that contains the essential dynamics of the full model. In

the other sub-sections, we use dynamic simulation, the main tool of model usage, to elucidate the strength of the policy instrument, to check that the model solution generates the properties of the actual data, and whether simulation over a long forecast horizon gives the steady state we expect from the theoretical analysis above. We also discuss optimal policy response, forecast properties, and strategies to reduce the damage that structural breaks have on forecasts from equilibrium correction models. Finally in this section, we raise the more fundamental question of testing non-nested hypotheses about the supply-side of the economy; our example will be the New Keynesian Phillips curve against the model of wage and price adjustment that has been presented above.

17.4.1 Tractability: stylized representations

There is a marked difference between the intricate and complex dynamics often found in empirical models – at least if they model the data – and the very simplified dynamics typically found in theoretical models. The purpose of this section is to enhance the understanding of the properties of a model through the use of stylized representations. A dynamic model, e.g.:

$$\begin{aligned}\Delta y_t = {} & 2 - 0.4\Delta y_{t-1} - 0.6\Delta y_{t-2} \\ & + 0.2\Delta x_t - 0.5\Delta x_{t-1} + 3\Delta x_{t-2} - 1\Delta x_{t-3} - 0.5\left(y_{t-3} - 4x_{t-4}\right) + v_t,\end{aligned}$$

can be approximated by a stylized model with simplified dynamics, in this example:

$$\Delta y_t = 1 + 0.85\Delta x_t - 0.25\left(y - 4x\right)_{t-1}.$$

This is achieved by using the mean of the dynamics of the variables.[14]

In the same way as above, we let lower cases of the variables denote natural logarithms, so $\Delta z_t \approx \frac{Z_t - Z_{t-1}}{Z_{t-1}} = g_{Z_t}$. If we assume that, on average, the growth rates are constant – the variables could be "random walks with drift" – the expected values of the growth rates are constants:

$$\begin{aligned}E\Delta y_t &= g_y \forall t \\ E\Delta x_t &= g_x \forall t.\end{aligned}$$

If the variables also are cointegrated, the expectation of the linear combination in the equilibrium correction term is also constant, so:

$$E\left(y_{t-3} - 4x_{t-4}\right) = E\left(y_{t-1} - 4x_{t-1}\right) = \mu \forall t.$$

Under these assumptions, the mean dynamics of the model becomes:

$$\begin{aligned}E\Delta y_t = {} & 2 - 0.4E\Delta y_{t-1} - 0.6E\Delta y_{t-2} \\ & + 0.2E\Delta x_t - 0.5E\Delta x_{t-1} + 3E\Delta x_{t-2} - 1E\Delta x_{t-3} \\ & - 0.5E\left(y_{t-3} - 4x_{t-4}\right) + Ev_t \\ g_y\left(1 + 0.4 + 0.6\right) = {} & 2 + \left(0.2 - 0.5 + 3 - 1\right)g_x - 0.5\mu\end{aligned}$$

$$g_y = \frac{2}{2} + \frac{1.7}{2} g_x - \frac{0.5}{2}\mu$$
$$g_y = 1 + 0.85 g_x - 0.25\mu.$$

We can therefore write the mean-approximated, or stylized, dynamic model as:

$$\Delta y_t = 1 + 0.85\Delta x_t - 0.25\left(y - 4x\right)_{t-1}.$$

To illustrate, the dynamic behavior of the model and its mean approximation are shown in Figure 17.4. The upper panel shows the dynamic, or period, responses in y_t to a unit change in x_{t-i}. The lower panel shows the cumulative, or interim, response. The graphs illustrate how the cyclical behavior – due to complex roots – is averaged out in the stylized representation.

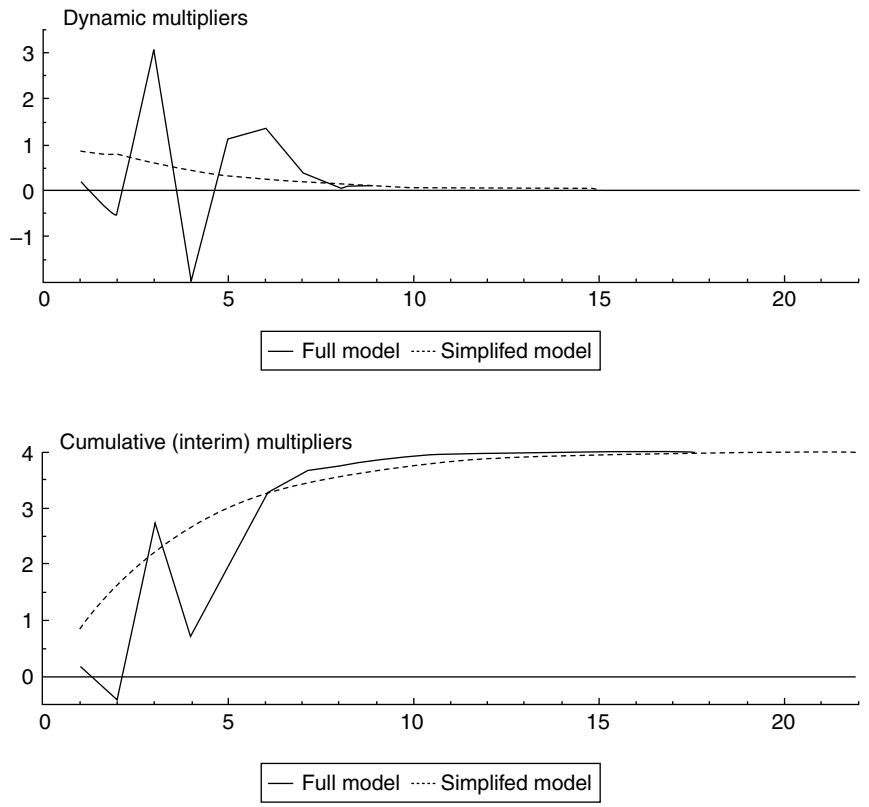

Figure 17.4 The dynamic responses of the example model and its mean approximation

Note that all that is done is to exploit so-called growth coefficients (see Patterson and Ryding, 1984; Patterson, 1987). The steady-state growth:

$$g_y = 4g_x$$

implies the steady-state mean μ:

$$(4 - 0.85)\, g_x = 1 - 0.25\mu$$
$$\mu = 4 - 12.6 g_x,$$

so the steady-state relationship between the variables is:

$$y_t = (4 - 12.6 g_x) + 4 x_t,$$

which will hold both for the complete as well as the stylized dynamic representation of the model.

Using this approach, the full econometric model reported in section 17.3.1 can be given the following stylized representation:

$$\Delta v_t = -0.04\Delta(R - R^*)_t - 0.04\{\left(v + p^* - p\right) - 0.12 \times \left[(R - \pi) - \left(R^* - \pi^*\right)\right]\}_{t-1} \tag{17.60}$$

$$\Delta\left(pi - pi^* - v\right)_t = -0.1\Delta v_t - 0.43\left[\left(pi - pi^* - v\right) - 0.55\left(p - p^* - v\right)\right]_{t-1} \tag{17.61}$$

$$\Delta p_t = -0.09\Delta z_t + 0.03\Delta pi_t + 0.08\Delta pe_t + 0.06\Delta y_t - 0.07\left[p - 0.7(w - z) - 0.3pi\right]_{t-1} \tag{17.62}$$

$$\Delta\left(w - p\right)_t = -0.04\Delta u_t + 0.73\Delta T1_t - 0.07\left[(w - p - z) + 0.1u\right]_{t-1} \tag{17.63}$$

$$\Delta z_t = 0.09\Delta\left(w - p\right)_t - 0.24\left[z - 0.47\left(w - p\right) - 0.003Trend - 0.03u\right]_{t-1} \tag{17.64}$$

$$\Delta u_t = -0.23\left\{u - 7.65\Delta\left(w - p\right) - 4.46\left[0.01\left(R_L - \pi\right) - 4\Delta y\right]\right\}_{t-1} \tag{17.65}$$

$$\Delta R_{L,t} = 0.58\Delta R_t - 0.33\left(R_L - 0.41R_B - 0.76R\right)_{t-1} \tag{17.66}$$

$$\Delta\left(R_B - R_B^*\right)_t = 0.43\Delta R_t - 0.17\left(R_B - 0.43R - 0.57R_B^*\right)_{t-1} \tag{17.67}$$

$$\Delta y_t = 0.16\Delta g_t + 0.38\Delta\left(l - p\right)_t - 0.12\left[y - 0.9g_{t-1} - 0.16(v + p^* - p) + 0.06\left(R_L - \pi\right)\right]_{t-1} \tag{17.68}$$

$$\Delta\left(l - p\right)_t = 0.3\Delta y_t - 0.09\left[\left(l - p\right) - 2.65y + 0.04(R_{L,} - R_B)\right]_{t-1}, \tag{17.69}$$

where the constants are omitted for ease of exposition. This representation reproduces the same steady state as the full model, but with stylized dynamics. The averaged transmission mechanisms can be traced through the interrelationships of the mean dynamic effects of shocks to the model – in contrast to the steady-state effects described above (see the discussion in section 17.3.1 for an example).

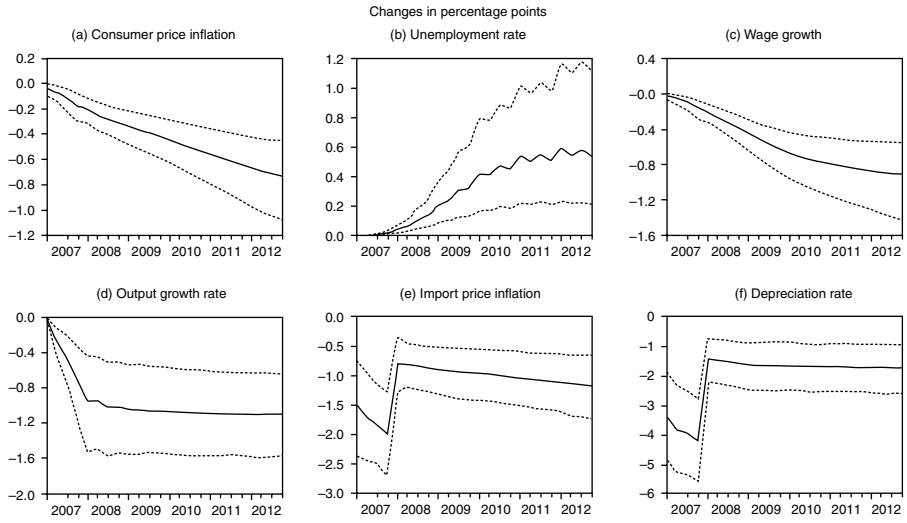

Figure 17.5 Dynamic multipliers from a permanent increase in the money market interest rate of 100 basis points, 2007(1)–2012(4)
The multipliers are shown as deviations from the baseline simulation in Figure 17.3. The distance between the two dotted lines represents the 95% confidence intervals.

17.4.2 Shock analysis: dynamic simulations

It seems obvious that a model for policy analysis should be empirically adequate to a high degree, and that care must be taken not to compromise this property for other desirable properties. However, in the same way as stability and invariance, "data fit" is a relative concept. Models that are outperformed in terms of fit might still be useful for policy analyses because they are highly relevant for the purpose, as noted by, e.g., Pesaran and Smith (1985). This sub-section will discuss relative model adequacy – also compared to optimal monetary policy.

17.4.2.1 How strong is the policy instrument?

As a background to policy analysis it is important to obtain a quantitative view of the transmission mechanisms, specifically to see whether the policy instrument has a sizeable effect on the variables that are subject to central bank targeting (in formal or more informal ways). The open version of the model, with exogenous interest rate (R_t), is then relevant, since among the parameters of the model are the dynamic multipliers of the endogenous variables with respect to the policy instrument.

Since the main channel of interest rate transmission is through the exchange rate, output and the level of unemployment, the interest rate is actually quite effective in counteracting demand shocks. However, shocks on the supply side, e.g., in wage-setting (such as permanently increased wage claims), or in foreign inflation, can be more difficult to curb by anything but huge increases in the interest rate.

Hence, stabilization of inflation after a supply shock may represent a formidable challenge to monetary policy.

The recent monetary history of Norway has demonstrated the relevance of this analysis: since mid 2003, core inflation rate has been consistently below the target of 2.5%, for long periods less than 1%, despite determined interest rate cuts in 2003, and no interest rate increases before July 2005, and then only gradually and in small steps.

The interest rate multiplier on inflation is shown in panel (a) of Figure 17.5. Panel (f) shows that the effect first goes through the *exchange rate channel*: the impact multiplier is a 3% appreciation, and in steady state there is an appreciation of 1.2%, thus illustrating equation (17.57). Panel (e) shows that import price growth is affected in the same way as the exchange rate (see equation (17.59)), but the impact effect is smaller. Panels (b), (c) and (d) show the *labor market* and *demand channels*. Wage growth is reduced, as predicted by (17.58), leaving real wage growth unaffected in steady state, as this is determined by productivity growth. Unemployment increases, since real interest rates increase, while negative GDP growth follows from increasing real interest rates and appreciation of the real exchange rate.

17.4.2.2 Fitting the facts

In this section we document how well the econometric model NAM explains the evolution of important endogenous variables over the 17-quarter period 2003(3)–2007(3).

The solutions are conditional upon the actual values of the non-modeled variables.[15] Experience has shown that particularly important explanatory variables are foreign interest rates (R^* and R_B^*) and consumer (p^*) and producer prices (pi^*). Domestic government expenditure (g) and electricity prices (pe) are also very important for the overall fit of the model. Finally, the oil price (in \$US) is a highly relevant explanatory variable, mainly through the market for foreign exchange.

The interest rate has been the instrument of monetary policy during the solution period. We therefore use the (more) closed version of the model, where the domestic money market interest rate is estimated as a function of the core inflation gap and the unemployment rate gap in equation (17.46).

Figure 17.6 shows that NAM generates the features of the macroeconomic development. Inflation in panel (a), the rate of unemployment in panel (b), GDP growth in panel (d), and the money market interest rate in panel (g) are very well explained by the model solutions. The graph of actual and simulated nominal currency depreciation in panel (i) shows that movements in the exchange rate are also well explained, brought about by the interest rate differential and equilibrium correction with respect to the real exchange rate – which is shown in panel (f).

17.4.2.3 Shock analysis with dynamic multipliers

Next, we investigate how the economy, according to the model, is likely to respond to shocks. We use the same model version as in section 17.4.2.2. Amongst the many shocks of interest to a small open economy, we here consider a negative foreign price shock. The deflationary 5% shock occurs in 2007(1), and Figure 17.7, panels

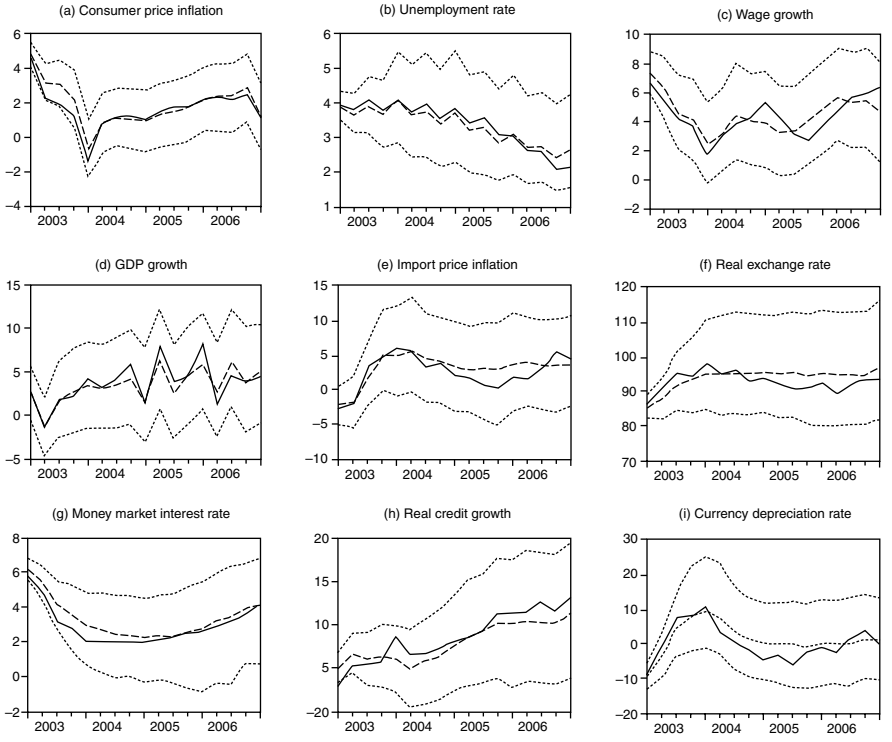

Figure 17.6 Dynamic simulation of NAM 2003(1)–2007(1)
Actual values are indicated by solid lines, and model solution by dashed lines. The distance between the two dotted lines represents 95% prediction intervals. The units on all the vertical axes are percentage points, and time is along the horizontal axes.

(a)–(f), reports the dynamic multipliers for inflation, wage increases, the rate of unemployment, GDP growth, the increases in the import price index, and the rate of currency depreciation. Since all variables in the graph are measured in percentage points, the multipliers shown are absolute deviations from the baseline. In the same way as in Figure 17.5, parameter uncertainties are indicated by the dotted lines, representing 95% confidence intervals.

Since it is a temporary shock to foreign inflation, there is no reason to expect a permanently lower rate of domestic inflation. Panels (a) and (c) of Figure 17.7 confirm that presumption, but also show that the initial multipliers of price and wage inflation are negative and significant. Part of the adjustment to a lower nominal path of the economy involves a higher unemployment rate and lower GDP growth (cf. panels (b) and (d)), which are explained by the initial appreciation of the real exchange rate. The nominal depreciation in panel (f), due to a lower domestic interest rate (not shown), is not enough to offset the loss of competitiveness, initiated by the deflationary price shock.

The nominal rigidities in the model, which transform the nominal shock into a change in the real exchange rate, are an important property in explaining the

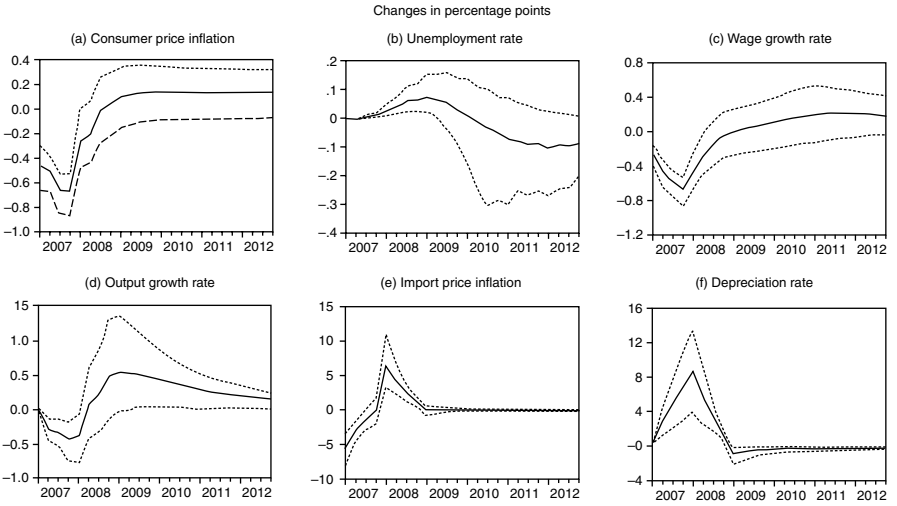

Figure 17.7 Dynamic multipliers from a permanent reduction in exogenous (foreign) prices by 5%, 2007(1)–2012(4)
The distance between the two dotted lines represent the 95% confidence intervals. The units on the vertical axes are percentage points in all panels.

multipliers. The rigidities are not due to "incredibly long" adjustment lags in price- and wage-setting: domestic inflation is seen to return to its baseline path after two and a half years. Instead, there is a second wave of effects due to the interaction between product and labor markets. Hence the experiment demonstrates rather well the important theoretical point made in section 17.2.6.4, namely that the steady-state inflation rate does not imply a unique equilibrium rate of unemployment, since the rate of inflation reaches its steady state long before the multipliers of the rate of unemployment have died out.

17.4.3 Aspects of optimal policy: the impact of model specification on optimal monetary policy

As noted above, the version of NAM with an econometrically modeled interest rate makes no claims of representing optimal interest rate-setting under inflation targeting or optimal policy response to a shock. Instead, the multipliers of the last paragraph should be interpreted as counterfactuals: they show the response that would occur if the interest rate reacted *as if* it followed the econometrically estimated interest rate equation.

However, in a recent paper, Akram and Nymoen (2008) show how optimal monetary policy can be implemented in NAM, and how the predicted economic outcome depends on the specification of the supply side of the model. For that purpose, they replace the econometrically modeled interest rate equation with a theoretically derived interest rate rule due to Akram (2007):

$$R_{t+m} = R_0 + (1 - \varrho_H)\frac{\beta_\varepsilon}{(1-\phi)}\varepsilon_t + \varrho_H(R_{t+m-1} - R_0),\ m = 0, 1, 2, \ldots, H. \quad (17.70)$$

This rule defines an interest rate path corresponding to a specific policy horizon H. The response coefficient $\beta_{\varepsilon,H} \equiv (1-\varrho_H)\frac{\beta_\varepsilon}{(1-\phi)}$ determines by how much the interest rate must deviate initially from the neutral rate R_0 to counteract the inflationary effects of a shock ε_t. A high value of the smoothing parameter ϱ_H can be associated with a strategy of gradualism in interest rate-setting. Thus two preference parameters $\beta_{\varepsilon,H}$ and ϱ_H depend on the policy horizon, H. The last parameter in the theoretical interest rate equation is ϕ, which represents the (objective) degree of persistence in the inflation shock.

In addition to the preferences about policy horizon and gradualism captured by (17.70), the optimal interest rate response is influenced by the user's choice of macroeconomic model. Akram and Nymoen (2008) focus on the labor market channel, since this part of the transmission mechanism has been the focus of most model controversy. In one model version, used to derive optimal policy, the incumbent model of the supply side, with equilibrium correction in both wage- and price-setting, is used. As explained in section 17.2.6, this model is called the incomplete model of wage- and price-setting and is referred to as ICM in Figure 17.8. The two other versions are the model with wage and price Phillips curves, PCM in the figure, and a version with a vertical Phillips curve, PCMr in the figure. As noted in section 17.2.6.4, among these three specifications, it is the PCMr that represents the consensus view in modern monetary economics.

Akram and Nymoen show that econometric encompassing tests favor the ICM model of the supply side, but also that the PCM and the PCMr appear to be well specified on their own terms, e.g., the residual properties of the two Phillips curve models do not signal any problems. Hence there is a question about whether the outcome of the encompassing test has any practical (or "economic") significance, or whether this test of model adequacy has only an academic interest. The analysis suggests that the econometric test result contains valuable information.

Consider, e.g., Figure 17.8, which presents the economic performance of (optimal and sub-optimal) policies employed in response to the supply shock. The left column of the figure shows that there is a trade-off between price and output stabilization for different ranges of policy horizons. Specifically, in the case of ICM and PCM there is a trade-off in the range of 0–8 quarters. Policy horizons that are longer than 8 quarters appear inefficient as both price and output stabilization can be improved by shortening the policy horizon. The opposite is the case for PCMr. In this case, the trade-off curve is associated with policy horizons that are longer than 6 quarters, while policy horizons shorter than 6 seem inefficient. In the right-hand column of the figure, it transpires that the three models recommend substantially different policy horizons. Even though the efficiency frontiers for ICM and PCM are defined by almost the same policy horizon, the optimal horizon is 3 quarters conditional on ICM, but 6 quarters in the case of PCM. In the case of PCMr the policy horizon is 11 quarters.

Based on the above and several other simulation experiments, Akram and Nymoen (2008) find that econometric differences bear heavily on (model-based) policy recommendations and are thus not merely of academic interest. Their analysis quite strongly suggests that differences in model specifications and even in

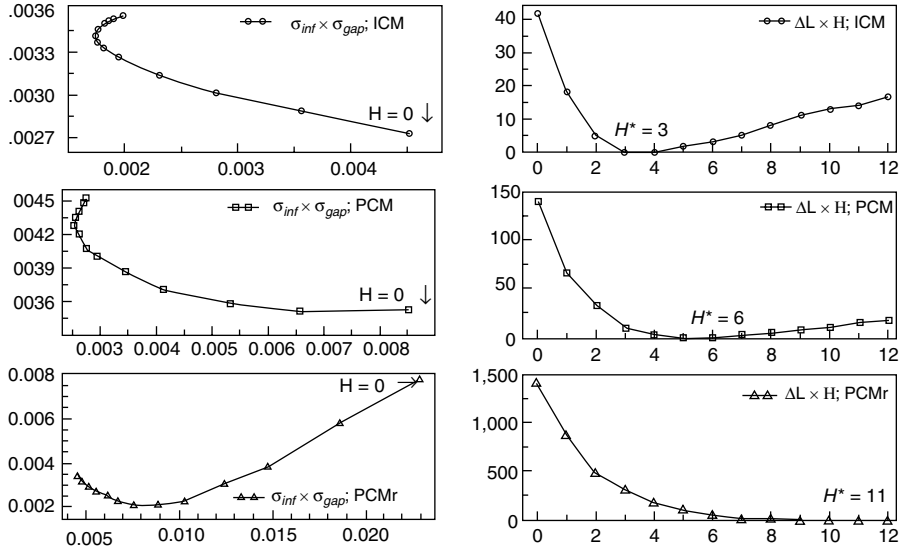

Figure 17.8 Economic performance and optimal policy suggested by three specifications of the supply side in the face of a supply shock

Left column: trade-offs between standard deviations of inflation gap, σ_{inf}, and output gap, σ_{gap} (horizontal axis) associated with different (policy) horizon-specific rules in response to the demand shock. The trade-offs are plotted for rules associated with policy horizons (H) in the range of 0–12 quarters. The trade-offs associated with different horizons follow each other, where the one for $H = 0$ is indicated. *Right column*: values of the relative loss function, denoted ΔL (in %), at the different policy horizons (horizontal axis) (Akram and Nymoen, 2008).

parameter values across models can lead to widely different policy implications. Interestingly, it appears that imposing a set of parameter restrictions may have stronger influence on policy implications than choosing a different functional form of the model. Monetary policy based on a model that turns out to be an invalid characterization of the economy and its transmission mechanism may lead to substantial losses in terms of economic performance, even when policy is guided by gradualism, e.g., in the form of a long policy horizon.

17.4.4 Theory evaluation: the New Keynesian Phillips curve

Macroeconomics is an evolving science. New hypotheses and theories are put forward, sometimes with far-reaching consequences, for policy, teaching and, of course, also for model-building. A macroeconomic model project that lasts for some time is therefore bound to face the need to adapt to new theoretical developments. However, new ideas in macroeconomics are usually partial, and can claim superiority with respect to existing ones only by replacing old *ceteris paribus* clauses by new ones. In a macroeconometric modeling context it therefore makes sense to test the new theories before they are implemented. If the model is in operational use, say for policy recommendations, this step may be as much of a virtue

as a necessity, since unverified changes in policy response and forecasting may critically damage beliefs in the relevance of model analysis.

In this section we discuss some approaches to how the model of the supply side presented in section 17.2.6 can be tested against a new and important development represented by the New Keynesian Phillips curve.

As shown by Bårdsen *et al.* (2005, Chs. 4–6), three important and much used models of inflation and unemployment are consistent with the view that wages and prices are equilibrium correcting $I(1)$ variables, while the rate of unemployment is $I(0)$. They are the incomplete competition model in equilibrium correction form, the standard open economy wage Phillips curve, and the wage Phillips curve with homogeneity restrictions; in other words, ICM, PCM and PCMr of section 17.4.3. *Qua* equilibrium correction models, these theories can readily be identified as special cases of a VAR.

Cointegration is thus a common feature of the three models. They can be identified by their different theories about the main adjustment mechanisms at work. In the case of the ICM, wages equilibrium correct with respect to deviations from the wage level predicted by the theoretical bargaining model. In the case of the PCM, by definition, wages do not equilibrium correct with respect to lagged wages, so in this model equilibrium correction has to be *indirect* and via the reaction of the rate of unemployment (see Bårdsen and Nymoen, 2008). In section 17.4.3 these properties were shown to be relevant for the assessment of different supply-side models for policy analysis.

We will show below that the same insight also applies to the New Keynesian Phillips curve, meaning that its equilibrium correction implications can be tested against the ICM or (any version) of the conventional Phillips curves. However, we first give a brief summary of the current empirical status of the New Keynesian Phillips curve.

17.4.4.1 The New Keynesian Phillips curve

The New Keynesian Phillips curve, hereafter NKPC, has become regarded by many as the new standard model of the supply side in the macro-models used for monetary policy analysis. This position is due to its theoretical underpinnings, laid out in Clarida, Gali and Gertler (1999), and to the supportive empirical results in the studies of Gali and Gertler (1999) (henceforth GG) on US data, and Gali, Gertler and López-Salido (henceforth GGL) (2001) on euro-area data.

The hybrid NKPC is given as:

$$\pi_t = \underset{\geq 0}{a^f} E_t[\pi_{t+1}] + \underset{\geq 0}{a^b}\pi_{t-1} + \underset{\geq 0}{b}\, s_t, \tag{17.71}$$

where π_t is the rate of inflation, $E_t\left[\pi_{t+1}\right]$ is expected inflation one period ahead and s_t is a time series of firms' real marginal costs. The "pure" NKPC is (17.71) with $a^b = 0$, and represents the case where all firms (that are aggregated over) form rational expectations. Both the pure and hybrid forms are usually presented as "exact," i.e., without an error term. When $E_t[\pi_{t+1}]$ is replaced by π_{t+1} for estimation, a moving average error term is implied. This has motivated "robust" estimation with,

e.g., pre-whitening switched on in generalized method of moments (GMM), and leading papers downplay the relevance of congruency for the evaluation of the NKPC.

After assessing some of the critiques that have been directed towards the NKPC, Gali, Gertler and López-Salido (2005) assert that the NKPC, in particular the dominance of forward-looking behavior, is robust to the choice of estimation procedure and to possible specification bias. They conclude that the following three results are proven characteristics of NKPC for all datasets:

1. The two null hypotheses $a^f = 0$ and $a^b = 0$ are rejected both individually and jointly.
2. The coefficient on expected inflation exceeds the coefficient on lagged inflation substantially. The hypothesis of $a^f + a^b = 1$ is typically not rejected at conventional levels of significance, although the estimated sum is usually a little less than one numerically.
3. When real marginal costs are proxied by the log of the wage share, the coefficient b is positive and significantly different from zero at conventional levels of significance.

As mentioned, critics of the NKPC have challenged the robustness of all three, but with different emphases and from different perspectives. The inference procedures and estimation techniques used by GG and GGL (2001) have been criticized by Rudd and Whelan (2005, 2007) and others, but GGL (2005) show that their initial Results 1 and 2 remain robust to these objections.

When it comes to Result 3, GGL (2005) overlook that several researchers have been unable to confirm their view that the wage share is a robust explanatory variable in the NKPC. Bårdsen, Jansen and Nymoen (2004) showed that the significance of the wage share in the GGL (2001) model is fragile, as it depends on the exact implementation of the GMM estimation method used, thus refuting that Result 3 is a robust feature of NKPC estimated on euro-area data.

Fanelli (2008), using a vector autoregressive regression model on the euro-area dataset, finds that the NKPC is a poor explanatory model. On US data, Mavroeidis (2006) has shown that real marginal costs appears to be an irrelevant determinant of inflation, confirming the view in Fuhrer (2006) about the difficulty of obtaining a sizeable coefficient on the forcing variable in the US NKPC. Already the studies cited represent evidence that refutes the claim that Result 3 is robust. Instead it is to be expected that, depending on the operational definition of real marginal costs, the estimation method and the sample, the numerical and statistical significance of b will vary across different studies.

Of course, Result 3 is just as important as Results 1 and 2 for the status of the NKPC as an adequate model, so if that part of the model is non-structural, it might be that that Results 1 and 2 have another explanation than the intended, which is that there is a good match between the NKPC and the true inflation process. Bårdsen, Jansen and Nymoen (2004) (euro-area) and Bjørnstad and Nymoen (2008)

(OECD panel data) demonstrated that the significance of a^f can be explained by a linear combination of better forcing variables which reside among the overidentifying instruments. Their presence is revealed by the significance of the Sargan (1964) specification test. Importantly, the re-specified models in the two studies lend themselves directly to interpretation either as conventional Phillips curves, or as an equilibrium-correction price equation consistent with the theory of monopolistic competition in the product market and a certain element of coordination in wage-bargaining (see Sargan, 1980; Nymoen, 1991; Bårdsen *et al.*, 2005, Chs. 4–6). Hence, the NKPC fails to parsimoniously encompass these models.

17.4.4.2 The equilibrium correction implications of the NKPC

The original NKPC makes no reference to open economy issues. Batini, Jackson and Nickell (2005) have shown that the main theoretical content of the NKPC generalizes, but that consistent estimation of the parameters a^f, a^b and b requires that the model is augmented by variables which explain inflation in the open economy case. Hence, the open economy NKPC is:

$$\Delta p_t = \underset{\geq 0}{a^f}\,\Delta p^e_{t+1} + \underset{\geq 0}{a^b}\,\Delta p_{t-1} + \underset{\geq 0}{b}\,s_t + c\,x_t, \tag{17.72}$$

where x_t, in most cases a vector, contains the open-economy variables, and c denotes the corresponding coefficient vector. The change in the real import price, $\Delta(pi_t - p_t)$ in our notation, is the single most important open economy augmentation of the NKPC. The results in Batini, Jackson and Nickell are, broadly speaking, in line with GG's and GGL's Results 1–3 above, but, as noted, those properties are not robust when tested against the existing UK model in Bårdsen, Fisher and Nymoen (1998).

We follow GG and measure s_t by the log of the labor share:

$$s_t = ulc_t - q_t, \tag{17.73}$$

where *ulc* denotes unit labor costs (in logs) and q is the log of the price level on domestic goods and services, compare section 17.2.6. Next, define the aggregate price level as:

$$p_t = \zeta q_t + (1-\zeta)\,pi_t, \tag{17.74}$$

with $(1-\zeta)$ as the import share. If we solve for q_t, insert in (17.73) and rewrite, we obtain the following equation for the wage share:

$$s_t = -\frac{1}{\gamma}\left[p_{t-1} - \gamma\; ulc_{t-1} - (1-\gamma)\,pi_{t-1}\right] + \Delta ulc_t - \frac{1}{\gamma}\Delta p_t + \frac{1-\gamma}{\gamma}\Delta pi_t. \tag{17.75}$$

We can then rewrite the open economy NKPC as:

$$\begin{aligned}\Delta p_t = {} & \frac{a^f}{\left(1+\frac{b}{\gamma}\right)}\Delta p^e_{t+1} + \frac{a^b}{\left(1+\frac{b}{\gamma}\right)}\Delta p_{t-1} - \frac{b}{(\gamma+b)}\left[p_{t-1} - \gamma\; ulc_{t-1} - (1-\gamma)\,pi_{t-1}\right] \\ & + \frac{\gamma\; b}{(\gamma+b)}\Delta ulc_t + \frac{b\,(1-\gamma)}{(\gamma+b)}\Delta pi_t + \frac{\gamma\; c}{(\gamma+b)}\,x_t,\end{aligned}$$

or:

$$\Delta p_t = \alpha^f \Delta p^e_{t+1} + \alpha^b \Delta p_{t-1} + \beta(ulc_{t-1} - p_{t-1}) - \beta(1-\gamma)(ulc_{t-1} - pi_{t-1}) \quad (17.76)$$
$$+ \beta\gamma \Delta ulc_t + \beta(1-\gamma)\Delta pi_t + \psi x_t,$$

where we have defined α^f, α^b, β and ψ as new coefficients for simplification.

Equation (17.76) brings out that the NKPC implies an equilibrium-correction price equation which is very similar to the "incumbent" model in NAM (cf. equation (17.30) in section 17.2.6). However, there are two notable differences. First and foremost, the forward-looking term Δp^e_{t+1} with an expected high coefficient α^f. The incumbent model implicitly restricts this coefficient to zero. Second, in the NKPC, there are parameter restrictions on the coefficients of the following variables: Δulc_t, Δpi_t , $(ulc_{t-1} - p_{t-1})$ and $(ulc_{t-1} - pi_{t-1})$; in fact, they are functions of the underlying parameters β and γ.

It follows that, for the purpose of testing the NKPC, we can start with an equilibrium correction model with a lead in the inflation term:

$$\Delta p_t = \alpha^f \Delta p^e_{t+1} + \alpha^b \Delta p_{t-1} + \beta_1(ulc_{t-1} - p_{t-1}) + \beta_2(ulc_{t-1} - pi_{t-1}) \quad (17.77)$$
$$+ \beta_3 \Delta ulc_t + \beta_4 \Delta pi_t + \psi x_t,$$

and test the following hypotheses: H^a_0: $\alpha^f = 0$, H^b_0: $\beta_3 = \beta_1 + \beta_2$ and H^c_0: $\beta_4 = -\beta_2$. Rejection of H^a_0 together with non-rejection of H^b_0 and H^c_0 constitute evidence that support the NKPC, while non-rejection of H^a_0 is telling evidence against the NKPC.

As noted above, NKPC models are usually specified with the rate of change in the real import price as one of the elements in x_t. Equation (17.77) is consistent with that interpretation, the only caveat applies to β_4 and H^b_0, since $\beta_4 = -\beta_2$ no longer follows logically from the NKPC. This is because β_4 is a composite parameter also when the NKPC is the valid model.

17.4.4.3 Testing the equilibrium-correction implications of the NKPC

Consider the hybrid NKPC of the form (17.72) where we allow for two lags of inflation as well as three deterministic seasonals. This is because NAM makes use of seasonally unadjusted quarterly data. The wage share variable s_t is treated as an endogenous variable, but we also include electricity prices (Δpe_t) and import prices (Δpi_t) in the x_t vector of exogenous variables. As already noted, inflation is measured by the consumer price index. Instrumental variable (IV) estimation gives:

$$\begin{aligned}\Delta p_t \;=\;& \underset{(0.107)}{0.3659}\ \Delta p_{t+1} + \underset{(0.0228)}{0.04122}\ s_t + \underset{(0.0772)}{0.08759}\ \Delta p_{t-1} \\ &+ \underset{(0.0653)}{0.2676}\ \Delta p_{t-2} + \underset{(0.00597)}{0.06385}\ \Delta pe_t + \underset{(0.0169)}{0.04024}\ \Delta pi_t \\ &+ \textit{constant and seasonals} \\ &\text{IV, } T = 111 \text{ (1979(3) - 2007(1))} \\ &\chi^2_S(9) = 11.664[0.2329].\end{aligned} \quad (17.78)$$

The results shows a significant coefficient on the forward term of the same magnitude as the sum of the coefficients on the two lagged inflation rates. The wage

share s_t has the correct positive sign and is significant at the 10% level. By and large, these results are in line with the typical NKPC Results 1–3 discussed above.

The instruments include $ulc_{t-1} - p_{t-1}$ and $ulc_{t-1} - pi_{t-1}$, as explained above, together with lags of productivity growth, lagged electricity price growth, the same wage dummy as in NAM and lagged unemployment. The Sargan (1964) test of instrument validity ($\chi^2_S(n)$) is insignificant. However, residual misspecification tests reveal that (17.78) is not a congruent model, since there is substantial heteroskedasticity, autocorrelation and non-normality. In order to obtain a more congruent NKPC model we may use the dummy saturation technique in Autometrics (see Doornik, 2008).

$$\begin{aligned}\Delta p_t = {} & \underset{(0.102)}{0.622}\ \Delta p_{t+1} + \underset{(0.013)}{0.02509}\ s_t + \underset{(0.0533)}{0.2614}\ \Delta p_{t-2} \\ & + \underset{(0.00675)}{0.0549}\ \Delta pe_t + \textit{constant and 11 dummies} \\ & \text{IV, } T = 111 \text{ (1979(3) - 2007(1))} \\ & \chi^2_s(15) = 19.442[0.1944].\end{aligned} \tag{17.79}$$

The 11 dummies include both seasonals and break dummies, showing that the NKPC equation is not a completely time-invariant structural model. However, abstracting from that problem, equation (17.79) is seen to adhere even closer to the stylized facts of the NKPC than equation (17.78).

As explained above, we want to test the hypothesis that (17.79) encompasses the price equation of the incumbent model. To do that, we first include $ulc_{t-1} - p_{t-1}$ and $ulc_{t-1} - pi_{t-1}$ as explanatory variables to obtain an empirical version of the embedding equation (17.77) above. We then do a general-to-specific search by means of Autometrics in PcGive. The preferred model is reported as equation (17.80):

$$\begin{aligned}\Delta p_t = {} & \underset{(0.069)}{0.003849}\ \Delta p_{t+1} + \underset{(0.0259)}{0.08832}\ \Delta ulc_t + \underset{(0.0577)}{0.1515}\ \Delta p_{t-2} \\ & + \underset{(0.0143)}{0.09883}\ (ulc_{t-1} - p_{t-1}) - \underset{(0.00478)}{0.01943}\ (ulc_{t-1} - pi_{t-1}) + \underset{(0.00518)}{0.05164}\ \Delta pe_t \\ & + \textit{constant and 4 dummies} \\ & \text{IV, } T = 111 \text{ (1979(3) – 2007(1))} \\ & \chi^2_S(16) = 25.434[0.0625].\end{aligned} \tag{17.80}$$

It is seen that the estimated forward coefficient $\hat{\alpha}^f$ is practically zero in (17.80) compared to 0.62 in the NKPC in (17.79). Hence $H^c_0\colon \alpha^f = 0$ cannot be rejected statistically at any meaningful level of significance.

17.4.5 Forecasting for monetary policy

A hallmark of modern and flexible inflation targeting is that the operational target variable is the forecasted rate of inflation (see Svensson, 1997). One argument

for this choice of target is to be ahead of events, rather than to react after actual inflation has deviated from target. In this way one may hope to achieve the target by a minimum of cost to the real economy in terms of, e.g., unwanted output fluctuations or large fluctuations in the exchange rate. However, any inflation forecast is uncertain and might induce the wrong use of policy. Hence, a broad set of issues related to inflation forecasting is of interest for those concerned with the operation and assessment of monetary policy.

A favorable starting point for inflation targeting is when it can be asserted that the central bank's forecasting model is a good approximation to the inflation process in the economy. In this case, forecast uncertainty can be represented by conventional forecast confidence intervals, or by the fan charts used by today's best practice inflation targeters.[16] The point of the probabilistic forecasts is to convey to the public that the forecasted inflation numbers will only coincide with the actual future rate of inflation on average, and that neighbouring inflation rates are almost as probable. By the same token, conditional on the forecasting model's representation of uncertainty, still other inflation rates are seen to be wholly improbable realizations of the future.

However, the idea about model correctness and stationarity of macroeconomic processes is challenged by the high incidence of failures in economic forecasting (see, e.g., Hendry, 2001a). A characteristic of a forecast failure is that forecast errors turn out to be larger, and more systematic, than what is allowed if the model is correct in the first place. In other words, realizations which the forecasts depict as highly unlikely (e.g., outside the confidence interval computed from the uncertainties due to parameter estimation and lack of fit) have a tendency to materialize too frequently. Hence, as a description of real-life forecasting situations, an assumption about model correctness is untenable and represents a fragile foundation for forecast-based interest rate-setting (see Bårdsen *et al.*, 2003).

17.4.5.1 Assumptions about the forecasting situation

In modern monetary policy the forecasted rate of inflation is the intermediate target. It is then of interest to clarify as closely as possible what are the realistic properties of the forecast. Anticipated forecast properties are closely linked to the assumptions we make about the forecasting situation. A useful classification (see Clements and Hendry, 1999, Ch. 1) is:

A The forecasting model coincides with the true inflation process except for stochastic error terms. The parameters of the model are known constants over the forecasting period.
B As in A, but the parameters have to be estimated.
C As in B, but we cannot expect the parameters to remain constant over the forecasting period – structural changes are likely to occur.
D We do not know how well the forecasting model corresponds to the inflation mechanism in the forecast period.

A is an idealized description of the assumptions of macroeconomic forecasting. There is still the incumbency of inherent uncertainty represented by the stochastic

disturbances – even under **A**. Situation **B** represents the situation theoretical expositions of inflation targeting conjure up (see Svensson, 1999). The properties of situation **A** will still hold – even though the inherent uncertainty will increase. If **B** represents the premise for actual inflation targeting, there would be no forecast failures, defined as a significant deterioration of forecast performance relative to in-sample behavior (see, e.g., Hendry, 2006). The within-sample fit of section 17.4.2.2 corresponds to situation **B**, subject to the assumption that NAM is a congruent model of the aggregate Norwegian economy.

The limited relevance of situation **B** for inflation targeting becomes clear once we recognize that, in practice, we do not know what kind of shocks will hit the economy during the forecast period. We generally refer to such changes as *regime shifts,* and their underlying causes include changes in technology and political decisions and, more generally, "the complexity and instability of human behaviour" (Elster, 2007, p. 467). A forecast failure effectively invalidates any claim about a "correct" forecasting mechanism. Upon finding a forecast failure, the issue is therefore whether the misspecification was detectable or not at the time of preparing the forecast. It is quite possible that a model which has been thoroughly tested for misspecification within-sample nevertheless forecasts badly, which may occur in situation **C**.

As discussed by Clements and Hendry (1999), a dominant source of forecast failure is regime shifts in the forecast period, i.e., *after* the preparation of the forecasts. Since there is no way of anticipating them, it is unavoidable that *after-forecast* breaks damage forecasts from time to time. For example, when assessing inflation targeting over a period of years, we anticipate that the forecasters have done markedly worse than they expected at the time of preparing their forecasts, simply because there is no way of anticipating structural breaks before they occur. The task is then to be able to detect the nature of the regime shift as quickly as possible, in order to avoid repeated unnecessary forecast failure.

However, experience tells us that forecast failures are sometimes due to shocks and parameter changes that have taken place prior to the preparation of the forecast, but which have remained undetected by the forecasters. Failing to detect a *before-forecast* structural break might be due to the low power of statistical tests of parameter instability. However, the power is actually quite high for the kind of breaks that are most damaging to model forecasts (see Hendry, 2000). There are also practical circumstances that complicate and delay the detection of regime shifts. For example, there is usually uncertainty about the quality of the provisional data for the period that initialize the forecasts, making it difficult to assess the significance of a structural change or shock.

Hence both after- and before-forecast structural breaks are realistic aspects of real-life forecasting situations that deserve the attention of inflation targeters. In particular, one should seek forecasting models and tools which help cultivate an adaptive forecasting process. The literature on forecasting and model evaluation provide several guidelines (see, e.g., Hendry, 2001a; Granger, 1999).

Situation **D** brings us to the realistic situation, namely one of uncertainty and discord regarding what kind of model approximates reality; in other words, the issues of model specification and model evaluation. In section 17.4.3 we saw that in policy

analysis there is a clear gain from using the congruent model, and avoiding basing policy recommendations on a misspecified model of the supply side. In forecasting, the link between model misspecification and forecast failure is not always as straightforward as one would first believe. The complicating factor is again non-stationarity, regime shifts and structural change. For example, a time series model formulated in terms of the change in the rate of inflation adapts quickly to changes in equilibria – a location shift – and is therefore robust to before-forecast structural breaks of this type, even though it is clearly a misspecified model of the DGP over the historical data period (see Clements and Hendry, 1999, Ch. 5). Therefore a double-differenced device (DDD) can deliver near-unbiased forecasts when a location shift has occurred prior to the preparation of the forecast. Conversely, a forecasting model of the equilibrium correction type is less adaptable. Indeed, following an equilibrium shift, EqCM forecasts tend to move in the opposite direction to the data, thereby causing forecast failure (cf. Hendry, 2006). Eitrheim, Husebø and Nymoen (1999) have shown that this new theory of forecasting has practical relevance for understanding the properties of forecasts from a medium-sized forecasting model of the Norwegian economy, in particular the more adaptive nature of DDD to several historical examples of structural breaks.

The new theory of forecasting that we build on does not deliver carte blanche for using non-congruent models for prediction, though. DDD and near-equivalent forecasting devices are robust for one particular reason: they do not equilibrium correct, and are therefore insulated from changes in the parameters that are most pernicious for forecasting. Replacing a congruent and adequate EqCM with another, less adequate, EqCM model for forecasting is not a good idea. The non-congruent EqCM is also subject to forecast failure on its own premises and, without location shifts, it will forecast worse than the congruent EqCM. In this respect there is a cost to compromising model adequacy also in forecasting. In terms of the contesting supply-side models of section 17.4.3, this is illustrated by Bårdsen, Jansen and Nymoen (2002), who show that, although the PCM is robust to some of the location shifts that can damage forecasting from the ICM, the cost of high forecast variance and bias due to misspecified equilibrium correction dominates.

17.4.5.2 Real-time forecast performance

As mentioned above, NAM is part of the Normetrics system of models which was initiated in 2005. Model-based forecasts for the Norwegian economy are produced in January, March, June and September each year and published on the web. So far, these model-based forecasts have performed relatively well compared to competing forecasts. As an example, Figure 17.9 shows forecasts for core inflation in 2006. Because of inflation targeting, this variable is among the most thoroughly analyzed variables by professional forecasters both in the private and public sectors.

Figure 17.9 shows Norges Bank's projections together with the average of other professional Norwegian forecasters. The third line in the graph shows the sequence of forecasts from the two Normetrics forecasting models, automatized inflation forecasts (AIF) and NAM.[17] The figure shows that Normetrics forecasts were never

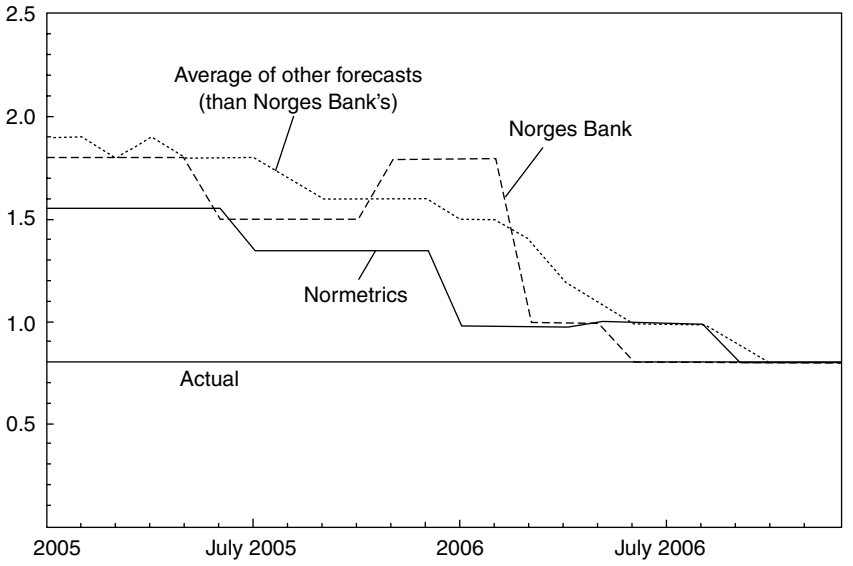

Figure 17.9 Forecasts for annual core inflation in 2006, published at different times. Percent. Monthly figures, January 2005 to December 2006
Source: Norges Bank, *Monetary Policy Report* January 2007, and http://folk.uio.no/rnymoen/Normetrics.

any worse than the average forecasts, and most vintages of Normetrics forecasts are considerably better. All Normetrics forecasts produced in 2005 also improve on Norges Bank's forecasts (June 2005 is the exception). In the period November 2005 to February 2006 the gap between Normetrics and Norges Bank actually widens – as Norges Bank's forecasts were adjusted upward, away from what eventually became the actual inflation rate of 0.8%. However, the forecast in *Monetary Policy Report* February 2006 is accurate, while the Normetrics forecast stays at 1% until September 2006.

Since equilibrium-correction is ubiquitous in macroeconometric models, one can safely assume that some of the "other forecasts" are based on EqCMs. Specifically, Norges Bank's forecast are based on the rational expectations solution of an equilibrium-correction model with leads in variables. Hence, all forecasts in Figure 17.9 may have been damaged by any location shifts that took place in 2006 – they were *after-forecast* structural breaks. In particular, the forecast that was published (early) in 2005 had a large exposure to forecast failure. For the same reason, the forecast errors are reduced as more "2006 information" is conditioned upon. In that perspective we can interpret the figure as evidence that the Normetrics forecasts are more adaptive than the other equilibrium-correction forecasting mechanisms covered by the graph.

The accuracy of the model-based forecasts in Figure 17.9 are less impressive when compared to forecasts from a simple DDD, though. For example, at the start of 2005 a forecast based on the double difference of the log of the CPI-AET (consumer price

index adjusted for electricity and taxes) index would predict a 2006 inflation rate of 0.3%, which is a more accurate forecast than any of the econometric or professional forecasts that were produced in 2005. The DDD forecast is not improved on by Normetrics before January 2006, nor by Norges Bank before the *Monetary Policy Report* January 2006 (from March). However, by this time the DDD forecast could also be have been updated, most simply by replacing 0.3% by the actual rate of inflation in 2005, which was 1.0%. This forecast is practically identical to Normetrics forecasts from before September 2006, and it is not beaten by Norges Bank's forecast before the *Monetary Policy Report* February 2006.

2006 is not the only year for which the Normetrics forecasts compete well with the central bank's forecasts for the monetary policy target variable. Juel, Molnar and Røed (2008) note that, for a relatively long period of time, the automated forecasts from an empirically validated inflation model, AIF above, have been better than Norges Bank's forecasts. Figure 17.10 illustrates the point.

The figure can be used to assess the *ex ante* forecasts based on forecast errors for the period 2004(2)–2007(3). The forecasted variable is the annual rate of CPI-AET inflation. The graphs in the upper panel in the figure show the MFEs. A negative MFE means that the inflation forecasts are on average higher than the actual inflation rates in the period. The biases of the econometric model (AIF) forecasts are

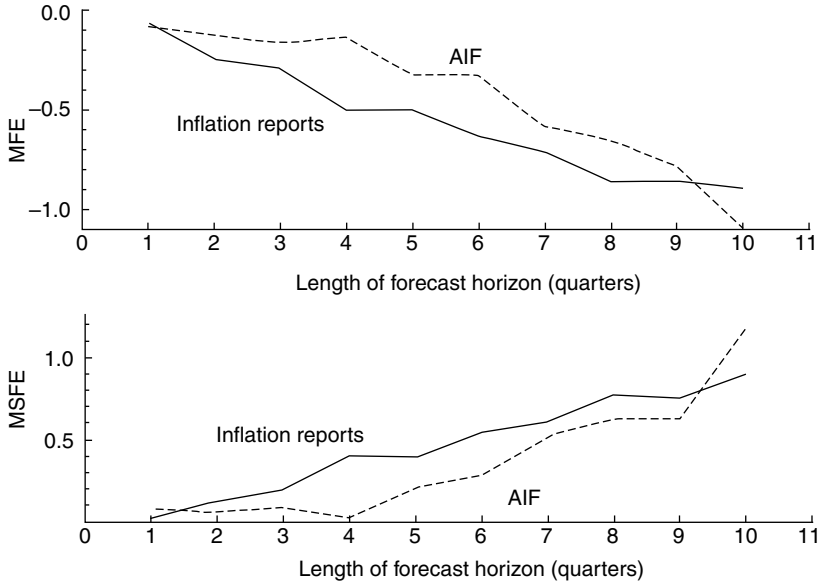

Figure 17.10 Forecasts from an empirically validated inflation model compared to inflation report forecasts

First panel: mean forecast errors (MFEs) for core inflation (annual rate of change in CPI-AET). Inflation report forecasts and AIF forecasts. *Second panel*: mean squared forecast errors (MSFEs).

small for forecast horizons 1, 2, 3 and 4: the MFEs are less than 0.25 percentage points. Norges Bank's inflation forecasts from the *Inflation Report*/*Monetary Policy Reports* are more biased than AIF for horizons 2–8 quarters ahead. The biases of AIF become markedly bigger for forecasts of length 7–10 quarters, and are not much different from the bias of forecasts produced by Norges Bank. The second panel of the figure shows the MSFEs, to which large forecast errors contribute more than small errors. This measure gives more or less the same picture at the MFEs.

17.4.5.3 Ex post *forecast evaluation and robustification*

The discussion of Figure 17.9 illustrated the general point that, although EqCMs forecast well when a process is difference-stationary, they are non-robust if there are non-stationarities due to location shifts in the forecast period. In this particular case, the mean of the rate of inflation seems to have changed, in 2004 or earlier, and the DDD is a more adaptable forecasting mechanism than the EqCMs in the case of the before-forecast structural break. The main benefit of DDDs for model-based forecasting, where one wants to retain the causal information of the model, is that DDDs can help the forecaster to robustify the EqCM forecasts, by intercept corrections. The cost associated with DDDs is, of course, that the forecasts are more "noisy" than EqCM forecasts, hence the forecast-error variances associated with robust forecasts can become large, such as when the first difference of an autoregressive process doubles the one-step forecast variance. In a model with one or two endogenous variables this cost may not be much of an issue, but in a multi-equation forecasting setting there may be a problem of extracting "signal from noise" in practice. In the rest of this section we illustrate these issues by considering system forecasts.

Figure 17.11 shows dynamic NAM forecasts for the period 2003(1)–2007(3).[18] The sample period for the estimation ends in 2002(4). Unlike the inflation forecasts in Figure 17.9 which are real-time *ex ante* forecasts, we now consider *ex post* forecasts, which are conditioned by the true values of the non-modeled variables. Hence the forecasts are not influenced by location shifts in the non-modeled variables (foreign CPI inflation, e.g.), but they are subject to location shifts that are due to changes in the means of the estimated cointegration relationships, or the autonomous growth rates (captured by intercepts after subtraction of equilibrium correction means).

Figure 17.11 serves as the reference case for discussion of the degree of adaptation of NAM forecasts, and for the properties of more robust forecasting devices that we investigate for comparison. There are no less than five possible instances of location shifts in the forecast of these nine variables. First, there is systematic overprediction of the rate of inflation (we use CPI inflation here) over the length of the forecast horizon. In the light of the 70% prediction interval, inflation overprediction is significant (forecast failure) in 2003. Second, unemployment is overpredicted and GDP growth in underpredicted for the three quarters of 2007. Third, the short-term interest rate is significantly overpredicted in 2003(2)–2004(4). Fourth, real credit growth is underpredicted (significantly) from

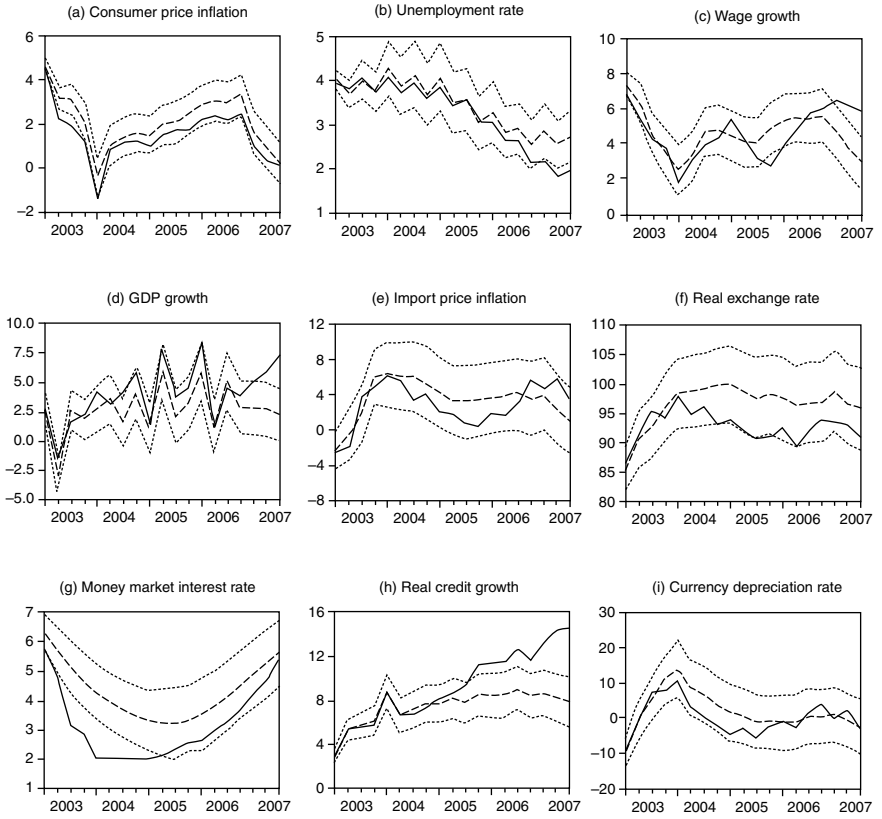

Figure 17.11 Dynamic NAM forecasts 2003(1)–2007(3), with end-of-sample for estimation of parameters in 2002(4)

Actual values are shown by solid lines, and forecasts by dashed lines. The distance between the two dotted lines represents 70% prediction intervals.

2005(3). Finally, the real exchange rate is systematically overpredicted from 2004(4) and onwards – the real appreciation of the Norwegian krone is not captured by the forecasts.

In the following we show how well the NAM forecasts adapt to these location shifts when we condition on 2004(4) and then 2006(4). In each dynamic forecast the coefficient estimate is updated. Figure 17.12 shows that the 2005(1)–2007(3) forecasts for inflation and, in particular, for the interest rate and the real exchange rate, have improved relative to Figure 17.11. For the other variables there is little change and, if anything, the forecast failures for the rate of unemployment and for GDP growth stand out more clearly than before (also showing that there is a knock-on effect of the high employment forecast on wage inflation). The explanation may be that NAM is unable to adapt, or that the location shifts of the variables are of the after-forecast type.

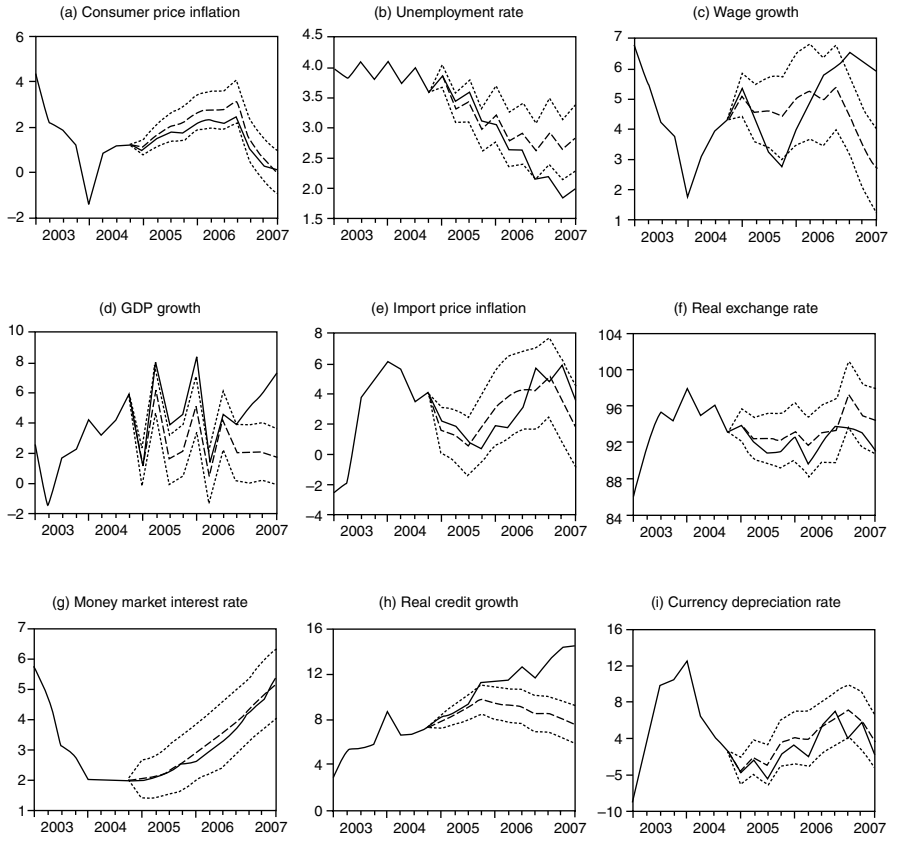

Figure 17.12 Dynamic NAM forecasts 2005(1)–2007(3), with end-of-sample for estimation of parameters in 2004(4)
Actual values are shown by solid lines, and forecasts by dashed lines. The distance between the two dotted lines represents 70% prediction intervals.

Figure 17.13 focuses on the last three "problem variables" in terms of forecast failure. The rate of unemployment is now much better forecasted in 2007(1)–2007(3), which is a sign of adaptation to a location shift which is of the before-forecast category, where 2006(4) is in the information set. For GDP and real credit growth the forecast failures persist. In the present version of NAM, the high growth rates of 2007 can, in part, be explained by the effects of very high oil prices on demand. In fact, that modeling device was used in Figure 17.6, showing the goodness-of-fit, but clearly would not be known or of any help to a forecaster preparing a forecast for 2007 late in 2006.

As mentioned above, using differencing (DDD) to forecast provides a more robust forecast when non-stationarities are due to location-shifts. As discussed by Hendry (2006), a differenced version of the EqCM may be interpreted as an augmented DDD forecasting rule. We therefore consider forecasts from the differenced NAM

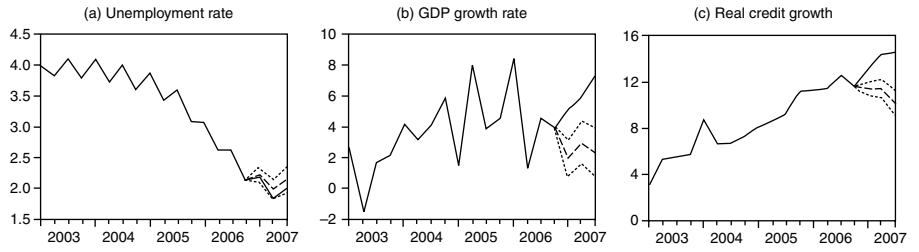

Figure 17.13 Dynamic NAM forecasts 2007(1)–2007(4), with end-of-sample for estimation of parameters in 2006(4)

Actual values are shown by solid lines, and forecasts by dashed lines. The distance between the two dotted lines represents 70% prediction intervals.

model, and refer to these as dEqCM forecasts. In the differenced forecasting systems, some of the causal information embedded in NAM is retained. The dEqCM has no constants either in the form of means of cointegration relationships or in the form of separate intercept terms (see Hendry, 2006). Hence forecasts from the dEqCM do not equilibrium-correct, thereby reducing the risks attached to EqCM forecasts.

Figure 17.14 shows the dEqCM forecast for the 2003(1)–2007(3) period. Comparison with the NAM forecasts in Figure 17.11 shows that the increase in forecast variance is not a small cost in this case – note the difference in scaling as well. The absolute forecast errors appear to be much worse than the NAM forecast errors as well. For example, unemployment is predicted by the dEqCM to increase over the forecast horizon, and credit growth is underpredicted for the length of the horizon.

Figure 17.15 shows the dEqCM forecasts when we condition on information including 2004(4). Compared to the NAM forecasts that condition on the same information (see Figure 17.12) there is little to be gained in these forecasts. We note that the dEqCM interest rate forecast has adapted, but the same happened with the NAM forecasts. The dEqCM forecasts are still uninformative about the behavior of unemployment and credit growth over the 2006(1)–2007(3) period.

Figure 17.16 indicates that for the three quarters of 2007, the dEqCM forecast for the rate of unemployment is better than the (already quite good) NAM forecasts. However, for GDP growth and credit growth, the dEqCM still does not adjust to the location shift. These results suggest that, in practice, a more discretionary approach may be called for. For example, instead of taking away all the equilibrium correction by differencing, one may concentrate on the sub-set of equations which have failed because of location shifts in recent forecasting rounds, since that will also induce lack of adaptation in the overall forecasting picture. To illustrate the possible benefit from such an approach, Figure 17.17 shows the 2007 forecasts for a dEqCM, where only the equilibrium variables of the aggregate demand and credit equations have been "differenced away." To avoid confusion with the dEqCM used above we refer to this forecasting model as *partial* dEqCM. Figure 17.17 shows the one-step forecast, since any difference in adaptability is then easier to see.

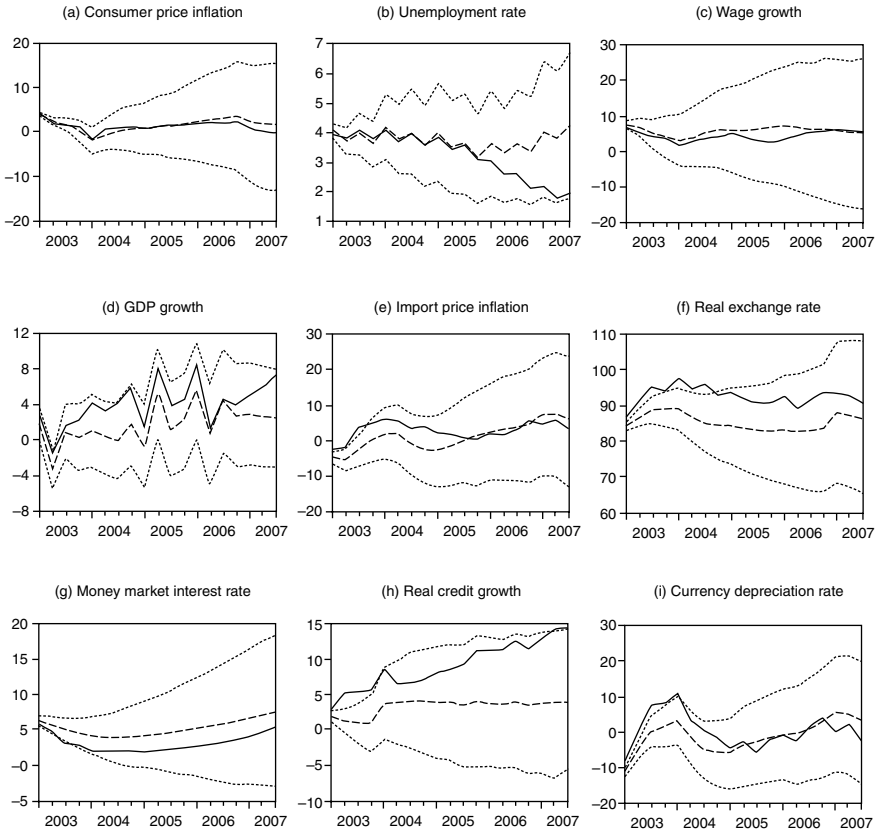

Figure 17.14 Dynamic dEqCM forecasts 2003(1)–2007(3), with end-of-sample for estimation of parameters in 2002(4)

Actual values are shown by solid lines, and forecasts by dashed lines. The distance between the two dotted lines represents 70% prediction intervals.

Panels (a) and (b) show the NAM forecasts. The forecasts for 2007(1) are the same as in Figure 17.16 for these two variables, but 2007(2) and 2007(3) are different since the NAM forecasts are now conditional on first- and second-quarter information for exogenous and predetermined variables (the coefficients are not updated). The lack of adaptation to the location shifts of the growth rate of the actual series is apparent. Panels (c) and (d) show the corresponding partial dEqCM forecasts. For GDP growth there is less underprediction already in 2007(1), and in 2007(2) the forecast has adapted. Panel (c) shows a marked improvement in adaptation also in the credit growth rate, although not before the second quarter of 2007(2).

17.5 Conclusion

This chapter has presented a case for continuing to use macroeconometric models for policy analysis, including such analyses that rely on instrument use to attain a

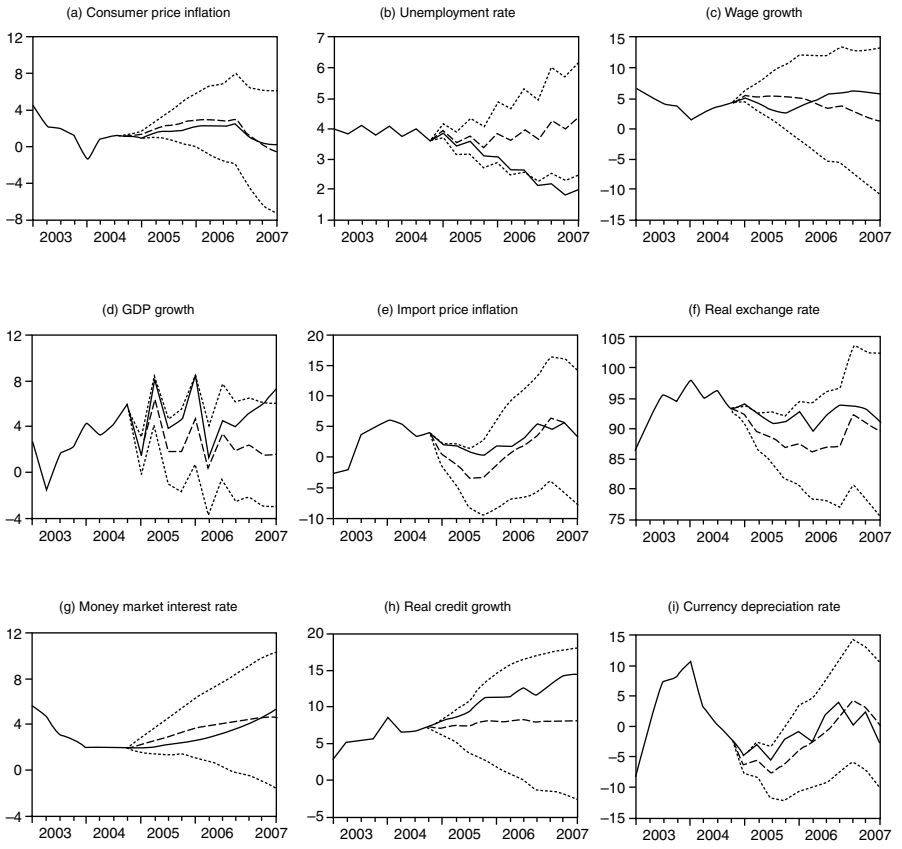

Figure 17.15 Dynamic dEqCM forecasts 2005(1)–2007(3), with end-of-sample for estimation of parameters in 2004(4)
Actual values are shown by solid lines, and forecasts by dashed lines. The distance between the two dotted lines represents 70% prediction intervals

certain forecast for a target variable like inflation. Paradoxically, perhaps, the main line of argument starts from the recognition that accurate forecasting is a near impossibility in macroeconomics because of the inherent non-stationarity of the economic time series included in the model. Non-stationarity takes different forms, with different implications for macroeconometric modeling and forecasting, and we have distinguished between unit roots and non-stationarity due to structural breaks. We have demonstrated that macroeconometric models can be developed theoretically and empirically in a way that is consistent with a unit root assumption. At the modeling and estimation stage, non-stationarity due to unit roots can in principle be handled by cointegration methods and, given that approach, unit roots are unlikely to be a source of forecast failures. On the contrary, a correct unit root assumption can help in concentrating on predictable functions of variables, like growth rates and linear combinations of target variables.

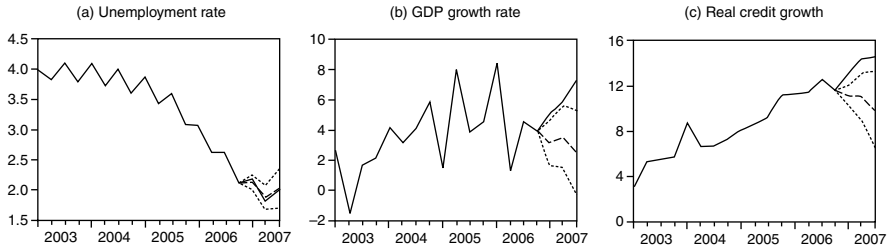

Figure 17.16 Dynamic dEqCM forecasts 2007(1)–2007(4), with end-of-sample for estimation of parameters in 2006(4)
Actual values are shown by solid lines, and forecasts by dashed lines. The distance between the two dotted lines represents 70% prediction intervals.

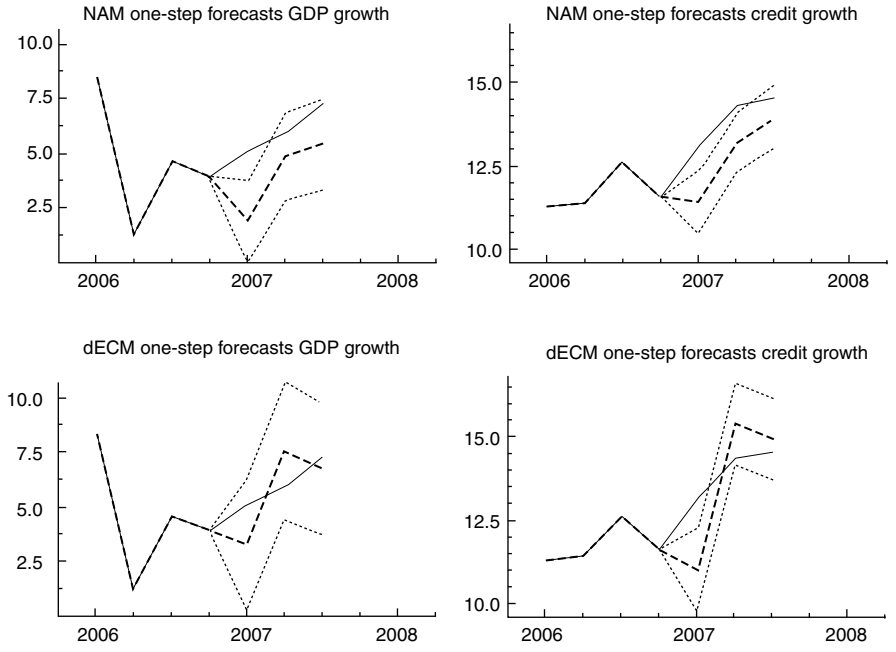

Figure 17.17 One-step forecast from NAM and a partial dEqCM
The forecasts are the dashed lines. The distance between the dotted lines represents 70% prediction intervals.

Non-stationarity due to structural breaks in functional relationships of the economy seem to represent the real challenge to macroeconometric modeling. Structural breaks in the forecast period are particularly harmful since they are untraceable and will make the model forecasts go toward pre-break steady-state relationships. When the sample period is extended, structural breaks represent valuable sample information that provide power to tests of economic hypotheses,

and from that perspective structural breaks are seen to be not entirely negative, since there can be progress in macroeconometric modeling through forecast failure.

It follows from our approach that we agree with those who conclude that guidance from economic theory is important in the forecasting process (cf. Elliott and Timmermann, 2008). But theory and modern econometrics do not provide immunity from new structural breaks. Nevertheless, the case for macroeconometric system of equations models may, to a large extent, depend on their ability to forecast relatively well compared to competing forecasting methods. Making models sufficiently adaptive to a structural break, once the evidence is there that it has occurred, is a necessary step in that project.

It is possible to look to other forecasting disciplines for inspiration. Meteorologists developed their forecasting theory, models and routines between the two world wars. Those forecasts were based on a deterministic model of the dynamics of the atmosphere. Then, in the mid 1960s, the understanding of the dynamics were completely altered with the development and acceptance of chaos theory, with the logical consequence that accurate weather forecasting is impossible. Thirty years after the arrival of the meteorologists' "impossibility theory" for forecasting, the weather forecasts are undeniably more accurate than ever. Hence, the weather is predictable even ten days ahead, despite the chaos represented by the underlying forecasting models. It is perhaps unlikely that we will witness something similar in economics, but there are nevertheless parallels. Meteorologists have precise theory and almost continuous updating of initial conditions. Policy-oriented modeling may have to live with idealized or partial theories, and with variables that are measured at relatively long time intervals, and which are influenced by measurement errors. Yet, as a discipline we have developed methods and strategies that are quite good at making the most of "small data amounts." Hence, while meteorologists can rely on the theoretically specified model of weather dynamics, the interaction between economic theory, econometric theory, good model selection procedures, and diagnostic testing have together greatly improved our capability of modeling the macroeconomy, thus providing models that can aid policy decisions.

Appendix: Data definitions and equation statistics

Variables

The model employs seasonally unadjusted data. Unless another source is given, all data are taken from FPAS, the database of Norges Bank.

The model is developed and estimated with Oxmetrics 5 (http://www.oxmetrics.net) and then re-estimated and simulated with Eviews 6 (http://www.eviews.com).

V Trade-weighted nominal value of the krone based on import shares of trading countries.
G Government sector consumption expenditure, fixed 1991 prices. Millions (Mill): Norwegian krone (NOK).
L Nominal credit volume. Mill. NOK.
R Money market interest rate (three month euro–krone interest rate).

R^* ECU interest rate. For the period 1967(1)–1986(3): effective interest rate on foreign bonds, NOK basket weighted. For the period 1986(4)–1996(4): ECU weighted effective rate on foreign bonds.
R_L Average interest rate on bank loans.
R_B Yield on six year government bond, quarterly average.
R_B^* Yield on long-term foreign bonds. NOK basket weighted.
P Consumer price index (CPI).
P_C "Core" CPI.
P^* Consumer prices abroad in foreign currency.
P_E CPI, electricity, fuel and lubricants.
P_O $US oil price, per barrel Brent–Blend.
P_I Price deflator of total imports.
P_I^* Producer price index, trading partners.
Y Total value added at market prices in the mainland economy (defined as total economy minus North Sea oil and gas production and international shipping). Fixed base year (1991) prices. Mill. NOK.
Z Mainland economy value added per man hour at factor costs.
$T1$ Payroll tax rate, mainland economy.
U Registered rate of unemployment.
W Nominal hourly wage costs in the mainland economy. NOK.

In addition, there is a step dummy, accounting for the introduction of inflation targeting:

$$IT = 0 \text{ until } 2001(1),\ 1 \text{ from } 2001(2).$$

Notation for estimation and misspecification tests

In Table 17.1, the estimation method, which is either OLS or full information maximum likelihood (FIML), is indicated in the first line below each equation, along with the sample size (number of quarterly observations), which is denoted by T, and the residual standard error ($\hat{\sigma}$). For equations estimated with OLS, statistics for residual autocorrelation and ARCH are reported in the second line below the equation. As indicated by the notation, these two statistics are F-distributed under their respective null hypotheses. For example, $F_{AR(1-4)}(4, 44)$ in the exchange rate equation denotes the F-distributed test statistics with 4 and 44 degrees of freedom for the null hypothesis of no autocorrelation against the alternative of fourth-order autocorrelation. In the third line below the estimated OLS equations, we report the chi-square-distributed test of residual normality, and the F-distributed test of heteroscedasticity due to squares of the regressors. For the equations estimated with FIML, systems versions of the misspecification tests are reported and are indicated by the extra subscript *vec*, as $F_{vec,\mathsf{AR}(1-4)}$. The numbers in brackets are p-values for the respective null hypotheses. These, as well as the other standard diagnostics tests, are explained in Doornik and Hendry (2007a) (single-equation diagnostics), and Doornik and Hendry (2007b) (system and simultaneous equations diagnostics).

Acknowledgments

We thank Q. Farooq Akram and Kerry Patterson for helpful comments and discussions.

Notes

1. See, e.g., Hendry (1995a, Ch. 2.3 and 15.3) for a concise definition of structure as the invariant set of attributes of the economic mechanism.
2. This line of thought may lead to the following practical argument against large-scale empirical models: since modeling resources are limited, and some sectors and activities are more difficult to model than others, certain euations of any given model are bound to have less structural content than others, i.e., the model as a whole is no better than its weakest (least structural) equation.
3. See Nymoen (2005) for an analysis of a recent failure in inflation forecasting.
4. Sub-sections 17.2.1–4 draw on Bårdsen, Hurn and Lindsay (2004).
5. Presently, we let the unemployment rate be constant and disregard it for simplicity. We return to the role of the rate of unemployment in section 17.2.6.
6. The distinction between the inferential and model validation facets of modeling is due to Spanos (2008), who conclusively dispels the charge that misspecification testing represents an illegitimate "reuse" of the data already used to estimate the parameters of the statistical model; see also Hendry (1995b, pp. 313–14).
7. It might be noted that the income tax rate $T2$ is omitted from the analysis. This simplification is in accordance with previous studies of aggregate wage formation (see, e.g., Nymoen, 1990, and Nymoen and Rødseth, 2003, where no convincing evidence of important effects from the average income tax rate $T2$ on wage growth could be found).
8. Note that, due to the log-form, $\zeta = is/(1 - is)$, where is is the import share in private consumption.
9. Strictly, we take the expectation through in both equations.
10. NAM is a model project which extends from the early econometric assessment of wage and price inflation in Nymoen (1991), further developed in Bårdsen, Fisher and Nymoen (1998), Bårdsen and Fisher (1999), and the monetary transmission model of Bårdsen and Klovland (2000). Earlier versions of the model are documented in Bårdsen and Nymoen (2001), Bårdsen, Jansen and Nymoen (2003) and Bårdsen *et al.* (2005).

    NAM is used for both research purposes and teaching. The macroeconomic data is from the model databases of Statistics Norway (KVARTS model) and Norges Bank (FPAS database). Specific versions of the model are currently operative for (a) econometric forecasts of the Norwegian macroeconomy (NAM-EF) and (b) model-based analysis of financial stability in Norway (NAM-FS).
11. See http://folk.uio.no/rnymoen/normetrics_index.html.
12. In practice, the policy instrument is the sight deposit rate set by the central bank, but since the sight deposit rate represents (banks') marginal funding cost, changes in the sight rate are transmitted to the money market rate immediately.
13. The size of the depreciation will depend upon the risk premium, and whether expectations counteract or strengthen the initial effect of the interest rate cut, etc. (cf. section 17.3.3).
14. Although the derivations are presented for a single equation with exogenous regressors, for ease of exposition, the techniques are, of course, the same for systems.
15. A full listing of variables is given in the appendix to this chapter.
16. See, e.g., Ericsson (2001) for an accessible discussion of forecast uncertainty, and its presentation in published forecasts.
17. Automatized econometric inflation forecasts have been published twice a year, starting in July 2004. The forecasts are automatized, with a minimum of intervention after the econometric specification of the forecasting mechanism is completed.

18. In this section, we use the model version used for the October 2007 NAM forecasts: see http://folk.uio.no/rnymoen/namforecast_okt07.pdf.

Monetary Policy, Beliefs, Unemployment and Inflation: Evidence from the UK

S.G.B. Henry

Abstract

Recent applied macroeconomic research has been concerned with the effects of both labor market reforms and the delegation of monetary policy to an inflation-averse central bank as ways of improving inflation and unemployment outcomes. The experiences of the UK following the introduction of changes to the labor market in the 1980s and of inflation targeting and instrument independence for the Bank of England in the 1990s, have often been held up as illustrations of the beneficial effects of regime changes of this sort. Others have contradicted these views, including those who have drawn attention to the weakness in the empirical evidence favoring effects from labor market reforms, and others who argue that a combination of beneficial international events and monetary policy mistakes have played an important part in the UK's recent economic improvement.

We review the case for regime change from either of these sources, labor market and monetary, in an application to the UK using a model that integrates both. The results indicate two things: the importance of allowing for the openness of the UK economy in "behavioral" econometric models of the natural rate, and the importance of allowing for policy "mistakes." Based on our analysis, we conclude that recent changes in UK monetary policy or labor market institutions seem unlikely to have made an important contribution to the improvements in UK economic performance. Effects originating overseas appear to play an important role in unemployment changes in the UK. Policy mistakes have had important effects on inflation over the last two decades, and a proper allowance for these is needed before any firm judgments of the benefits of the delegation of monetary policy can be reached.

18.1 Introduction: inflation and unemployment in the UK

Inflation in the UK over the last 25 years has varied substantially (Figure 18.1). It had a period of seriously high inflation for a decade starting from the early 1970s, with two distinct episodes each coinciding with a huge increase in oil prices.[1] Although this phase was brought under control towards the end of the 1980s, there followed a second – smaller – surge from then until the early 1990s. Although this second phase was less serious than each of the two peaks of the first, it was nevertheless important enough for the UK to join the Exchange Rate Mechanism (ERM) in an effort to control it.

From the date of its departure from the ERM, inflation, growth and unemployment have been unusually good by UK standards although, as Figure 18.2 shows,

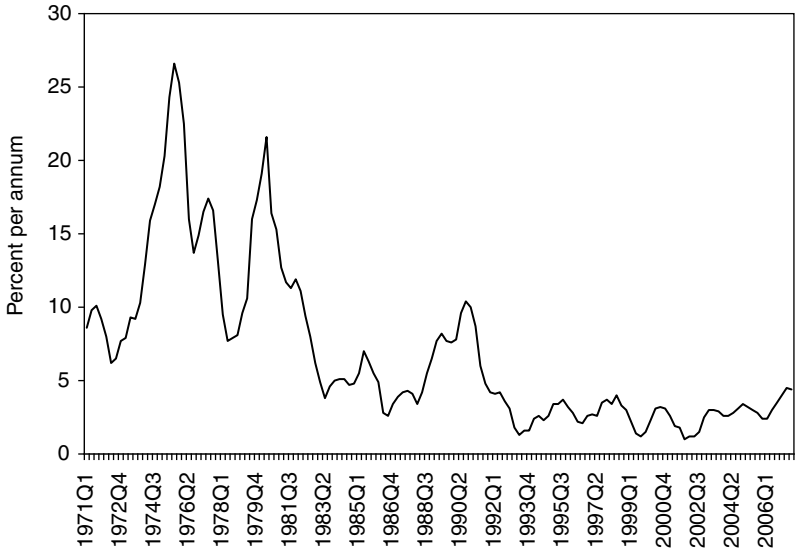

Figure 18.1 RPI inflation in the UK

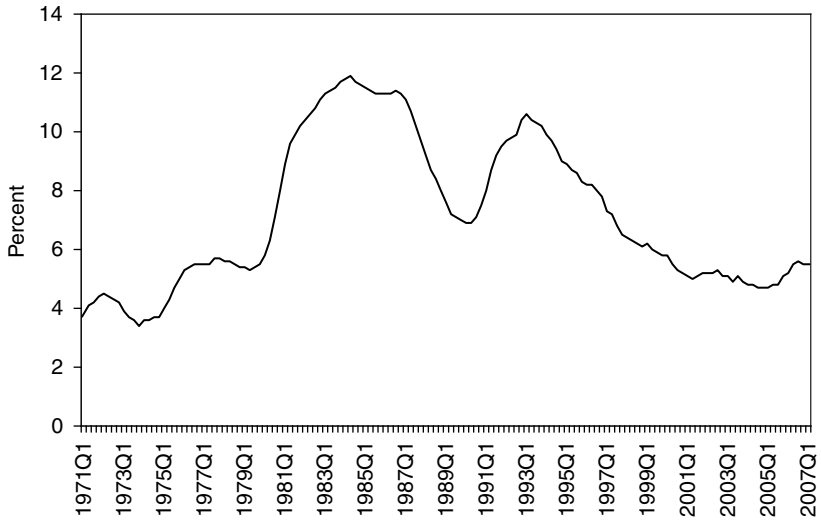

Figure 18.2 UK unemployment (ILO measure)

it was not until 1997 that unemployment fell to the level it reached before the UK joined the ERM.

Starting in 1992, monetary policy has been based on inflation targeting and, from 1997, the Bank of England (BoE) was delegated to set interest rates in pursuit of a preset inflation target (see BoE, 2007, for details). These changes have been heralded as decisive in achieving simultaneously low inflation and unemployment over the last 15 years, both in official circles (Balls and O' Donnell, 2002; BoE, 2007) and elsewhere (Cechetti, 2000). But, in a large US literature focused on testing for structural change in monetary policy, other explanations of improved inflation and growth performance have been suggested. Thus the importance of "good luck" – unusually benevolent world economic developments – has been cited, and yet other US research has emphasized policy mistakes, mainly due to uncertainties about the rate of productive potential and the natural rate (references to these and other parts of the US literature are given in section 18.2). Neither of these issues has received much attention in the UK, where there has been an even longer-standing debate on the possibility that there has been a decline in the UK non-accelerating inflation rate of unemployment (NAIRU) due to labor market reforms in the 1980s. These reforms were largely industrial relations changes to closed-shop arrangements and to procedures for settling industrial disputes, for example, but also included changes to the availability and duration of income out of work. Added to this set of possible alternatives another, which has recently surfaced in the UK, attributes an important and continuing effect on inflation and growth to the UK's membership of the ERM in 1989–92 (see Budd, 2004).

This chapter is directed at assessing some of these alternative explanations for the changes in inflation and unemployment in the UK since the early 1980s. It proceeds

by bringing together what have hitherto been treated as two distinct – and largely separate – possibilities for regime change: that the 1980s labor market reforms had significant effects on unemployment, and the possibility that important effects on inflation and unemployment followed from switching to inflation targeting and central bank independence. The first of these two possible sources of regime change refers to a large "shocks versus institutions" literature (see Blanchard and Wolfers, 2000, amongst others). The other relies on the pioneering research by Sargent (1999) which derives optimal monetary policy in a natural rate model where expectations are formed by recursive learning. As with other research on the policy model, section 18.5 considers to what extent a model of optimal monetary policy with learning conforms to the broad features of UK inflation since 1980. To do this, however, it amends the policy model in the light of econometric results on the determinants of long-run unemployment from section 18.4. These econometric results conclude that the evidence does not support the "wage push" interpretation of changes in long-run unemployment. Instead, it is shown that extensions to the unemployment model that give a major role to international factors, such as real oil prices and measures of international competitiveness, are needed for the model to capture the broad movements in UK unemployment. Once this extension is made to the policy model, it is found that optimal inflation solutions from it conform to the broad pattern of changes to inflation observed over the last 25 years or so without appealing to any regime change. As is evident in this account, the break-point for possible labor market regime changes is the early 1980s and monetary policy regime change is taken to be from the end of 1992 since, as is evident from references listed later, these are the alleged break-points in most of the labor market and monetary policy debates in the UK. Hence, we do not attempt any sort of estimation and inference about likely break-dates, which is an important, but separate, topic to what is presented here.[2]

18.2 A selection of background literature

18.2.1 A baseline New Keynesian policy model

It is helpful, pedagogically, to relate the principal papers referred to later to a "baseline" New Keynesian policy model (NKPM), since they can often be viewed either as a form of complete NKPM or as single equations from it, such as the aggregate supply (AS) or the policy rule for interest rates (the "Taylor rule"). The aggregate demand (AD) equation has received less attention in the literature, and that is the line adopted here.[3] The example below is the closed-economy model found in Henry and Pagan (2004). This baseline NKPM is given by equations (18.1)–(18.3), and microfoundations of these equations are discussed in, *inter alia*, Svensson (2000).

$$\pi_t = \alpha_\pi \pi_{t-1} + (1-\alpha_\pi)\pi^e_{t+1} + \alpha_y(y_{t-1} - y^*_{t-1})] + \xi_t \tag{18.1}$$

$$y_t = \beta_y y^e_{t+1} - \sigma(r_t - \pi^e_{t+1}) + \nu_t \tag{18.2}$$

$$r_t = \bar{r}_t + \beta(\pi^e_{t+1} - \pi^*) + \gamma(y_t - y^*_t). \tag{18.3}$$

Equation (18.1) is the AS (or Phillips curve) equation, where π_t is domestic inflation and $(y_t - y_t^*)$ is the output gap. As written, this is in the so-called "hybrid" form for the New Keynesian Phillips curve (NKPC), which depends on both lagged and future expected inflation rates. Equation (18.2) is the AD equation dependent on expected output and the real interest rate. The last equation (equation (18.3)) is a simple form of policy rule for interest rates, r, which is shown as depending on deviations of expected inflation from target and the output gap.[4] A significant difference in practice is how this equation is treated. First, it may be explicitly derived by optimising a dynamic objective function depending on government macroconomic objectives (inflation and output deviations from their equilibrium levels) subject to the constraints given by the model above, as in Ball (1997) and as in the models in sections 18.3 and 18.5 later, for example. But, most often the policy rule is taken as simply a reasonable description of the authority's behavior and is estimated; however, substantial problems can arise when it is estimated, and some of it is discussed next in a short review of US literature.

18.2.2 Evidence for and against monetary regime change in the US

Under the heading of the "Great Moderation," considerable effort has been directed at finding possible explanations of the marked reduction in the volatility of inflation and output in the US (BoE, 2007, draws attention to similar developments in the UK). It is probably fair to say that the results of this have been inconclusive, with some papers finding evidence for regime change in monetary policy whilst others have reported equally strong findings against. In part, this reflects different modeling approaches, as we illustrate immediately below.

There are now many examples of single equation estimates of both NKPCs and interest rate policy rules, both of which are directed at detecting changes in the effectiveness of monetary policy. They mainly assume that expectations are formed rationally. In the research on the NKPC, a major interest has been whether the degree to which the equation is forward-looking has increased, but this issue is largely unresolved. Thus, for example, using marginal costs rather than output gaps as the driving variable in the equation, Rudd and Whelan (2005) argue for the unimportance of forward-looking terms. In turn, Gali, Gertler and Lopez-Salido (2005) rebut this by observing that Rudd and Whelan use incorrect weights in forming the required forward-looking terms. Turning to the estimated policy reaction function (that is, the estimated version of (18.3) above), this has typically been of the form:

$$r_t = (1-\rho)\alpha + (1-\rho)\beta\pi_{t+n} + (1-\rho)\gamma x_t + \rho r_{t-1} + \varepsilon_t. \tag{18.4}$$

In this equation $\alpha = \bar{r} - \beta\pi^*$, where $\bar{r}$ is the long-run equilibrium nominal interest rate, π^* the target inflation rate and β is the weight on inflation deviations from target in the authority's objective function. The variable x_t is defined as $y_t - y^*$, and in (18.4) allowance is made for interest rate smoothing with a weight ρ. Henry and Pagan (2004) draw attention to a problem of the interpretation of such equations when they are used to infer what central banks' behavior has been. An example of such an interpretation is found in Clarida, Gali and Gertler (2000). Drawing such

inferences from equations like (18.4) is possible only if future expected inflation and output gaps were actually exogenous, which they are not. Complete system adjustments are needed to judge what the interest rate response to changes in either of the right-hand-side variables would be. This interpretative issue is addressed by Dennis (2004), who argues that judgments on the relative weights attached to inflation versus output stabilization require that central bank preferences be estimated, and this requires that all the parameters in the system be estimated.[5] A further econometric issue in these single-equation studies (both the NKPC and the estimated Taylor rules) is the problem of weak instruments. Often, large numbers of instrumental variables are used, and the risk is that the equations may be "overfitted," with predicted values being very close to actual values, with results that are close to ordinary least squares (OLS), as noted by Henry and Pagan (2004).

Moving to complete model estimates, there have been many studies using vector autoregressive models (VARs) and structural vector auto regressive models (SVARs) to evaluate the relative statistical contribution that changes in exogenous shocks versus changes in model structures play in accounting for the changes in output and inflation dynamics. Representative examples used here are Stock and Watson (2002) (henceforth SW) and Boivan and Giannoni (2003) (henceforth BG). SW provide decomposition results for the observed changes in inflation and output volatility in the US, using estimated reduced form VARs of structural models akin to (18.1)–(18.3) above,[6]

$$\tilde{X}_t = \Phi(L)\tilde{X}_{t-1} + u_t, \tag{18.5}$$

where $\tilde{X}_t$ is a four variable vector of gross domestic product (GDP) growth, inflation, the Federal Funds rate and the growth in commodity prices.[7] This latter equation is appended as an *ad hoc* equation, so the set of variables in (18.5), $\tilde{X}_t$, differs from those in the baseline NKPM (18.1)–(18.3) above. SW's VAR estimates are fourth-order VARs for two sub-samples of the period 1960–2001, pre- and post-1984Q1, and the empirical results are noteworthy in that they show that it was changes in the covariance matrix of the unforecastable components of the VARs that account for almost all of the changes in the observed volatility of output. BG also report unrestricted VAR estimates over two sub-samples divided at the end of the 1970s. Broadly speaking, their findings are in line with the results of SW in that BG's unrestricted VAR results show that, if anything, monetary policy effects appear weaker in the second sample.

However, comparative results from the SVARs reported by SW and BG give different conclusions as to the effectiveness of monetary policy over time in the US, although each use a related, but different, version of the NKPM to identify their structural VAR. Thus SW use *a priori* values of the slope of the AD curve, the slope of the AS curve and the weight on forward-looking inflation in the AS curve. When estimated over the two periods, their structurally identified decomposition of output variability implies that most of the reduction in the second period is accounted for by changes in the variability of shocks, not changes in monetary policy coefficients. Although the paper by BG also takes a model based on the closed-economy

version of the NKPM augmented by an *ad hoc* equation for commodity price inflation, their structural model is different. In their "stylized structural model" they use a variant of a dynamic AD function composed of all interest sensitive spending, so amalgamating consumption (the dynamics of which depend on habit persistence) with investment (with dynamics dependent on adjustment costs). Their main finding is that over the later sub-period monetary policy appears more stabilizing, a finding at variance with those reported by SW.

In sum, the evidence from the results of this short, but fairly representative, summary of single-equation and small-complete models of the NKPM sort shows there are findings supporting monetary regime effects in the US, but equally there are findings which reach the opposite conclusion. In spite of this somewhat inconclusive state of play, we take the view that much of the research reviewed here points to the importance of more emphasis on econometric testing. SVAR studies, in particular, have reached diametrically opposite conclusions, in part because different theoretical identifying restrictions are employed by different authors. More, rather than less, empirical testing is one possible way out of this impasse. Also, a lesson from the single-equation research is the probable gains of a more complete treatment of the system as represented by (18.1)–(18.3) above, since there are evident shortcomings in testing for regime change effects with single equations only.

18.2.3 The importance of uncertainty

Much of the research described so far, particularly that in section 18.2.2, has used the rational expectations hypothesis. But there is a burgeoning literature, which again is largely found in applications to the US, which emphasizes uncertainty about the effects of regime change, transmission mechanisms and shocks hitting the economy.

Among the alternative approaches under this heading, the first is the argument, primarily associated with Sargent (1999), emphasizing changes in governments' beliefs as central to inflation and unemployment behavior. In this approach, as in the rest of the literature reviewed here, information is assumed to be symmetric between private and public sectors, with neither side having an informational advantage.[8] In the Sargent model, the crucial assumption is that the authorities learn about the "true" economy over time. (This model is discussed more fully in section 18.3.) An emphasis on more general forms of uncertainty is found in the important work by Orphanides and associates on the effects of uncertain natural rates of unemployment, as in Orphanides (2001, 2002) and Orphanides and Williams (2006). A related development has considered the effects of uncertain rates of technical progress, including work on the effects of technology shocks on monetary policy performance, an example of which is given in Gali, Lopez-Salido and Valles (2003). Much of this line of analysis comes broadly under the "policy mistakes" heading. Lastly, there is the "bad luck" view, which figured in the previous section, and which argues that it was the volatility of exogenous, non-policy, shocks that were primarily responsible for the high volatility of inflation and growth in the 1970s and subsequent falls in these exogenous shocks that were responsible for the improved US performance in later decades. The paper by

Stock and Watson (2002), reviewed above, is an example of this, though it is also emphasized by Sims and Zha (2006), among others.

18.2.4 The effects of openness

It is also the case that the openness of the economy has become a major preoccupation in macroeconomics in general, and this is reflected in recent research on the NKPM, where there has been very considerable debate about the effects of changes in the nominal exchange rate and their "pass-through" into domestic inflation, and this debate continues. At one end of the spectrum comes the so-called "isomorphism" described by Clarida, Gali and Gertler (2001), where closed- and open-economy versions of the "canonical" model with complete pass-through are isomorphic, in the sense that the properties of the model and of its implied monetary policy rules are the same in each version. In recent contributions this characterization is rejected and incomplete pass-through is adopted (examples are Monacelli, 2003, and Engel, 1999, among others). Micro-explanations have been advanced for this incomplete pass-through, such as pricing to market (PTM) or the importance of non-traded goods in consumption, as have macro-explanations such as slow adjustment of prices at the consumer or importer level (see Devereux and Yetman, 2002, and, for UK applications, Balakrishnan and Lopez-Salido, 2002; Kara and Nelson, 2003; Herzberg, Kapetanios and Price, 2003; Batini, Jackson and Nickell, 2005). Unsurprisingly, allowing for non-unitary pass-through fundamentally alters the analysis of monetary policy in an open economy as compared with the closed economy.

In concluding this section, we note the input that this short review provides for the applications reported later in the chapter. Following the account of open-economy issues, an extension of the NKPM to the open economy case is called for; thus section 18.4 calls on the recent empirical research on international determinants of UK price margins contained in some of the work noted immediately above. Section 18.4 also builds on some of the contributions emphasizing model uncertainty, especially those of Sargent (1999) and Orphanides and Williams (2006), when analyzing the effects of monetary policy. The application to the UK reported in section 18.5 uses a model of the aggregate-supply equation that is econometric, following the comments made at the end of section 18.2.2. But, before moving to the application of model uncertainty to the UK case, the next section outlines the basic Beliefs model which underpins it.

18.3 Beliefs and monetary policy

18.3.1 Motivation

A brief outline of Sargent's (1999) model is that it is the Kydland and Prescott (1977) model coupled with the assumption of learning by the authorities, with the results being directed at accounting for variations in US inflation and unemployment. The fundamental assumption is that the authorities have a misspecified model of the Phillips curve, but update the parameters of this in the light of prediction errors. The remarkable finding in Sargent, and confirmed in other studies,

is that, even where the Phillips curve is taken to be static, the model's dynamics due to learning reveal a tendency for the economy to settle in a high-inflation equilibrium regime from which it occasionally "escapes" to occupy a low-inflation one. These "escapes," in turn, depend on an unusual sequence of shocks which move the economy from a sub-optimal high inflation but time-consistent (Nash) strategy, based on the misspecified view of the Phillips curve, to the neighborhood of the low-inflation optimal time-inconsistent strategy based on the "true" Phillips curve. Further analysis identifying the shocks which lead to "escapes" is found in Cho, Williams and Sargent (2002), and other applications from this by now large literature include Tetlow and von zur Muehlen (2001), Sargent, Williams and Zha (2004), McGough (2006) and Ellison and Yates (2007).

18.3.2 A basic learning model of monetary policy

The example of the learning model of monetary policy given below is a closed economy one. Open-economy issues are developed in section 18.4 and are used in the extension to the model in section 18.5. From here on, the approach will be referred to as the "Beliefs" model. The methodology of the Beliefs model is broadly in line with calibration exercises, which posit an AS equation and an assumed government objective function defined over unemployment and inflation, which is then optimized using the systematic part of inflation as the control variable.[9] It is thus a numerical optimal control exercise, the added complication being that the authorities are assumed to have a misspecified Phillips curve, but update their estimate of this according to a recursive updating procedure.

Sargent (1999) and Cho, Williams and Sargent (2002) describe a number of different dynamic versions of their Beliefs model, but it is the one which assumes a static Phillips Curve that will be used to motivate what follows.[10] The basic building block is a government characterized as setting monetary policy dependent upon (their) approximating (that is, misspecified) model of the economy, which is a non-expectational Phillips curve. The true data-generating mechanism, in contrast, is taken to be a vertical expectational Phillips curve in which the natural rate is assumed to be given.[11] The actual or "true" model of the economy used is:

$$u_t = u^* - \theta(\pi_t - \hat{\pi}_t) + \upsilon_{1t} \tag{18.6}$$

$$\pi_t = \hat{\pi}_t + \upsilon_{2t}. \tag{18.7}$$

Equation (18.6) is a natural rate Phillips curve (with u^* being the natural rate), and equation (18.7) shows that actual inflation is then a systematic part ($\hat{\pi}_t$) set by government, together with a random term υ_{2t}.[12] To obtain the policy rule for $\hat{\pi}_t$, the model assumes that the authorities have a perceived (misspecified) Phillips curve of the simple linear form:

$$u_t^p = \gamma_{0t} + \gamma_{1t}\pi_t + \varepsilon_t, \tag{18.8}$$

where u_t^p is perceived unemployment, and it depends on time-varying parameters.

The government's optimal rule for setting the systematic part of inflation is then derived by solving the following control problem:

$$MinE \sum_{t=0}^{\infty} \delta^t (u_t^2 + \pi_t^2), \tag{18.9}$$

where δ^t is the discount rate, using $\hat{\pi}_t$ as the control variable, subject to the authority's misspecified view of the Phillips curve, equation (18.8) above, and equation (18.7). Assuming that, in each period, the government believes its current estimate of the Phillips curve is correct, the optimization problem is also a static one, with the time-varying control rule:

$$\hat{\pi}_t = [-\gamma_{1t}/(1 + \gamma_{1t}^2)]\gamma_{0t}. \tag{18.10}$$

In the cited applications it is assumed that these parameters are updated sequentially using recursive least-squares with constant gain. As noted above, the optimization proceeds by assuming that, in each period. the government treats that period's uncertain parameters as if they were true and optimizes subject to that assumption. Tetlow and von zur Muehlen (2001) review this point and find that the properties of the Beliefs model are robust to wider classes of uncertainty.

Unlike the AS equation (18.1) in the "baseline" NKPM above, this one uses a static Phillips curve, both for the "actual" (18.6) and the "perceived" equation (18.8) where, in each, unemployment is the dependent variable and the "actual" Phillips curve is built on the assumption of a fixed natural rate, from which only inflation surprises produce temporary deviations. Dynamics enter through the distinction between these two Phillips curves, coupled with the crucial assumption of "learning" about the parameters of the perceived Phillips curve using recursive estimation.[13] In this example, these are defined by the equations

$$\gamma_{t+1} = \gamma_t + gP_t^{-1} X_t (u_t - \gamma_{0t} - \gamma_{1t}\pi_t) \tag{18.11}$$

$$P_{t+1} = P_t + g(X_t X_t' - P_t), \tag{18.12}$$

where γ_t is the column vector $(\gamma_{0t}, \gamma_{1t})'$, X_t the vector $(1, \pi_t)'$ and $g = 1 - \vartheta$, where ϑ measures the rate at which past information is discounted. P_t is the 2×2 precision matrix.

An important property of the model is that it depicts the government as pessimistic about the unemployment level needed to reduce inflation, but optimistic about the effect of higher inflation in reducing unemployment; they tend, therefore, to continue to pursue a high inflation policy, which is the basis of the self-confirming equilibrium (SCE) property of the model.[14] However, solutions of the model show that, even when the government is making this assumption, the time path of inflation can undergo abrupt changes, suddenly dropping from high rates to sustained low rates of inflation. Crucially, in this model this happens only because there is a special sequence of shocks which shifts the economy from the SCE of the Nash solution. These dynamics are a highly original way to use this

model, with its underlying assumption of a fixed natural rate and a static Phillips curve to account for the onset of periods of low inflation, and are defined as the most likely path that (government) beliefs will take if they deviate from their mean dynamics in a significant way.[15]

Two recent extensions to Sargent's model are related to the application reported later in section 18.5. Each alters what is taken to be the "true" Phillips curve used above by including further exogenous variables in it. In the first, Ellison and Yates (2007) extend the model to allow for an additional shock which, however, the government is assumed to perceive correctly. The second, by McGough (2006), is closer to the general procedure we follow. He extends the model of the natural rate to allow an effect from real oil prices (OIL), so that equation (18.6) is modified as:

$$u_t = u^* - \theta(\pi_t - \hat{\pi}_t) + \psi OIL_t + \nu_{1t}. \tag{18.13}$$

In this model, the government's approximating model does not have the "true" parameter on this OIL variable and so is:

$$u_t^p = \gamma_{0t} + \gamma_{1t}\pi_t + \varphi_t OIL_t + \psi_t . \tag{18.14}$$

Hence, the assumption is that the government believes that real oil prices may affect the level of unemployment but is unsure of the size of this effect. A related model to this is described and applied to the UK in section 18.5.

18.4 Long-run unemployment: evidence from wage and price equations

In section 18.5, the baseline Beliefs model set out in section 18.3 is extended by embedding in it a long-run unemployment equation estimated, using cointegration, on UK quarterly data. This will be our version of "actual" unemployment (equation (18.6) above) and, like that, uses an aggregate supply equation with unemployment as the dependent variable.[16]

Cointegration analysis is needed to estimate this unemployment equation since the data involved are non-stationary. Ignoring non-stationarities in the variables, and the possibility that cointegrating vectors may exist between them, leads to misspecification, even where the model is estimated in levels, as the cross-equation restrictions due to cointegration will be ignored. It follows that the policy inferences in our later applications are, to this extent, empirically based. In the rest of this section, we will refer only to the long-run results for the unemployment equation, in keeping with the static form of the AS equation of the Beliefs model.

18.4.1 Behavioral models of the labor market

The intention of the rest of the chapter is to integrate tests of the beliefs model, to be given in section 18.5, with the very active program of research by labor economists that uses "behavioral" models of the labor market. The term "behavioral" is used in the sense that the underlying models are derived from flow or stock models of

the labor market, in contrast with more statistical (or time series) models of unemployment, such as Ball and Mankiw (2002) for example. Using such behavioral models, when estimated as reduced-form unemployment equations, many labor economists have concluded that labor supply factors play a crucial role in determining long-term unemployment. For a recent affirmation, see Layard, Nickell and Jackman (2005) and the review of this book by Blanchard (2007). But the empirical claims that effects of labor supply-side or wage-pressure variables, such as unionization, income out of work and the rigor with which rules on this are applied, have been so important is challenged by other economists.[17] Among others, these critics include Madsen (1998), Oswald (1997), Henry and Nixon (2000) and Blanchflower (2007). Empirical reasons for not accepting the claims of the supply-side proponents are discussed in section 18.4.2. The alternative model suggested there is that, based on econometric evidence, the labor supply variables that have characterized much of UK research do not satisfactorily account for the large changes in unemployment since the early 1970s, so the alternative emphasizes other possible determinants of unemployment, based on effects from the external economy.

To make the present study comparable with existing research, the model of wage and price determination used here starts from the model described in Layard, Nickell and Jackman (2005) and Nickell (1998), the basic equations of which are a price equation based on markup pricing and a wage equation derived from union–firm bargaining, which are solved to give an unemployment equation.[18] Thus the price and wage equations (ignoring time subscripts) are:

$$p - w = z_p - \beta_2(p - p^e) \tag{18.15}$$

$$w = \gamma_2 p^e + (1 - \gamma_2)p - \gamma_1 u - \gamma_{11}\Delta u + z_w, \tag{18.16}$$

where p^e is expected prices. Solving (18.15) and (18.16) for u, ignoring the price surprise terms, gives a lagged equation in unemployment and the exogenous wage and price variables (z_p, z_w), that is,

$$u = \frac{\gamma_{11}}{\gamma_1}\Delta u_{-1} + \frac{z_p + z_w}{\gamma_1}. \tag{18.17}$$

This shows that in the long run (where unemployment is not changing, so $\Delta u = 0$), unemployment depends on z_w and z_p, the "push" or driving variables in the underlying wage and price equations respectively. Details on the components of each of these "push" variables are discussed next.

From this point on, the approach is to review the empirical role of each of a large set of wage and price "push" variables, taking those used in recent research on both the wage and the price equation as the starting point. Recent examples of wage "push" variables (where each is an element in the z_w term in (18.17) above) have included the terms of trade (*TT*), a measure of skill shortage (*Skill*), the tax and price wedge (*T*), the replacement ratio (*RR*), a measure of union power (*UP*), an index of industrial turbulence (*IT*), and the real interest rate (*r*) (see, for example, Nickell, 1998, for models of the UK). From the pricing side, recent open-economy

models of UK price formation have included secular trends in the price markup, real import prices and relative competitors prices (the world price of domestic GDP relative to home prices) as determinants of domestic prices (Herzberg, Kapetanios and Price, 2003). Also an empirical (*ad hoc*) effect has been found for real oil prices (Batini, Jackson and Nickell, 2005).[19]

18.4.2 An empirical assessment of the wage and price push variables

Empirical results using sets of the dozen or so contending variables in long-run unemployment equations are reviewed in the rest of this section. In all cases the data are for the UK, and are defined in a short appendix to this chapter. The section starts with a summary of earlier findings by Henry and Nixon (2000) and Henry and Kirby (2007), which both found that the case for using the wage "push" variables listed in the previous section was rejectable in terms of standard statistical criteria. These findings are summarized next and, since this is in the nature of a critique of previous research, uses a sample of quarterly data from 1964Q4 to 1992Q4, which is the sample period used by Nickell (1998), one of the leading proponents of the wage-pressure approach. Following that, the case for using "push" variables from the pricing side is summarized and this uses a sample of quarterly data from 1980Q1 to 2005Q1, as this is the period over which a monetary policy regime change is alleged to have happened, and is the period the application in section 18.5 is concerned with.[20]

The argument of the remainder of this section is that, via a process of testing for parameter stability and weak exogeneity, and using the concept of a minimal set of cointegrating variables, it is possible to arrive at a parsimonious model of long-run unemployment.

18.4.2.1 The wage push variables

Much existing empirical research on long-run unemployment in the UK has emphasized wage "push" variables (z_w in (18.17)) only, in effect treating the driving variables in the price equation as zero. This set of wage "push" variables has used up to seven separate regressors from the wage "push" side to try to account for changes in long-run unemployment. Others have argued that smaller sets of regressors perform better on the grounds of parameter stability of the resulting equation over different sub-samples and the (related) requirement that the regressors in such equations be weakly exogenous. Henry and Nixon (2000), for example, make a case for including only real oil prices, the terms of trade and real interest rates in the long-run unemployment equation.

More recently, Henry and Kirby (2007) reconsider the empirical results for the unemployment equation based on such a large set of regressors according to how the equation is estimated. The equation in question is as follows:

$$\ln u = \beta_1 TT + \beta_2 Skill + \beta_3 T + \beta_4 RR + \beta_5 UP + \beta_6 IT + \beta_7 r. \tag{18.18}$$

Two estimation methods have been used to test the wage "push" thesis: long-run equations that are solutions of autoregressive distributed lag (ARDL) equations,

as in Nickell and Bell (1995) and Nickell (1998); and estimates of a cointegrating equation using Johansen's maximum likelihood (ML) method, as in Nickell and Bell (1995). Henry and Kirby argue that neither satisfactorily explains long-run trends in unemployment in the UK as its proponents claim. Reasons for this are summarised below. First, however, ARDL estimates of the long-run equation are shown in Table 18.1.[21] For this test, the full sample period is 1964Q4 to 1992Q4 as in Nickell (1998). The variables are described in the appendix to this chapter: full definitions are found in Nickell and Bell (1995) and Henry and Kirby (2007).

Table 18.1 ARDL estimates of long-run unemployment equations

Const.	*IT*	*RR**	*TT*	*Skill*	*UP*	*T*	*r*

(5.6)	(1.6)	(0.4)	(1.8)	(2.6)	(2.2)	(4.5)	(2.6)

Notes: Each uses a maximum lag of 4 on each variable. *t*-statistics are in (.).
*Nickell and Bell (1995) report estimates of the parameter for this variable of 8.95 and 4.88 for the ARDL and Johansen estimates respectively and appear to use the log of the replacement ratio. The estimate above from Nickell (1998) is apparently its level. We use the former throughout.
**No *t*-statistic is given in the original.

The first equation is taken from Nickell (1998). It is clear that the remaining estimates reveal substantial variation in the estimated parameters and, in crucial cases, a complete turnaround in the significance of the estimates. This feature of parameter instability confirms what a number of critics have pointed out, namely that such wage-pressure variables are unlikely to account for long-run movements in unemployment since they were no worse in the mid 1980s than in the 1960s, yet unemployment still rose.

On a more methodological note, the use of ARDL to estimate long-run equations is not generally acceptable as it requires that the right-hand-side variables do not

themselves cointegrate, though tests in this case show they clearly do (see Henry, Kirby and Riley 2007, for further details). The right-hand-side variables should be weakly exogenous too, which, as discussed later, they are not. However, the problems with the model are not simply due to ARDL estimation, and the difficulty of treating the equation (18.18) as a long-run unemployment equation is not resolved by using an alternative such as the Johansen ML method to estimate a single cointegrating vector, normalized on unemployment, which is then treated as "the" unemployment relationship as in Nickell and Bell (1995). We review problems with the use of Johansen estimation with this dataset next. The purpose of this is not estimation, but to describe what would be required to estimate (18.18) so that it had a behavioral interpretation. This review, incidentally, provides on explanation for the parameter instability noted in Table 18.1.

As the data are mainly non-stationary (see below), the dynamic model underlying equation (18.18) can be written as a vector error correction model (VECM), with eight equations, one for each of the variables in (18.18), as illustrated next:

$$\Delta z_t = \sum_{j=1}^{p-1} \Gamma_j \Delta z_{t-j} + \gamma \alpha' z_{t-1} + \varepsilon_t. \tag{18.19}$$

Here z is a column vector of n variables, n being the eight variables (including the unemployment rate) from equation (18.18). The Γ_j $(j = 1, \ldots, (p-1))$ are a set of (8×8) matrices of parameters on the dynamic terms of the model, where the preset lag-length of the model is p. Attention is focused on the long-run part of the VECM, where γ and α' are the loading weights and cointegrating vectors respectively, and γ is nxr to reflect the reduced rank of the system, where it is implicitly assumed that there are $r < n$ cointegrating vectors in the model, and ε_t is a vector of white-noise error terms, with $\varepsilon_t \sim N(0, \Sigma)$.

Tests of orders of integration of the eight variables reported Table 18.2 reveal that one, *IT, is* $I(0)$ while the others are $I(1)$. In this set it appears there could be up to three cointegrating vectors. Tests for $r \leq 3$ give 32.8 (34.4) for the Johansen eigenvalue test (λ) but 75.2 (75.9) for the Johansen trace test (95% significance levels in brackets).[22] Tests of weak causality show that only the terms of trade (TT) and the tax wedge (T) are weakly exogenous (Table 18.3). In the light of these first-stage results on orders of integration and exogeneity tests, the implied model appears to be a five-equation conditional model plus a two-equation marginal model for TT and T, that is,

$$\Delta y_t = \sum_{j=1}^{p-1} \Gamma_{1j} \Delta z_{t-j} + \gamma \alpha' z_{t-1} + \eta_t \tag{18.20}$$

$$\Delta x_t = \sum_{j=1}^{p-1} \Gamma_{2j} \Delta z_{t-j} + \upsilon_t \tag{18.21}$$

where y_t and x_t are (5×1) and (2×1) column vectors of $I(1)$ endogenous ($\ln u$, *Skill*, *RR*, *UP* and *R*) and $I(1)$ weakly exogenous variables (TT and T), respectively.

Table 18.2 Tests of orders of integration, sample 1964Q4–1992Q4

Variable	*DF*	*ADF(4)*	*DF*	*ADF(4)*
ln u	−0.7	−1.3	−5.4	−4.0
IT	−3.0	−3.4	−8.7	−6.1
T	−2.3	−2.3	−13.5	−4.2
TT	−1.0	−0.3	−13.8	−4.9
Skill	−1.5	−3.3	−4.8	−5.7

UP	−1.3	−1.5	−4.0	−3.6
r	−2.1	−2.4	−3.3	−2.7

Notes: The first two columns are for levels, the second two for first differences (ADF followed by ADF(4) in each case). 95% critical value is 2.9.

Table 18.3 Tests for weak exogeneity, sample 1964Q4–1992Q4

Variable	*Wald statistic*
ln *u*	21.9
IT	–
T	2.9
TT	6.4
Skills	22.2
RR	19.7
UP	17.1
r	22.4

Note: The relevant test statistic with three cointegrating vectors is $\chi^2(3)$ with 95% critical value of 7.8.

The stationary variable *IT* is assumed to enter in the Δz_{t-1} vector in a level form.[23] Γ_{1j} are (5×8) and Γ_{2j} are (2×8) matrices of parameters on the dynamic terms of all the variables.

To just identify the cointegrating vectors in the model, r^2 restrictions need to be accepted, with each of the r cointegrating equations having exactly r restrictions successfully applied, as demonstrated in Pesaran and Shin (2002).[24] Further, Wickens and Motto (2001) show that when the cointegrating vector α' in (18.20) is exactly identified, additional overidentication lies in successfully applying restrictions on the loading matrix γ.[25] By applying these procedures, it could, in principle, be possible to derive an equation like (18.18) from the conditional model (18.20), if all the required restrictions on the long-run vectors and the loading matrix needed to get from (18.20) to a single equation of the form of (18.18) were

successfully upheld. Then, estimates of the structural disturbances for the model for which the VECM (18.19) is the reduced form could be obtained, as shown by Wickens and Motto (2001). That is, the responses of unemployment to structural shocks, that is, e_t, defined as $B^{-1}\varepsilon_t$, where B is the matrix of contemporaneous coefficients in the structural model underlying (18.19), could be estimated.[26] In the light of the earlier results on weak exogeneity, such overidentifying restrictions on the loading matrix, in particular, are unlikely to hold.

Hence the status of single-equation estimates of (18.18), such as those given in Nickell (1998), for example, and repeated as the first equation in Table 18.1 above, is then unclear. It is hard to treat it simply as "the" long-run unemployment equation as claimed. Rather, it appears to be part of a fuller dynamic system which involves equations which could be interpreted as determining the real interest rate, movements in skill shortages and the union–non-union wage markup, amongst other things.

The purpose of this last exercise is not to suggest estimation of the full system underlying (18.19) as the way ahead to resolve this issue. Instead, it highlights the dangers of using large sets of potentially $I(1)$, and possibly jointly endogenous, variables if the intention is to estimate a single equation for long-run unemployment. Thus, one important conclusion from this exercise is to emphasize the importance of the approach by Davidson (1998) of determining an irreducible cointegrating (IC) equation. He recommends minimal cointegrating sets of variables as contenders for structural (that is, behavioral) long-run relations.

In what follows, a simpler alternative is proposed which places emphasis on external factors in accounting for the changes in unemployment over the last 25 years.

18.4.2.2 The price push variables

The long-run, or equilibrium, pricing equation which underlies most recent studies on the NKPC is:

$$P_t = \mu_t MC_t, \tag{18.22}$$

where:

$$MC_t = (1/\alpha)(W_t N_t / Y_t).$$

In this equation MC_t is nominal marginal cost, W_t is wages, N_t is employment and Y_t is real output. Assuming a Cobb–Douglas (CD) technology and a constant elasticity demand function, real marginal cost is (in logs):

$$mc_t - p_t = -\ln\alpha + s_{Lt}, \tag{18.23}$$

where s_{Lt} is the labor share. An extension is where technology is not restricted to be CD, and it may be shown that real marginal cost is then affected by the real price of imports (*RPM*) (see Bentolila and Saint-Paul, 1999). In turn, a long-run "equilibrium" price can de defined as P_t^*, where $P_t^* = \mu_t^* MC_t$ and *MC* is nominal (not real) marginal cost, and this equilibrium markup is likely to be time-varying (see Batini, Jackson and Nickell, 2005). Potential determinants of this varying markup

are measures of international price competition (*COM*) and the real price of imports (*RPM*) (see Balakrishnan and Lopez-Salido, 2002; Herzberg, Kapetanios and Price, 2003; Batini, Jackson and Nickell, 2005, amongst others). Other, more *ad hoc* additions which have figured in the empirical literature are also included, such as the real oil price (*OIL*) (see Batini, Jackson and Nickell, 2005; Stock and Watson, 2002; Henry and Nixon, 2000; Boivin and Giannini, 2003). The real exchange rate (*RXR*) has also been used in the wage equation on the grounds of capturing real wage resistance effects (Nickell, 1988), as well as being a way of extending the standard model to allow for internal and external balance (see Layard, Nickell and Jackman, 2005).

Equating the real wage and markup again leads to a long-run unemployment equation, this time of the form:

$$u_t = \beta_1 + \beta_2 COM_t + \beta_3 RPM_t + \beta_4 \tilde{z}_{wt} + \beta_5 RXR_t + \beta_6 OIL_t, \tag{18.24}$$

where $\tilde{z}_{wt}$ is now taken to be the price and tax wedge variable (T).[27]

18.4.2.3 Cointegration results for unemployment

The strategy adopted here is to take the set of possible determinants of unemployment from equation (18.24) and derive a parsimonious version of the long-run unemployment equation using cointegration methods.[28] From earlier findings it appears that there is only one variable (T) which survives as a potential determinant of long-run unemployment from the wage setting side and, in the light of this, the rest of this section considers the empirical case for the use of variables from the price-setting side reviewed above.

The complete set of variables used initially is given in (18.24). In this set there is probably one cointegrating vector. Tests for $r \leq 1$ give 47.4 (40.53) for the Johansen eigenvalue test (λ) and 120.1 (102.6) for the Johansen trace test (95% significance levels in brackets). The tests reject the hypothesis that $r \leq 2$ with $\lambda = 26.3$ (34.4) and *Trace* = 72.7 (76.0). Even so, it remains likely that sub-sets of these six variables also cointegrate, and we build on this idea in following the approach suggested in Davidson (1998) of selecting minimal sets of non-stationary variables as contenders for the long-run equation. This explores the results of dropping each variable (except unemployment) from the cointegrating vector, and the results can be summarized as follows. It is found that a minimal set comprising the two variables *COM* and *OIL*, together with unemployment, form a cointegrating vector (for $r \leq 1$; $\lambda = 40.3$ (22.0) and *Trace* = 51.4 (34.9)). Other contending sub-sets of the six either do not cointegrate or have inappropriate signs and other theoretical shortcomings (further details are given in Henry, Kirby and Riley, 2007).

The minimal cointegrating set selected is then:

$$u_t = 0.76 + 0.85\ OIL_t + 10.7\ COM_t. \tag{18.25}$$

(Tests for orders of integration of these variables are given in Table 18.4.) Although this is simple by design, this long-run relation enters significantly in the error correction model for changes in unemployment based on the just-identified VECM, with a negative loading factor of 0.53 and a t-statistic of 4.6. Tests also show that all

Note: The relevant test statistic with one cointegrating vector is $\chi^2(1)$ with a 95% critical value of 3.8.

variables except unemployment are weakly exogenous as required (see Table 18.5). It is this empirical model of long-run unemployment that is used in the application of the Beliefs model in the next section.

18.5 Applying the Beliefs model to the UK

This section brings together the positive policy model emphasizing the role of beliefs set out in section 18.3 and the econometric analysis of the UK natural rate from section 18.4. It outlines optimal control solutions from the Beliefs model when the crucial equation for long-run unemployment in the Beliefs model of section 18.3 (equation (18.6)) is replaced with the cointegrating equation (equation (18.25)) derived in the previous section. This econometric equation has important "exogenous" determinants of the natural rate which arguably account for its longer-term variation. In common with other examples of the Beliefs model, it takes a static model of the supply side, and dynamic implications are then due to the assumptions made about the authorities' uncertainty and their processes of learning. This change to the determination of long-run unemployment is profound in its effect on the dynamic properties of the model, which are described later. Uncertainties about the variation in the natural rate, due to changes in the external economy, are advanced as a principal explanation for changes in UK inflation since 1980.

18.5.1 The model

The econometric model of long-run unemployment (equation (18.25)) is taken to represent the "actual" model of the economy but, when solving the model, this is amended to conform more closely to equations used so far in this literature. Thus, the "actual" equation is as shown next:

$$u_t = u^{**} - \theta(\pi_t - \hat{\pi}_t) + d_1 W_{1t} + d_2 W_{2t} + \nu_{1t}, \tag{18.26}$$

where $W_1 = OIL$ and $W_2 = COM$, and the variable u^{**} is the long-run level of unemployment that obtains in the absence of effects from the external economy and inflation surprises. The cointegrating equation derived in section 18.4 (equation (18.25)) is thus taken to be (18.26) when inflation surprises are zero.[29] Inflation surprises are introduced when solving the model below, where the parameter θ in (18.26) is then set at unity, as is standard in the Beliefs literature. Continuing with the rest of the model, actual inflation is again:

$$\pi_t = \hat{\pi}_t + \upsilon_{2t}, \tag{18.27}$$

which gives actual inflation as the systematic part of inflation, $\hat{\pi}_t$, set by the authorities by optimizing (18.9) subject to their "approximating" unemployment model of the economy (18.28):

$$u_t^p = \gamma_{0t} + \gamma_{1t}\pi_t + \delta_{1t} W_{1t} + \delta_{2t} W_{2t} + \eta_t. \tag{18.28}$$

As is evident, it is assumed in the "approximating" model that the authorities know that unemployment is affected by a set of exogenous variables but have a misspecified form of their effect. As written, (18.28) assumes – as in the Sargent model – that the authorities also have a mistaken belief in an exploitable trade-off between inflation and unemployment. As is clear, the time-varying parameters of (18.28) are $(\gamma_{0t}, \gamma_{1t}, \delta_{1t}, \delta_{2t})$, which are again assumed to be updated using standard constant-gain recursive least squares formulae,

$$\xi_{t+1} = \xi_t + g P_t^{-1} X_t (u_t - \gamma_{0t} - \gamma_{1t}\pi_t - \delta_1 W_{1t} - \delta_2 W_{2t}) \tag{18.29}$$

$$= \xi_t + g P_t^{-1} X_t (u^{**} - \theta(\pi_t - \hat{\pi}_t) + \nu_{1t} - \gamma_{0t} - \gamma_{1t}\pi_t + (d_1 - \delta_1) W_{1t} + (d_2 - \delta_2) W_{2t}) \tag{18.30}$$

$$P_{t+1} = P_t + g(X_t X_t' - P_t), \tag{18.31}$$

where $\xi_t = (\gamma_{0t}, \gamma_{1t}, \delta_{1t}, \delta_{2t})'$, $X_t = (1, \pi_t, W_{1t}, W_{2t})$, and P_t is now (4×4).

With this set-up, the solution giving the authorities' optimal setting of the control variable π_t is:

$$\hat{\pi}_t = -\frac{\gamma_{1t}}{1 + \gamma_{1t}^2}(\gamma_{0t} + \delta_{1t} W_{1t} + \delta_{2t} W_{2t}). \tag{18.32}$$

In the remainder of this section, optimal control solutions of the model given by equations (18.9) and (18.26)–(18.32) are described, and possible interpretations of these are advanced as we proceed.

18.5.2 Some model implications

18.5.2.1 Model solutions

Sargent's (1999) model is recursive and is solved given initial values of the natural rate (u^*) (assumed constant), the government's discount rate, the parameter on inflation surprises in the actual Phillips curve (θ) and the variances of the two error processes in the model. These parameters are assigned the values 5% for the natural rate, 0.98 for the discount rate, -1 for θ and the variances of the errors are each taken to be 0.3. The dynamic solutions are calculated over 400 and 1,000 periods, and it is in the latter that the escapes are a prominent feature (see, for example, *ibid.*, Ch. 8, p. 108).

The exercise we report next differs from Sargent's in important ways. It takes the model described in section 18.5.1 and, given the focus on the period since 1980, is solved over 100 quarters using actual data for the two exogenous variables in the unemployment equation starting from 1980Q1.[30] In these solutions, initial values for the parameters of the "perceived" Phillips curve, equation (18.28), $\gamma_{0t}, \gamma_{1t}, \delta_{1t}$ and δ_{2t}, are required and are set at -0.6, -0.9, 2.0 and 10.0, respectively.[31] In each solution, the discount rate is set at unity, θ is minus unity and the gain parameter in the updating equations is fixed at 0.0275 to ensure comparability across the solutions. Stochastic solutions are generated by additive drawings from standard normal distributions.[32]

18.5.2.2 Inflation with a time-varying natural rate

The present exercise is a Beliefs model, but one in which mistakes by the authorities about the evolution of the natural rate as well as a belief in an inflation–unemployment trade-off each can account for inflation dynamics.[33]

In Figure 18.3 the authorities are depicted as remaining uncertain about the effects of external shocks on the natural rate and this, together with their mistaken view about the existence of a trade-off, gives the initial higher rates of inflation. The interactions of their revisions to all the parameters of the perceived Phillips curve are then fairly complex, as we describe below. The effects of these are that they adopt a looser monetary policy to start with in order to reduce unemployment more than is actually required. Subsequently, the parameter estimates are updated and the effects of these changes are that monetary policy is tightened, so bringing down inflation over the first four to five years before it rises modestly and then falls again.

The falls in inflation can be traced to the evolution of the governments' estimates of the parameters on all the variables in the authorities' unemployment equation. As in the other examples of the Beliefs literature cited so far, the authorities' misperception about inflation "surprises" also matter. But, as shown in Figures 18.4(a)–(e), among the parameters in the authorities' misperceived Phillips curve, δ_{1t} and δ_{2t}, each fall, γ_{0t} increases and γ_{1t} falls in absolute value (though it remains negative). These revisions largely account for the changes in inflation shown in Figure 18.3, and they appear to show that the authorities do not learn the full extent of the

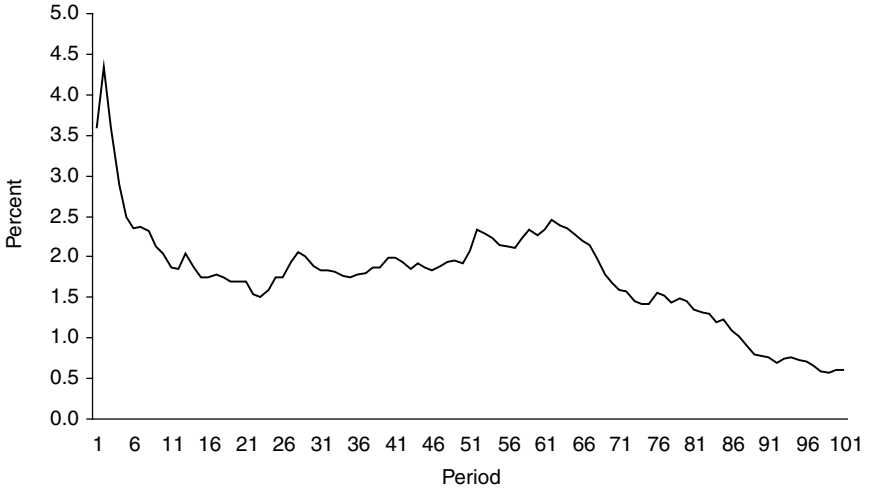

Figure 18.3 The first solution for inflation

dependence on unemployment of external shocks, but instead assume that the unemployment effect on inflation is increasing.

Inflation surprises, as shown in Figure 18.4(e), do not play a part in bringing about the reduction in inflation shown in Figure 18.3, in contrast to the "escapes" model of Sargent (1999), where unusual realizations of the noise processes are the sole explanation for switches between high and low inflation.

In keeping with properties of the Beliefs model, the present one also shows that the authorities' misspecified Phillips curve does not converge on the "true" Phillips curve, and the authorities' estimates of the parameters on the exogenous determinants of unemployment do not converge to their values in the "true" Phillips curve (as estimated separately). This finding is in line with Sargent's depiction of the solution being an SCE.

The next exercise considers what happens to inflation when the authorities are not aware of the effects of the exogenous variables at all, and the parameters on these ($\delta = (\delta_1, \delta_2)$) are set at zero and not updated. The resulting inflation dynamics are shown in Figure 18.5, which shows a significant increase in inflation. The interpretation of this solution advanced here is that it represents the effects of an optimistic view that the natural rate does not worsen in the face of adverse external shocks. Monetary policy is then set as if these adverse shocks had not happened. Below we argue that a parallel case to this is where the authorities believe that the trend rate of productivity growth in the economy has risen when in fact it has not, and this parallel motivates the comments on the economic events at the end of the 1980s made in the following section.

As in the previous case, there are substantial changes in the (γ_0, γ_1) parameters in the authorities' Phillips curve (see Figures 18.6(a) and (b)). This time, however, the authorities' beliefs about the sacrifice ratio (governed by their estimate of γ_1),

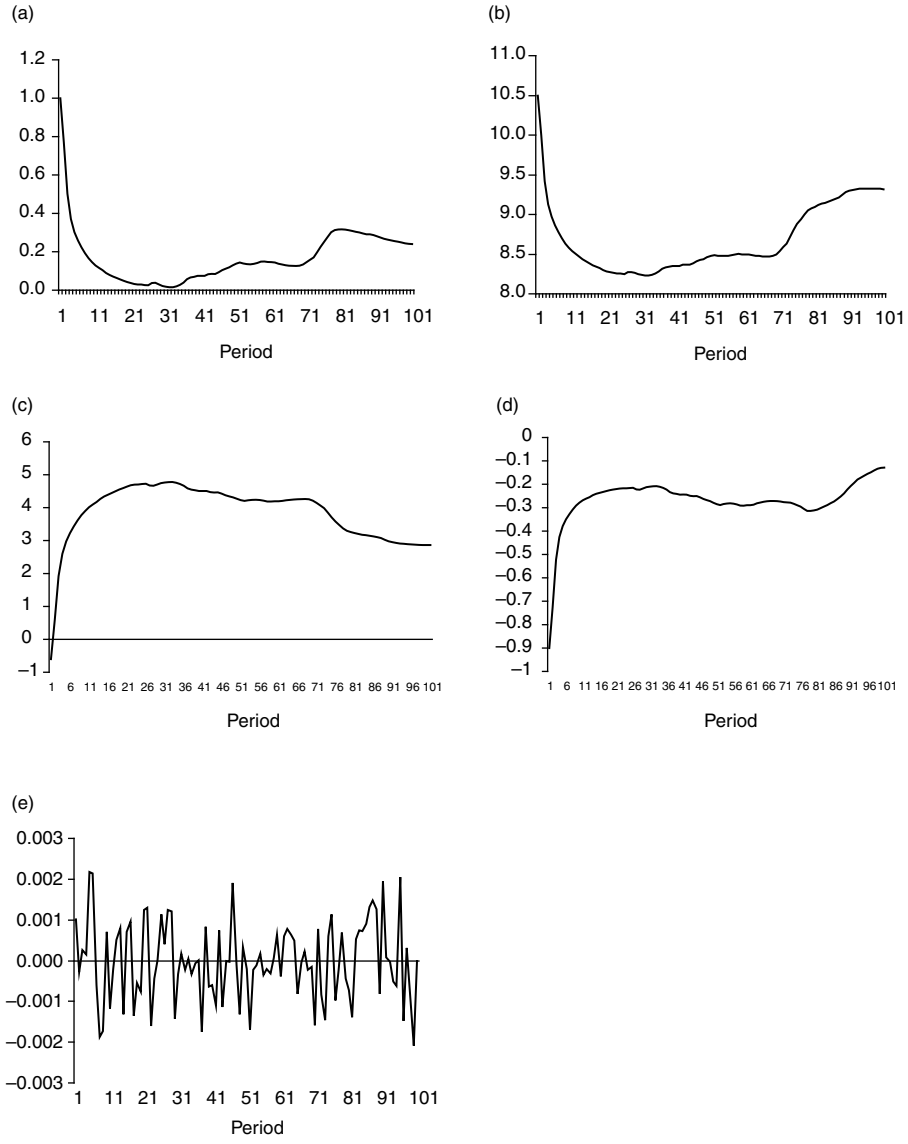

Figure 18.4 (a) δ_{1t}, (b) δ_{2t}, (c) γ_{0t}, (d) γ_{1t}, (e) Inflation surprises (v_{2t})

fluctuate around a fairly constant level, before changing sharply after about 75 quarters; these beliefs becoming more optimistic about the inflation consequences of reduced unemployment.

18.5.2.3 Relating the results to the UK since 1980

In keeping with this branch of the Beliefs literature, the main features of the dynamic solutions for inflation just given are related to events in the UK economy

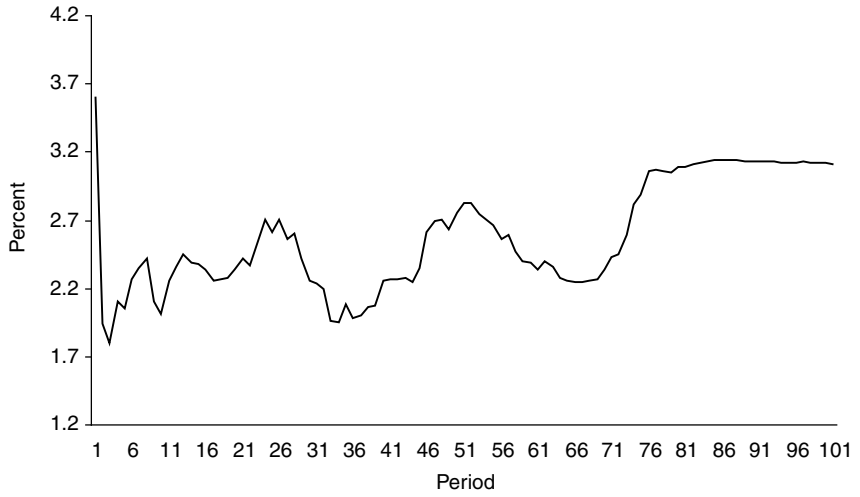

Figure 18.5 The second solution for inflation

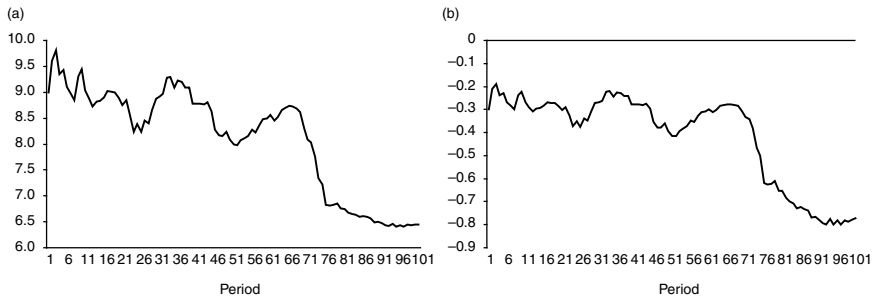

Figure 18.6 (a) γ_{0t}, (b) γ_{1t}

since the 1980s. Thus, starting at the beginning of the 1980s, UK output, unemployment and inflation were dramatically worsened by the 1979 oil price shock, but the effects of this were compounded by a significant switch in the 1980 budget to lower direct tax rates, aiming to offset this with increases in excise tax, petroleum revenue tax and increases in value added tax (VAT). The policy philosophy for control of inflation at this time was governed by the MTFS which was, in turn, predicated on targets for a wide monetary aggregate (£M3) and the (mistaken) belief in a predicable relation between changes in the monetary aggregate and inflation. The interpretation of these events offered here is that, because of its adherence to the MTFS, particularly its assumption that the natural rate was a given, the government expected the effect of the external shock to oil prices on unemployment to be smaller and shorter-lived than it was. In the event, it was not until 1986 that unemployment began to fall significantly. Inflation fell more quickly, and by 1983 was down to about 4%. The numerical solution of the

model shown in Figure 18.3 is broadly consistent with the events of the first half of the 1980s, and suggests that this can be seen as a high inflation outturn due to the authorities' mistaken belief about the natural rate, but revisions to the other parameters in the authorities Phillips curve lead to tighter monetary policy and inflation then falls to a relatively low rate after about three to four years.[34]

However, inflation rose markedly again at the end of the 1980s decade. The argument advanced here is that this further bout of higher inflation was due to yet another mistake by the authorities, this time about the probable trend rate of growth of productive potential in the economy. This mistaken assumption was in keeping with their view that a lower natural rate was to be expected following the "supply side" changes introduced by the government in the first part of the 1980s. The assessment of the evidence summarized in section 18.4 is that these alleged effects from the supply side did not happen. But official estimates of whole economy output per head show that in the period 1985–88 this was estimated to be at a rate of 3.25%, up from the 2% rate of growth for the period 1979–87 (FSBR, 1988, p. 30).[35] Due to this mistaken belief in a faster non-inflationary rate of growth, the Treasury appears to have significantly underpredicted inflation in 1989–90. Barrell, Khoman and Kirby (2007) report that the (retail price index) inflation forecasts made by the Treasury for 1988, 1989 and 1990 were, respectively, 4.5 (6.5), 5.5 (7.6) and 7.25 (10) (inflation outturns in brackets), each of which is evidence of a consistent and marked optimism about inflation. In later FSBR reports, in the face of a slowdown in the rate of output per head, the Treasury placed less emphasis on this trend improvement view. In other words, its belief in an improved productivity performance appears to have been short-lived. We argued above that this case is similar in its effects to the case shown in Figure 18.5, where the authorities are not aware that adverse external shocks on the economy have increased the natural rate and, as result of this mistake, inflation increases. The belief that potential growth is higher than it actually is would have a similar effect. But it is important to note that the solution shown in Figure 18.5 allows for permanent ignorance of the authorities about the effects of external shocks and inflation shoots up as a result. In reality this is too extreme. Thus, to relate this to the parallel case of a mistaken belief in an underlying productivity improvement in the late 1980s in the UK, it needs to be recognized that this belief soon evaporated. Even so, this temporary belief would have produced a spurt in inflation in line with what happened.[36]

18.6 Conclusions and proposals for future work

Evidently, both the empirical and the more theoretical material described in this chapter are limited. Thus, although we have sought to extend the policy model to allow for external (international) effects, in practice these are restricted to having effects only on the evolution of the natural rate. More direct transmissions of international changes in real commodity prices or international structural changes ("globalization") onto UK import price or consumer price inflation, for example, have been ignored and extensions to include some of these developments is an

urgent priority. The quantitative effects of future real oil price increases is another crucial area, with many arguing that future effects will not have the severe consequences that the previous oil price increases had on the international economy.[37] In equal measure, the theoretical model used here is clearly a limited one, and extensions to it, both to enlarge the model of the economy (including further extensions to open economy effects as just noted) and to give a more realistic rendering of monetary policy, are urgently needed. Important as these are, in our judgment, the outstanding item on the agenda is to extend the Phillips curve model used in the Beliefs literature, and in our examples above, to include nominal inertia in the inflation process.

With these important caveats in mind, there are nevertheless some important implications of monetary policy relevance which flow from what has been done here. The theme of the chapter is the central importance of uncertainty in determining the outcomes of monetary policy. The main uncertainty we have concentrated on is uncertainty in the model of the supply side the authorities use in forming their judgments about the appropriate settings for policy. Where it departs from the Sargent approach, which pioneered this research, is most obvious in its treatment of the evolution of the natural rate, where we have sought to combine his insights into the importance of the authorities' "learning" with the ongoing controversy in the UK about the determinants of the long-run movement in unemployment. On this latter point, our emphasis is on exogenous (and largely international) determinants of unemployment, against the prevailing model which places heavy emphasis on domestic labor supply-side factors such as income out of work and union strength. The argument in favor of our alternative is largely evidence-based; the standard model appears to fail conventional statistical tests, mainly because its putative determinants of unemployment would be consistent with little or no change in unemployment in the 1980s as compared with the 1960s when, in fact, actual unemployment rose substantially over this period.

Embedding this empirical model of long-run unemployment in a version of the Sargent model of monetary policy with learning, we suggest, illuminates the sequence of changes in inflation over the last 25 years, a part of which can be accounted for by the evolution of the natural rate, on the one hand, and "misperceptions" of it by the authorities, on the other. It portrays the decline in inflation by the mid 1980s as being a slow recovery from the oil price-induced inflation peak of 1979–80, as the authorities believed the natural rate was not significantly worsened by the shock. Inflation then fell back to reach quite low rates towards the end of the 1980s, so the next interpretive problem is to account for the rise in inflation at the end of the 1980s and early 1990s. In our account, this is portrayed as a further "policy mistake," as the so-called "Lawson boom" of the late 1980s was predicated on a perceived, but mistaken, increase in the economy's productivity trend.[38] We show that such a misperception of a decrease in the natural rate can indeed lead to hikes in the inflation rate. In this light, the subsequent UK membership of the ERM can be seen as an attempt at reducing inflation by importing credibility.[39] Broadly speaking, this interpretation agrees in some measure with the conclusion

reached by Budd (2004) that ERM membership contributed in an important way to the UK's inflation and unemployment record post-membership. According to the analysis here, the major movements in unemployment and inflation in the UK, heralded by some as due to the regime of inflation targeting and central bank independence, can, at best, be only part of the story. The analysis given earlier suggests that a mixture of external shocks and a slow process of recognition of the effects of these by the authorities may also have played an important part in the evolution of UK inflation. Occasionally, too, the economy is diverted by policy mistakes, such as our interpretation of the effects of the "Lawson boom" illustrates, and this conclusion concurs with much of the explanation of US behavior given by Orphanides (2001, 2002) and Primiceri (2005).

18.7 Appendix: Data – definitions and sources

Sample 1964Q4–1992Q4

TT. This is a terms of trade variable defined as $s \ln(P_m/P^*)$, where s is the import share in GDP, P_m is the import price index for the UK, and P^* is the unit value index of manufacturing exports in sterling.
UP. The log of the union/non-union markup, where the markup is a derived series as estimated in Layard, Metcalf and Nickell (1978).
RR. The replacement ratio (percentage) using a weighted average of different family types.
T. This is the tax wedge defined as the sum of the employment tax on firms, the aggregate direct tax rate and an aggregate indirect tax rate.
Skill. This variable is a measure of skill shortages faced by employers, derived from the Confederation of British Industry Industrial Trends Survey. It is the ratio of responses to the questions (i) limits on output due to skill labor shortage, (ii) limits on output due to other labor shortage.
IT. Industrial turbulence, defined as the absolute change in the proportion of employees in production industries as a proportion of total employees in employment.
r. The real interest rate, defined as the Treasury bill rate minus the rate of inflation in the GDP deflator.
ln*u*. Log of unemployment in the UK, males and females.

For sources of all the variables, see Nickell (1998).

Sample 1980Q1–2005Q4

Unemployment (*u*). ILO definition.
Real oil price (*OIL*). Brent spot price less the GDP deflator.
Real international prices (*COM*). Effective export prices for the G7 less GDP deflator.
Real import prices (*RPM*). Implicit price deflator for total imports less the GDP deflator.

Real exchange rate (*RXR*). Effective nominal rates, using the 2000 patterns of trade matrix, deflated by the consumer expenditure deflator.

Source: National Institute database.

Acknowledgments

Thanks are due to Ali Al-Eyd, Joe Pearlman and Malcolm Pemberton for their considerable help with the analysis in section 18.5. I would also like to thank Ray Barrell, Alan Budd, Richard Dennis, Mike Dicks, Stephen Hall, Richard Jackman, Joe Pearlman, Martin Weale and the editors of the Handbook, Terence Mills and Kerry Patterson, for their helpful comments on an earlier draft of the chapter. Simon Kirby provided crucial help at several stages in the preparation of the chapter. All the aforementioned are absolved from responsibility for the contents of this work, which is the sole responsibility of the author.

Notes

1. The inflationary increases of 1979–80 were also exacerbated by the switch from direct to indirect tax in the Budget. Further detail are given in section 18.5.2.4.
2. A recent clear review of this methodology is found in Perron (2006).
3. But see Kara and Nelson (2003) for an example.
4. In what follows, expectations are taken to be conditional on information available at period t.
5. Surico (2006) echoes this view when estimating the NKPC which, he argues, needs to allow for the interest rate reaction function actually in force at the time.
6. This uses the same notation as SW (2002) and follows their convention of ignoring the intercepts in the equations for notational convenience, though these are used in estimation.
7. The standard interpretation is that forward-looking expected variables enter in their lagged representation.
8. The so-called "timing protocol" is largely standard though, whereby the government first sets the systematic part of inflation and then the public form their expectation for inflation.
9. Perhaps the most sophisticated example of this class of studies is that of Svensson (2000).
10. This is largely standard in the cited examples. The present version draws on the Tetlow and von zur Muehlen (2001) account.
11. Note that throughout this chapter, the terms "natural rate" and "NAIRU" are used interchangeably. The switch from one to the other, though possibly confusing to the reader, is made to accord with what is used in the original papers.
12. This version of the AS equation, with unemployment as the dependent variable, is standard in the Beliefs literature. We will refer to it throughout the rest of the chapter as the Phillips curve, hopefully without risk of ambiguity.
13. There are some differences in the precise methods used in the literature. Primiceri (2005), for example, uses Kalman filtering.
14. See Ellison and Yates (2007) for the links between the model's mean dynamics, their stability conditions and the SCE.
15. To establish them a further optimal control problem is used where mean dynamics are perturbed and a weighting function is used that measures the likelihood of the shocks needed to perturb beliefs. For details of this, see Cho, Williams and Sargent (2002).
16. Section 18.5 discusses how the "inflation surprise" term is included in the model.

17. Note that we use the term "supply side" in a narrow sense to refer to the view that the labor market indices noted in the text have the predominant effect on the unemployment trend. This is an influential group in the UK. Elsewhere, economists such as Phelps, who emphasize the supply side, embrace a wider interpretation of supply side effects. See Fitoussi *et al.* (2000).
18. The use of a reduced-form unemployment equation is, in part, a reaction to the well known argument that the standard model of the labor market, such as that found in Layard *et al.* (1991), has a wage equation which is not identified. See Manning (1993) for a clear account of this. Hall and Henry (2006) argue that with non-stationary data this lack of identification is generally not found.
19. This accords with the inclusion of commodity prices in the SVARs estimated in Stock and Watson (2002) and Boivin and Giannoni (2003).
20. Results for longer samples are reported in Henry, Kirby and Riley (2007).
21. All equations in this sub-section use $\ln u$ as the dependent variable. For arguments favoring this, see Nickell and Bell (1995).
22. All tests of cointegrating rank in this chapter use asymptotic tests. For small sample corrections to these tests, see Johansen (2002).
23. See Wickens and Motto (2001) for a discussion of the treatment of $I(0)$ variables in the VECM.
24. These can be nonlinear restrictions.
25. This account ignores the possibility of using restrictions on the short-run dynamics, as our interest is in the long-run model only.
26. The structural model referred to here has unemployment and the remaining seven variables noted in the text as its contemporaneous variables, and not wages and prices. See note 18 for further comment on this point.
27. Full data definitions are given in the appendix to this chapter.
28. Parsimony is based on the concept of a minimal cointegrating vector introduced by Davidson (1998).
29. This treatment follows from the interpretation of equation (18.25) as a long-run unemployment equation.
30. We have also conducted long solutions of the same order as other studies, and these show the same sort of repeated escapes as reported by Sargent (1999) and McGough (2006), for example.
31. Al-Eyd *et al.* (2007) review some issues of the robustness of the findings with respect to these settings.
32. For v_{2t} the variance is scaled by the estimated variance of the acceleration in inflation over the period.
33. Arguably, UK governments at this time did not subscribe to the view that there was a trade-off. The adoption of a Medium Term Financial Strategy (MTFS) by the government in 1979 included a central assumption of a vertical Phillips curve. In spite of this, the model uses the assumption that government believes in a trade-off since, in practice, the government may have continued to act as if there was a trade-off in using the threat of higher unemployment consequences if "excessive" pay demands were accepted.
34. In this account, we are deliberately ignoring other transmission effects of oil price changes on inflation. This is in line with our treatment of these real shocks as impinging on unemployment only. But the partial nature of the account provided should be borne in mind throughout what follows.
35. The 3.25% for this period was partly a forecast.
36. A related issue is the effects of technology shocks on the performance of monetary policy. Recent US research has been directed at this issue too (see, for example, Gali, Lopez-Salido and Valles, 2003).
37. For an alternative view, however, see Nordhaus (2007).

38. It also involved great uncertainty about the measurement of the growth rates of the three measures of GDP at the time, though this plays no part in the analysis we give.
39. The argument at the time was that membership could reduce inflation at reduced unemployment cost due to the credibility gains inherent in "tying one's hands" – essentially the benefits of importing anti-inflation credibility from a then low inflation central bank (the Bundesbank). As unemployment rose to over 10% by 1992 and only reached its pre-entry rate by 1997, it is not clear that, in practice, these benefits actually accrued to the UK.

Estimation of Continuous-Time Stochastic Volatility Models

George Dotsis, Raphael N. Markellos and Terence C. Mills

Abstract

This chapter reviews some of the key issues involved in estimating continuous-time stochastic volatility models. Such models have become popular recently because they provide a rich variety of alternative specifications which often lead to closed or semi-closed solutions in a variety of asset-pricing applications. An empirical comparison of various stochastic volatility models is also undertaken, along with a discussion of some directions for future research.

19.1 Introduction

It is now widely accepted that volatility in financial markets evolves stochastically over time.[1] The stochastic behavior of volatility has important implications for asset allocation, the pricing and hedging of derivative securities, prudent risk management and the behavior of financial assets in general. There are two central facets to the modeling of time-varying volatility. The first is the estimation of the model's parameters, the second is the filtration of latent volatility given these parameter estimates. The filtration of volatility is particularly important for applications such as option pricing, value-at-risk and portfolio allocation, all of which require volatility estimates. One popular approach that tackles both of

these facets is based on the ARCH/GARCH model introduced by Engle (1982) and Bollerslev (1986).[2] In this approach latent volatility is modeled as a deterministic function of past data available to the econometrician. The significant advantage of the GARCH approach is that empirical estimation can be implemented easily using quasi-maximum likelihood (QML) techniques.

A second class of time-varying volatility models are those termed "stochastic volatility": these are usually specified in continuous time and allow for a separate error process to drive the dynamics of volatility. Continuous-time stochastic volatility models have become fashionable over recent years as they allow a rich variety of alternative specifications. Moreover, stochastic volatility models offer closed or semi-closed solutions in many important asset-pricing applications. Unfortunately, the estimation of stochastic volatility models with discretely sampled data is particularly difficult because the likelihood function is not usually available in a tractable form. This intractability has fueled a significant research effort by financial econometricians. Continuous-time stochastic volatility models originate from the mathematical finance and option-pricing literature.[3] As one of the fathers of continuous-time finance, the late Fisher Black, remarked: "suppose we use the standard deviation of possible future returns on a stock as a measure of its volatility. Is it reasonable to take that volatility as constant over time? I think not" (Black, 1976).

The "official" year of birth of continuous-time stochastic volatility models may be taken to be 1987 as, in that year, Hull and White (1987), Johnson and Shanno (1987), Scott (1987) and Wiggins (1987) all developed option-pricing models with stochastic volatility. These models extended those of Black and Scholes (1973) and Merton (1973) by allowing volatility to follow a separate diffusion process. Scott (1987) and Wiggins (1987) are early attempts in estimating the parameters of the model using a method of moments approach. In this chapter we provide a selective review of some of the other popular methods that have been proposed over the years for estimating continuous-time stochastic volatility models.[4]

The need to estimate stochastic or time-varying volatility stemmed from the desire to explain and reproduce some of the stylized facts that have been observed in financial data:

- *Fat tails*. Since the early studies of Fama (1963, 1965) and Mandelbrot (1963), it has been well documented that asset returns are leptokurtic and violate the assumption of normality. Continuous-time models such as Merton's (1976) jump diffusion can generate non-normality and fat tails.
- *Volatility clustering*. In most financial markets we can observe episodes of high volatility interspersed by episodes of low volatility, so that large returns tend to be followed by large returns and small returns tend to be followed by small returns, irrespective of sign. In fact, one of the reasons for the huge success of GARCH modeling is that it provides a direct link between time-varying volatility, conditional heteroskedasticity and unconditional leptokurtosis. The implied clustering effect is depicted in Figure 19.1, which shows the daily returns of the Standard and Poor (S&P) 500 over the period 1990–2007.

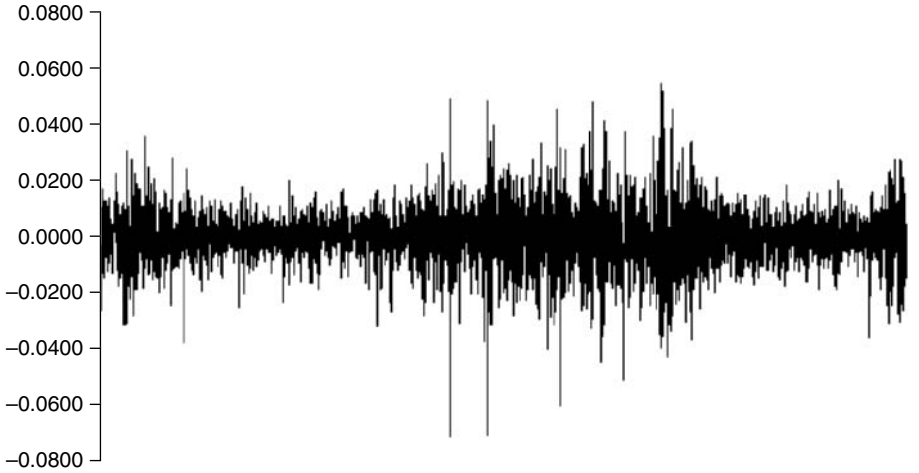

Figure 19.1 Logarithmic returns of the S&P500 over the period January 2, 1990, to December 31, 2007

- *Leverage effect*. Stock returns are negatively correlated with volatility, a phenomenon which Black (1976) coined the "leverage effect." When the stock price of a firm declines the leverage of the firm increases and hence the firm's price becomes more risky and volatile. Modified GARCH processes, such as the threshold-GARCH (TGARCH) model of Glosten, Jagannathan and Runkle (1993) and the exponential-GARCH (EGARCH) model of Nelson (1991), are designed to capture this leverage effect. However, many studies have shown that the asymmetric relationship between asset returns and volatility cannot be explained solely by leverage (for example, see Black, 1976; Christie, 1982; Schwert, 1989).
- *Information arrivals*. Information arrival is non-uniform through time. Clark (1973) linked asset returns to the arrival of information and was one of the first examples of stochastic volatility. The intuition here is that, when information arrival is non-uniform, randomness in business activity can generate randomness in volatility. Easley and O'Hara (1992) developed a market-microstructure model with time deformation that provided, amongst other things, a direct link between market volatility, trading volume and quote arrivals. In continuous-time finance there is a large literature that allows randomness in business time by using time-changed Lévy processes, which can generate stochastic volatility, fat tails and leverage effects (for example, Carr and Wu, 2004).
- *Volatility dynamics*. Stochastic volatility is usually assumed to follow a mean reverting process. Mean reversion in volatility is consistent with the clustering phenomenon and is also consistent with the economic interpretation of volatility as a measure of risk. It implies that volatility oscillates around a long run mean according to the speed with which it reverts to this mean level. The

mean reversion parameter has been found to alter dramatically at different data frequencies, suggesting that volatility may be driven by multiple factors (for example, Chacko and Viceira, 2003). Other studies (such as Bakshi, Ju and Ou-Yang, 2006) suggest that volatility displays nonlinear mean reversion with reversals at both high and low levels of the volatility spectrum. Empirical evidence shows that volatility displays so-called level effects (for example, Jones, 2003) whereby periods of high volatility usually coincide with periods of volatile volatility. Finally, recent studies suggest that volatility and asset returns display correlated jumps during times of market stress (for example, Eraker, Johannes and Polson, 2003).

- *Smiles, skews and implied volatility*. It has long been documented that the Black–Scholes (1973) model is not consistent with observed option prices. Given a set of option prices, one can invert the Black–Scholes formula and backout the implied volatility that sets the observed price equal to the Black–Scholes price. If the Black–Scholes model was correct, then, as a function of strike prices, implied volatility would be a flat line. However, it is well known that implied volatility displays a U-shaped pattern (the implied volatility "smile") in foreign exchange derivatives markets and a downward sloping curve (the implied volatility "skew") in index option markets (see Bates, 1996a). Continuous-time stochastic volatility models have been proposed as an alternative to Black–Scholes in order to explain the empirical patterns of implied volatility curves and smiles. Figure 19.2 depicts the evolution of daily S&P500 prices and the

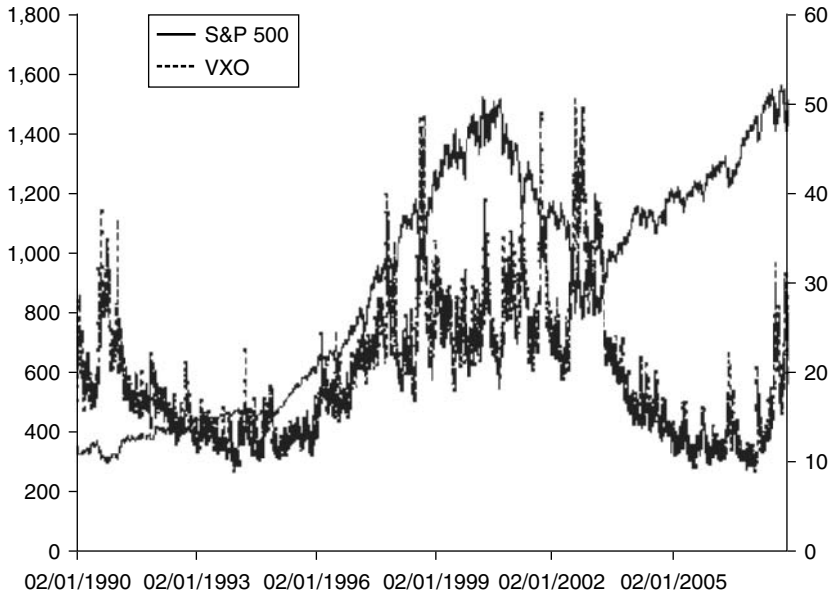

Figure 19.2 S&P500 prices (solid line) and VXO values (dotted line) over the time period January 2, 1990, to December 31, 2007

implied volatility VXO over the period 1990–2007.[5] The relationship appears to be negative, especially during times of market stress. Derivatives markets facilitate empirical estimation by providing an alternative source for backing-out latent volatility (for example, Pan, 2002; Aït-Sahalia and Kimmel, 2006).

The rest of the chapter is structured as follows. In section 19.2 we discuss the properties of some popular stochastic volatility models. Section 19.3 is devoted to the econometric methods used for drawing inferences in stochastic volatility models. First, we review estimation methods when volatility is treated as unobserved, such as efficient method of moments (EMM), Markov chain Monte Carlo (MCMC), and methods based on the empirical characteristic function (ECF). Subsequently, we discuss methods that incorporate information from the derivatives markets into the estimation procedure. Lastly, we review some recent methods that allow inferences to be made in stochastic volatility models using high frequency data. In section 19.4 we conduct an empirical comparison of various stochastic volatility models. Section 19.5 concludes and provides directions for future research.

19.2 Volatility specifications

We assume that the logarithms of an asset, $y_t = \ln(S_t)$, and its latent volatility, V_t, evolve over time according to the following general jump diffusion stochastic volatility model:

$$\begin{aligned} dy_t &= \left(\mu - \frac{1}{2}V_t\right)dt + \sqrt{V_t}dW_t^S + y_t^S dN_t^S \\ dV_t &= a(V_t, t)dt + \sigma(V_t, t)dW_t^V + y_t^V dN_t^V. \end{aligned} \tag{19.1}$$

Here, W_t^S and W_t^V are standard correlated Brownian motions. N_t^S and N_t^V are Poisson processes uncorrelated with these Brownian motions, with constant intensities λ_y and λ_v, and y_t^S and y_t^V are the jump sizes of the asset return and volatility, respectively. When $N_t^S = N_t^V$, jumps in asset returns and volatility occur simultaneously, and when $N_t^S \neq N_t^V$, the jump times are independent. The terms $a(\cdot)$ and $\sigma(\cdot)$ are the drift and diffusion functions of the volatility process, respectively. The parameter vector of (19.1) is denoted as Θ. For simplicity, we assume that the mean return of the asset, μ, is constant, although some models allow the conditional mean return to be a linear function of volatility, as in Merton (1980). In the late 1980s, stochastic volatility models were developed by assuming that the processes driving volatility and asset prices had continuous paths, that is, they followed diffusion processes. By the late 1990s, new types of stochastic volatility models had been introduced which were based on jump diffusion processes for the underlying asset price and, more recently, there have appeared stochastic volatility models that are founded on "double jump" processes, where both the underlying asset price and volatility follow jump-diffusion processes. In the following sub-sections we discuss various specifications of the $a(\cdot)$ and $\sigma(\cdot)$ terms that are nested within the general specification (19.1).[6]

19.2.1 Affine diffusions

The must popular stochastic volatility (SV) models are the so-called affine models. Broadly speaking, affine models are characterized by linearity of the drift and variance functions in (19.1) and provide computational tractability that leads to closed or semi-closed solutions in a variety of applications (see Duffie, Pan and Singleton, 2000). We examine the following affine specifications of the general stochastic volatility model in (19.1) when $N_t^S = N_t^V = 0$.

SV1
$$dV_t = k(\theta - V_t)dt + \sigma dW_t^V$$

SV2
$$dV_t = k(\theta - V_t)dt + \sigma\sqrt{V_t}dW_t^V.$$

In the SV1 model, also called the Ornstein–Uhlenbeck process, volatility follows a Gaussian mean-reverting process. The parameter k captures the speed of mean reversion, θ is the long-run mean of volatility and σ is the volatility of volatility. SV1 was first used by Vasicek (1977) for term structure modeling and has also been used for option pricing by Hull and White (1987), Scott (1987), Stein and Stein (1991), and Brenner, Ou and Zhang (2006), among others. This is the only stochastic volatility model for which the distribution of asset returns in (19.1) can be derived in closed form (see Stein and Stein, 1991). The conditional mean and variance of the SV1 model at time t for a time period $T > t$ is given by:

$$E_t\left(V_T\right) = \theta + \left(V_t - \theta\right)e^{-k(T-t)} \tag{19.2}$$

$$Var_t\left(V_T\right) = \frac{\sigma^2}{2k}\left(1 - e^{-2k(T-t)}\right). \tag{19.3}$$

Unfortunately, the SV1 model is not fully consistent with the empirical properties of volatility. In particular, SV1 implies that volatility can take negative values and that it is homoskedastic, which is evident from the fact that the conditional variance of the process does not depend on the level of volatility. Hence SV1 is not able to capture the positivity of volatility or the level effect. Consequently, despite the analytical tractability offered by this specification, it is no longer in common use.

SV2 was popularized after Heston (1993) and has been extensively used in a variety of applications. It was proposed as an alternative to SV1 that constrained volatility from taking negative values (see, for example, Bates, 1996b, 2000). Under this volatility parameterization the distribution of stock prices in (19.1) is not known in closed form but can be derived from the characteristic function (we discuss this methodology in section 19.3). The conditional mean and variance of the SV2 model are:

$$E_t\left(V_T\right) = \theta + \left(V_t - \theta\right)e^{-k(T-t)} \tag{19.4}$$

$$Var_t\left(V_T\right) = V_t\left(\frac{\sigma^2}{k}\right)\left(e^{-k(T-t)} - e^{-2k(T-t)}\right) + \left(\frac{\sigma^2}{k}\right)\left(1 - e^{-k(T-t)}\right)^2. \tag{19.5}$$

The conditional means of the two models are identical but, from (19.5), it can be seen that the conditional variance of SV2 depends on the level of volatility, thus making the process heteroskedastic.

19.2.2 Affine jump diffusions

Another popular class comprises the affine jump diffusion models, which incorporate a jump component in asset returns and/or volatility. Here we examine the case where jump times in asset returns and volatility occur simultaneously and jump sizes are correlated.

SV3
$$dV = k\left(\theta - V_t\right)dt + \sigma dW_t^V + y_t^V dN_t^V.$$

In SV3, $N_t^S = N_t^V$, the volatility jump size is drawn from an exponential distribution, $f(y^V) = \eta e^{-\eta y^V} 1_{\{y \geq 0\}}$, and the returns jump size follows the conditional distribution $y^S | y^V$: $N(\mu_S + \rho y^V, \sigma_S^2)$. The SV3 model has been used, for example, by Duffie, Pan and Singleton (2000), Eraker, Johannes and Polson (2003), Eraker (2004) and Broadie, Chernov and Johannes (2007). It allows for a rapidly moving and persistent factor to drive asset returns during times of market stress. Under this volatility parameterization the distribution of stock prices in (19.1) can again be derived from the characteristic function. The conditional mean and variance of SV3 are:

$$E_t\left(V_t\right) = V_t e^{-k(T-t)} + \theta\left(1 - e^{-k(T-t)}\right) + \frac{\lambda_v}{k\eta}\left(1 - e^{-k(T-t)}\right) \tag{19.6}$$

$$Var_t\left(V_T\right) = V_t\left(\frac{\sigma^2}{k}\right)\left(e^{-k(T-t)} - e^{-2k(T-t)}\right) + \left(\frac{\sigma^2\theta}{2k}\right)\left(1 - e^{-k(T-t)}\right)^2 + \frac{\lambda_v\sigma^2}{2k^2}\left(1 - e^{-k\tau}\right)^2\frac{1}{\eta} + \frac{\lambda_v}{k}\left(1 - e^{-2k\tau}\right)\frac{1}{\eta^2}. \tag{19.7}$$

19.2.3 Non-affine diffusions

Non-affine models are not particularly popular in the option pricing literature as they do not provide closed form formulae for option pricing. Neither the distribution nor the characteristic function of (19.1) can be obtained in closed form. However, these specifications have been widely used for econometric estimation purposes. Here we assume again that the dynamics in (19.1) do not incorporate a jump component.

SV4
$$dV_t = k\left(\theta - V_t\right)dt + \sigma V_t^{\gamma} dW_t^V$$

SV5
$$d\left(lnV_t\right) = k\left(\theta - \left(lnV_t\right)\right)dt + \sigma dW_t^V$$
$$dV_t = kV_t\left(\theta + \frac{\sigma^2}{2k} - \ln V_t\right)dt + \sigma V_t dW_t^V.$$

SV4 is also called the constant elasticity of variance process and has been used, for example, by Jones (2003) and Aït-Sahalia and Kimmel (2007). The functional form of the diffusion component implies that the model can easily accommodate the level effect. The conditional mean of SV4 generalizes those of SV1 and SV2, which are obtained by setting γ to zero and 0.5, respectively. However, the conditional variance does not have an analytical form and can only be derived using approximations.

SV5 is by far the most popular specification of discrete-time stochastic volatility models as it produces Gaussian log-volatilities (for example, Jacquier, Polson and Rossi, 1994; Kim, Shephard and Chib, 1998). In continuous-time settings, it has been used by Wiggins (1987) for the pricing of equity options, by Melino and Turnbull (1990) for the pricing of currency options, and by Detemple and Osakwe (2000) and Psychoyios, Dotsis and Markellos (2007) for the valuation of volatility options. Andersen, Benzoni and Lund (2002) and Chernov *et al.* (2003) estimated the model empirically. From the volatility levels process we can deduce, first, that the model accounts for the level effect of volatility and, second, that mean reversion depends on the level of V_t, that is, the larger V_t, the larger the mean reversion of the process. The first two conditional central moments are given by:

$$E_t\left(V_t\right) = V_t^{\exp(-k(T-t))} \exp\left(\left(1-e^{-\lambda t}\right)\mu + \frac{\sigma^2}{4\lambda}\left(1-e^{-2\lambda t}\right)\right) \tag{19.8}$$

$$Var_t\left(V_t\right) = V_t^{2\exp(-k(T-t))} \exp\left(2\left(1-e^{-k(T-t)}\right)\theta + \frac{\sigma^2}{2k}\left(1-e^{-k(T-t)}\right)\right) \times \left(\exp\left(\frac{\sigma^2}{2k}\left(1-e^{-2k(T-t)}\right)\right)-1\right). \tag{19.9}$$

19.3 Inference in stochastic volatility models

Although stochastic volatility models are built in continuous time, empirical data are only observed at discrete time intervals. Inference in stochastic volatility models is a difficult task because the likelihood function is typically not available in a tractable form. The Gaussian QML approach of Harvey, Ruiz and Shephard (1994) is appealing because of its simplicity, but many studies have shown that the method fails because volatility models are highly non-Gaussian.

Suppose that $y = \{y_1, \ldots, y_T\}$ is a discrete time series of observed data, $y_t = \log(S_t) - \log(S_{t-1})$, $t = 1, \ldots, T$, and $V = \{V_1, \ldots, V_T\}$ is the vector of latent stochastic volatility. We assume that y is stationary and that $x_t = (y_t, V_t)$ forms a Markov system. The system x_t can be treated as either fully or partially observed. If the former, latent volatility may be extracted from the derivatives markets, whereas, under the latter, volatility is treated as a latent variable that has to be integrated out of the likelihood function.

When $x_t$is fully observed the likelihood function for estimating the parameters is given by:

$$p(x;\theta) = p(x_1;\theta)\prod_{t=1}^{T-1} p(x_{t+1}|x_t;\Theta), \tag{19.10}$$

where $p(x;\Theta)$ is the joint density function and $p(x_1;\Theta)$ is the unconditional density. In many applications (for example, Aït-Sahalia and Kimmel, 2007) the density of the initial observation is omitted since, asymptotically, it does not affect the efficiency of the parameter estimates. Under this approach the difficulty lies in the fact that the conditional densities, $p(x_{t+1}|x_t;\Theta)$, of most stochastic volatility models cannot be derived in closed form. In principle, the transitional densities can be obtained numerically by solving the corresponding Fokker–Planck equation (for example, Lo, 1988). The conditional densities can also be obtained by Fourier inversion of the conditional characteristic function if the model belongs to the affine class or by other approximating methods.

When volatility is not directly observed it has to be integrated out of the likelihood function. In this case, the corresponding marginal likelihood function is given by:

$$p(y;\theta) = \int_{R^T} p(y, V;\Theta)dV = \int_{R^T} p(y|V;\Theta)p(V;\Theta)dV. \tag{19.11}$$

The dimension of the integral depends on the sample size, so that direct evaluation of the likelihood function is difficult. Moreover, when latent volatility is integrated out, the asset price alone is non-Markov due to the presence of correlation and the conditional density of the next period's return depends on the entire set of previous observations, $Y_{t-1} = \{y_{t-1}, \ldots, y_1\}$. The likelihood can be approximated by simulation methods such as MCMC or estimation can be implemented by avoiding the likelihood altogether and resorting to methods of moments estimation such as EMM or generalized method of moments (GMM).

In the next sections we discuss estimation methods when volatility is treated as unobserved and we then extend the analysis to the case where volatility is extracted from option prices.

19.3.1 Simulation-based inference

19.3.1.1 Efficient method of moments

The EMM, developed by Bansal *et al*. (1993, 1995) and Gallant and Tauchen (1996), is an extension of the simulated method of moments (SMM) of Duffie and Singleton (1993). EMM avoids direct computation of the likelihood function and resorts to efficient estimation via GMM and a cautious selection of the moment conditions. The parameter estimates are minimum chi-squared estimators and the optimized chi-squared criterion can be used to evaluate the statistical fitting of the various stochastic volatility models. Hence a significant advantage of the EMM procedure is that it allows empirical comparison between non-nested specifications, such as, for example, SV2 and SV5. However, EMM is computationally demanding and, as with all GMM procedures, it depends on the optimal choice of moment conditions. Estimation of stochastic volatility models with EMM has been undertaken by

Gallant, Hsieh and Tauchen (1997), Andersen and Lund (1997), Andersen, Benzoni and Lund (2002), Chernov and Ghysels (2000) and Chernov *et al.* (2003), while Andersen, Chung and Sørensen (1999) explore the efficiency of EMM estimators in a Monte Carlo study.

The starting point of the EMM procedure is to approximate the conditional density of the data as closely as possible with a discrete-time auxiliary model. This auxiliary model is not related to any particular stochastic-volatility model, its purpose being to capture the probabilistic structure of the data and to provide the moment conditions that must be satisfied by a postulated stochastic-volatility model, which in EMM applications is called the structural model. The auxiliary model usually involves an ARMA-GARCH specification and a semi-nonparametric density based on Hermite polynomials.

Suppose that the conditional density of the auxiliary model is $f_{\mathrm{K}}(y_t|Y_{t-1};.a)$, where α is the parameter vector of the auxiliary model. The parameters can be estimated by QML as follows:

$$\tilde{a} = \arg\max \frac{1}{n} \sum_{t=0}^{n} \log \left[f_{\mathrm{K}}(y_t|Y_{t-1};a \right]. \tag{19.12}$$

The ML estimates $\tilde{a}$ ensure that the quasi-score function satisfies the first-order conditions:

$$\frac{1}{T} \sum_{t=0}^{n} \frac{\partial}{\partial a} \ln f_{\mathrm{K}} \left(y_t|Y_{t-1};\tilde{a} \right) = 0. \tag{19.13}$$

In the second stage, EMM uses the expectation of the score functions of the auxiliary model as the moment conditions that deliver the estimates Θ of the structural model. The expectation is taken under the probability measure, $P\left(Y_t;\Theta\right)$, of the structural model:

$$m\left(\theta,\tilde{a}\right) = E^P \left[\frac{\partial \ln f_{\mathrm{K}}(Y_t;\tilde{a})}{\partial a} \right] = \int \frac{\partial \ln f_{\mathrm{K}}(Y_t;\tilde{a})}{\partial a} dP(Y_t;\Theta). \tag{19.14}$$

Given a set of parameters Θ, the expectation is calculated numerically, using a long simulated series, $\hat{y}_N(\theta)$, from the structural model, as:[7]

$$\tilde{m}\left(\theta,\tilde{a}\right) = \frac{1}{N} \sum_{t=1}^{N} \frac{\partial \ln f_{\mathrm{K}}(\hat{y}_t(\theta)|\hat{Y}_{t-1}(\theta);\tilde{a})}{\partial a}, \tag{19.15}$$

and, as $N \to \infty$, $\tilde{m}\left(\theta,\tilde{a}\right) \to m\left(\theta,\tilde{a}\right)$. The EMM estimator is then obtained by minimizing the quadratic function:

$$\hat{\Theta} = \arg\min_{\Theta} m_N(\Theta,\tilde{a})' W_T m_N(\Theta,\tilde{a}), \tag{19.16}$$

where the weighting matrix W_T is a consistent estimate of the inverse asymptotic covariance matrix of the auxiliary score function. Gallant and Tauchen (1996) show how to derive the weighting matrix and prove that the parameter estimates of the structural model are asymptotically normally distributed. Latent volatility can be filtered out using the reprojection method of Gallant and Tauchen (1998).

19.3.1.2 Markov chain Monte Carlo

The Bayesian Markov chain Monte Carlo method was initially applied by Jacquier, Polson and Rossi (1994) for the estimation of discrete-time stochastic volatility models. However, the method has also become very popular in the estimation of continuous-time models. Johannes and Polson (2006) provide an excellent survey of MCMC applications in a variety of continuous-time asset-pricing models. In the context of stochastic volatility, MCMC has been applied by, for example, Jones (2003), Eraker, Johannes and Polson (2003) and Eraker (2004).

The output of the Bayesian MCMC is the posterior density, $p(V, \theta|y)$, of the parameters and latent variables conditional on the data. The method quantifies parameter uncertainty and model risk, filters out latent volatility, jump times and jump sizes, and avoids optimization routines. However, under the MCMC it is difficult to make comparisons across non-nested models such as SV2 and SV5.

Under the Bayesian approach the posterior density $p(V, \theta|y)$ is proportional to:

$$p(y|V, \Theta)p(V|\Theta)p(\Theta), \tag{19.17}$$

where $p(y|V, \Theta)$ is the full likelihood, $p(V|\Theta)$ is the density of the latent variable, and $p(\Theta)$ is the prior density of the parameters. Sampling from the posterior density is difficult because of the latent variable and, especially, because of the high dimension of the density. The MCMC method samples from the posterior by forming a Markov chain over Θ and V that converges in distribution to $p(V, \theta|y)$. In practice, the posterior is further decomposed into the two conditional densities, $p(V|y, \Theta)$ and $p(\Theta|y, V)$ (see Johannes and Polson, 2006). The two most popular MCMC algorithms for sampling from the two conditionals are the Gibbs sampler and Metropolis–Hastings. If the conditionals can be sampled directly then the MCMC is performed with the Gibbs sampler; otherwise Metropolis–Hastings is applied.

19.3.2 Characteristic function methods

In stochastic volatility models the conditional density is rarely available in closed form. However, for models that belong to the affine class it is feasible to derive the conditional characteristic function. The advantage of the characteristic function methodology is that usually it does not require discretization of the continuous-time process. The characteristic function is a powerful tool that encodes the same information as the conditional density. Though the characteristic function solves the same Kolmogorov forward and backward equations as does the conditional density, the boundary condition for the characteristic function is smoother and this allows the derivation of the characteristic function in a tractable form.[8]

The joint characteristic function conditional on current stock price and volatility is defined as:

$$\phi\left(i\omega_1, i\omega_2, y_t, V_t, \tau; \theta\right) = E\left[e^{i\omega_1 y_{t+\tau} + i\omega_2 V_{t+\tau}} | x_t\right]. \tag{19.18}$$

To keep notation simple, we concentrate on specification (19.1) without jumps. The characteristic function of the process must satisfy the following partial differential

equation (PDE):

$$\frac{1}{2}V_t\frac{\partial^2\phi}{\partial y_t^2}+\rho\sqrt{V_2}\sigma(V_t;\theta)\frac{\partial^2\phi}{\partial y_t\partial V_t}+\frac{1}{2}\sigma(V_t;\theta)^2\frac{\partial^2\phi}{\partial V_t^2}+(\mu-\frac{1}{2}V_t)\frac{\partial\phi}{\partial y_t}+a(V_t;\theta)\frac{\partial\phi}{\partial y_t}-\frac{\partial\phi}{\partial\tau}, \tag{19.19}$$

subject to the boundary condition $\phi\left(i\omega_1, i\omega_2, y_t, V_t, 0, \theta\right) = e^{i\omega_1 y_T + i\omega_2 V_T}$.

When the stochastic volatility model belongs to the affine class, the solution of the joint conditional characteristic function has a simple exponential form, given by:

$$\phi\left(i\omega_1, i\omega_2, y_t, V_t, \tau; \theta\right) = e^{i\omega_1 y_t + A(i\omega_1, i\omega_2, \tau;\theta)V_t + B(i\omega_1, i\omega_2, \tau;\theta).} \tag{19.20}$$

The coefficients $A(i\omega_1, i\omega_2, \tau;\theta)$ and $B(i\omega_1, i\omega_2, \tau;\theta)$ can be derived by solving complex valued Ricatti equations. Duffie, Pan and Singleton (2000) show analytically how to derive the characteristic function for general affine diffusion-jump diffusion stochastic volatility models. Knowledge of the characteristic function also allows the derivation of non-central moments and cross-moments of affine continuous-time stochastic models via simple differentiations.

If volatility is treated as observed then, in principle, the transition density can be derived by Fourier inversion as:

$$p(y_{t+\tau}, V_{t+\tau}|y_t, V_t) = \frac{1}{(2\pi)^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\phi\left(i\omega_1, i\omega_2, y_t, V_t, \tau;\theta\right) \times e^{-i\omega_1 y_{t+\tau} - i\omega_2 V_{t+\tau}} d\omega_1 d\omega_2. \tag{19.21}$$

Estimation with the characteristic function has been applied in latent stochastic volatility models by Singleton (2001), Jiang and Knight (2002), Chacko and Viceira (2003) and Bates (2006). Chacko and Viceira (2003) derive from (19.20) the conditional characteristic function of the asset, $\phi\left(i\omega_1, 0, y_t, V_t, \tau;\theta\right)$, and then integrate out the latent volatility to obtain, in closed-form solution, the characteristic function conditional only on the current asset price, $\phi\left(i\omega_1, 0, y_t, \tau;\theta\right)$. They then estimate various stochastic volatility models using Hansen's (1982) method of moments. However, the estimates are not fully efficient because the only condition is on the current stock price and, as mentioned previously, when volatility is integrated out the stock price on its own is no longer Markov. Jiang and Knight (2002) use iterated expectations and derive the joint unconditional characteristic function up to $t-L$ observations,

$$\phi\left(i\omega_1, i\omega_2, \ldots i\omega_L, y_t, 0.\tau, \theta\right) = E\left[e^{i\omega_1 y_{t-1}, i\omega_2 y_{t-2}, \ldots i\omega_L y_{T-L}}\right].$$

In practice, the joint unconditional characteristic function is derived for a relatively small L. Jiang and Knight (2002) estimate a stochastic volatility model using GMM with non-central and cross-moments. Singleton (2001) and Bates (2006) achieve full efficiency by conditioning on the full history of returns. Singleton proposes a method that combines the simulated method of moments of Duffie and Singleton (1993) with the characteristic function technology. Bates (2006) develops a direct filtration-based maximum likelihood methodology using characteristic functions

and estimates various diffusion/jump diffusion stochastic volatility models. His method does not require any simulations and, in contrast to previous approaches, also allows the filtration of latent volatility.

19.3.3 Derivatives markets

The development of derivatives markets provides an alternative source for filtering latent volatility and estimating the parameters Θ. Some studies use only information from the derivatives markets, whereas others use both option prices and historical returns.

For affine diffusion/jump diffusion stochastic volatility models, European option prices can be obtained in closed form, up to numerical integration, using the characteristic function methodology. For example, the price of a European call option that depends on the parameter vector Θ is given by:

$$C(\cdot;\Theta^*) = SP_1 - Xe^{-rt}P_2. \tag{19.22}$$

Here, P_1 and P_2 are cumulative probability functions that can be calculated by Fourier inversion of the characteristic function (see Duffie *et al.*, 2000) and Θ^* is the set of risk neutral parameters. For a non-affine process, option prices can be calculated either by Monte Carlo simulation (for example, Christoffersen, Jacobs and Mimouni, 2006) or by solving the associated PDE. Many studies (for example, Bakshi, Cao and Chen, 1997; Broadie *et al.*, 2007) calibrate option pricing models with stochastic volatility to observed options prices via least squares:

$$SSE(t) = \min_{\theta} \sum_{i=1}^{N} \left(O_i - \hat{O}_i(\Theta^*)\right)^2, \tag{19.23}$$

where N is the number of options at date t, O_i is the observed option price with strike price K, and $\hat{O}_i(\Theta)$ is the model's implied price given the parameters Θ^*. Here we should note that the set of parameters Θ^* is not the same as the set obtained from historical returns because option prices are calculated under the risk-neutral probability measure. Hence, option prices contain volatility and jump risk premia that are incorporated into certain parameters. For example, under the assumption that the volatility risk premium is linear in volatility (Heston, 1993), the parameters of the SV2 model from calibration would be $k^* = k+\lambda$ and $\theta^* = k\theta/(k+\lambda)$, where λ is the market price of volatility risk. Calibration of the stochastic volatility model to option prices alone does not allow the identification of the risk premium parameter. Another drawback of this approach is that the model has to be recalibrated every day, which will usually produce different parameter estimates.

Another strand of the literature uses options prices and historical returns simultaneously. The advantage of this approach is that the time series V_t can be taken from option prices and it is also feasible to identify risk premia. This approach also imposes consistency between option prices and the time series properties of the underlying returns (see Bates, 1996a). Some well known studies that use option prices and historical returns are Chernov and Ghysels (2000), who use EMM, Pan (2002), using a GMM procedure, and Eraker (2004), employing MCMC. In a recent

breakthrough paper, Aït-Sahalia (2008) derives transition density approximations for multivariate diffusions. In Aït-Sahalia and Kimmel (2007) this method is applied for maximum likelihood estimation of a variety of stochastic volatility models, both affine and non-affine. Aït-Sahalia and Kimmel (2007) provide approximations for the joint density of asset returns and a vector of option prices or the joint density of asset prices and an implied volatility index, which is used as a proxy for latent volatility.

19.3.4 Integrated volatility

Recent advances in high frequency financial econometrics offer alternative methods for making inferences about latent stochastic volatility dynamics. Results from the theory of quadratic variation (e.g., Andersen *et al.*, 2001; Barndorff-Nielsen and Shephard, 2002) show that, when the sampling frequency becomes high, realized integrated volatility converges to the unobserved true integrated volatility. Figure 19.3 shows the evolution of the daily integrated volatility for the S&P500 over the period 1993 to 2004.[9] Integrated volatility over a period $[t, T]$ is computed from summing high frequency log returns and is given by:

$$\lim_{N\to\infty} \sum_{i=1}^{2^N} \left(y_{t+\frac{i}{2^N}(T-t)} - y_{t+\frac{i-1}{2^N}(T-t)} \right)^2 \overset{a.s.}{\to} IV_{t,T} = \frac{1}{T-t} \int_t^T V_s ds. \qquad (19.24)$$

Expression (19.24) contains rich information with respect to the stochastic process followed by the unobserved latent volatility. However, the expression is valid only under the assumption that the sample paths of the asset are continuous. In the presence of jumps in asset returns, integrated volatility also includes a jump component (see Barndorff-Nielsen and Shephard, 2006). For affine models, it is feasible

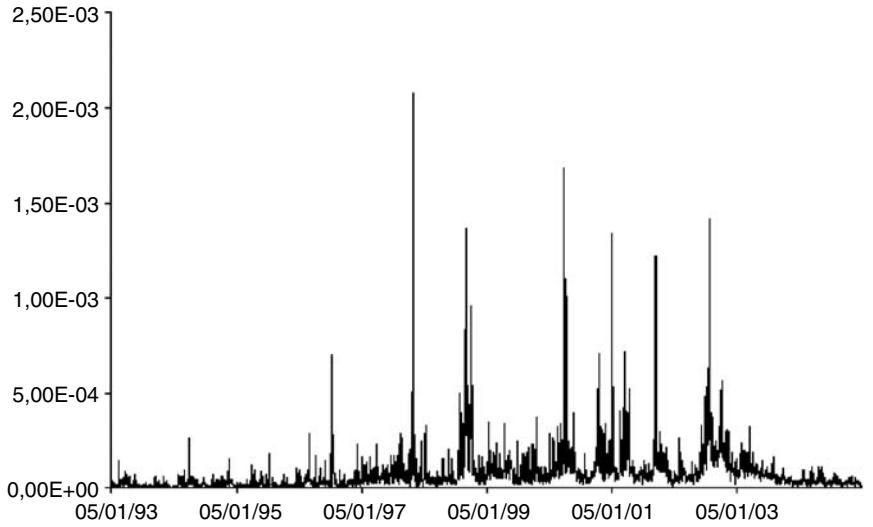

Figure 19.3 Daily integrated volatilities of the S&P500 over the period January 5, 1993, to December 31, 2004

to derive the conditional moments of integrated volatility. For example, the first moment has the general form $E_t\left(IV_{t,T}\right) = a(\tau, \Theta)V_t + b(\tau, \Theta)$. Bollerslev and Zhou (2002) derive the first two conditional moments of integrated volatility and apply a GMM procedure. In order to identify the correlation they also derive in closed form the cross-moment, $E_t\left(y_T IV_{t,T}\right)$. Barndorff-Nielsen and Shephard (2002) develop a QML procedure based on the time series of realized volatility. Chourdakis and Dotsis (2008) estimate non-affine specifications using maximum likelihood and a Markov chain approximation procedure.

19.4 Empirical comparison of volatility processes

In this section we provide an empirical comparison of the models described in section 19.2. A comparison of the econometric methods outlined is section 19.3 is beyond the scope of this chapter. Instead, we estimate the volatility processes autonomously using an implied volatility index.[10] This facilitates estimation but does not allow us to make inferences on the joint dynamics of asset returns and volatility. For reasons explained in Jones (2003) and Bakshi, Ju and Ou-Yang (2006), we consider as a proxy for volatility the implied volatility index VXO. Hence, we set $V_t \equiv VXO_t^2$ over the period 1990–2007, a total of 4,535 daily observations.

The parameters of the various processes are estimated by maximum likelihood, which requires the conditional density function $f[V(t+\tau)|V(t), \Theta]$ $(\tau > 0)$ of the process V_t, where τ denotes the sampling frequency of observations (daily in our application). For a sample $\{V_t\}_{t=1}^{T}$, the log-likelihood function that is maximized is given by:

$$\Im = \max_{\Theta} \sum_{t=1}^{T-\tau} \log\left(f\left(V_{t+\tau}\right)\left|V_t, \Theta\right.\right). \tag{19.25}$$

The standard errors of the estimates are retrieved from the inverse Hessian, evaluated at the estimates. For SV1, SV2 and SV5 the conditional density is known in closed form (see Dotsis, Psychoyios and Skiadopoulos, 2007; Psychoyios, Dotsis and Markellos, 2007). However, for SV3 and SV4, the transition density does not have a closed-form solution. The density of SV4 is obtained by the approximation method of Aït-Sahalia (1999, 2002). The transition density of the SV3 model is obtained by Fourier inversion of the characteristic function (see Singleton, 2001; Dotsis, Psychoyios and Skiadopoulos, 2007). The Fourier inversion of the characteristic function provides the required conditional density function $f[V(t+\tau)|V(t)]$ as:

$$f[V_{t+\tau}|V_t, \Theta] = \frac{1}{\pi}\int_0^{\infty} Re[e^{-isV_{t+\tau}}\phi\left(i\omega, V_t, \tau; \Theta\right)]d\omega. \tag{19.26}$$

Table 19.1 shows the ML estimates for VXO. For each of the processes, the estimated parameters (annualized), the t-statistics (within parentheses), the AIC (Akaike information criterion) and BIC (Bayesian information criterion), and the maximized log-likelihood values (LL) are reported. Likelihood ratio tests were also used to compare nested models: as these supported the ranking obtained from AIC, BIC and LL, they are not reported.

Table 19.1 The parameter estimates (annualized) and the *t*-statistics (reported in parentheses) are based on maximizing the log-likelihood (LL). The data cover the period January 2, 1990, to December 31, 2007, a total of 4,535 observations.

Parameter	*SV1*	*SV2*	*SV3*	*SV4*	*SV5*
k	6.780 (7.71)	5.809 (7.09)	7.999 (11.13)	0.759 (5.49)	3.810 (5.80)
θ	0.044 (19.96)	0.044 (11.52)	0.022 (24.05)	0.105 (−29.85)	−3.368 (−27.78)
σ	0.123 (93.71)	0.447 (93.88)	0.359 (51.34)	3.29 (22.21)	1.96 (94.46)
γ	–	–	–	1.157 (7.89)	–
λ	–	–	31.498 (9.14)	–	–
$1/\eta$	–	–	0.017 (4.56)	–	–
LL	15,459	17,457	17,694	18,446	18,390
AIC	−30,911	−34,908	−35,379	−36,884	−36,773
BIC	−30,892	−34,889	−35,347	−36,850	−36,754

All parameters are significant at the 1% level. According to all model selection criteria, the best fit is provided by SV4, followed by, in order, SV5, SV3, SV2 and SV1. Consistent with previous results in the literature, the Gaussian SV1 model provides a very poor approximation to the data. The square root specification of SV2 improves the fit substantially and the addition of a jump component improves performance further. In the SV3 model, the mean reversion parameter increases so as to pull back the process to its long run mean after a jump event. However, the increase in the speed of mean reversion shows that jumps do not have a persistent effect on volatility. All the statistical criteria suggest that SV5 outperforms the square root specifications. As also reported in Psychoyios, Dotsis and Markellos (2007), this result should not come as a surprise, since SV5 is capable of generating a large increase in volatility at high levels, followed by rapid mean reversion. The best model overall is the constant elasticity of variance specification SV4. The estimate of the exponent in the diffusion, $\hat{\gamma} = 1.16$, suggests that, as volatility increases, its own volatility increases at an even faster rate (see also Jones, 2003). The model also appears capable of capturing strong heteroskedasticity in volatility changes. The empirical results thus point to the conclusion that, at least under this simplified set up, non-affine specifications outperform affine processes.

19.5 Conclusions

The list of methods that we have discussed in this chapter is by no means complete. For example, we have omitted econometric approaches such as the SMM of

Duffie and Singleton (1993), the simulated maximum likelihood (SML) of Santa-Clara (1995) and Pedersen (1995a), the range-based QML estimation technique of Alizadeh, Brandt and Diebold (2002) and the Markov chain approximation of Chourdakis (2002).

We believe there are two avenues for future research. First, more work needs to be done on the comparison of non-affine and affine volatility models. Two questions (at least) suggest themselves – does analytical tractability come at the cost of empirical misspecification?, and what is the impact of non-affine specifications on derivatives valuation? Second, despite this plethora of statistical stochastic volatility models there is still a lack of understanding about the economic underpinnings of volatility. Carr and Wu (2008) show that the market price of volatility risk is large and negative, and Bollerslev and Zhou (2007) find that the volatility risk premium forecasts future excess returns. However, there is still no solid explanation of the economic sources of volatility risk premia and there is also a lack of understanding of the behavior of the pricing kernel as a function of both market returns and return volatilities.

Notes

1. There is a wide variety of interpretations of the term "volatility" within the financial and econometrics literature: for example, variance, (annualized) standard deviation, (total) risk, uncertainty, and so on. In the context of continuous-time models and throughout this chapter, the term is used to describe the latent instantaneous variance.
2. Baillie (2006), for example, provides a recent survey of ARCH/GARCH modeling.
3. See Sundaresan (2000) for a comprehensive review of the development and application of continuous-time methods in finance and Aït-Sahalia (2007) for a survey of estimation methods in continuous-time models. Merton (1990) is the benchmark book in continuous-time finance.
4. Ghysels, Harvey and Renault (1996) provide an extensive review of stochastic volatility models, but they are mainly concerned with models defined in discrete time.
5. VXO is the implied volatility of a synthetic at-the-money option on the S&P500 equity index with a constant time to maturity of 30 calendar days to expiry. In 2003, the Chicago Board Options Exchange (CBOE) introduced a new implied volatility index, coined the VIX. This is calculated in a model-free manner as a weighted sum of out-of-money option prices across all available strikes on the S&P500 index. Carr and Wu (2006) show that the VIX represents the conditional risk-neutral expectation of the return volatility under general market settings. In 2005 CBOE introduced futures on VIX and, in 2006, European calls/puts written on forward VIX.
6. Psychoyios, Skiadopoulos and Alexakis (2003) provide a comprehensive review of alternative volatility processes.
7. See Andersen, Benzoni and Lund (2002) for discussion on the simulation of diffusion/jump stochastic volatility models.
8. The characteristic function methodology has also been used for parameter estimation in discrete time independent and identically distributed (i.i.d) and autoregressive moving average (ARMA) processes by Feuerverger and McDunnough (1981a, 1981b) and Feuerverger (1990).
9. The realized volatilities are based on intraday transactions on the S&P500 index. This dataset has been used by Huang, Liu and Yu (2007) and is available from Professor Yu's web page (http://www.mysmu.edu/faculty/yujun/research.html). The construction

of realized volatility takes into account market microstructure noise using a technique proposed by Zhang, Mykland and Aït-Sahalia (2005).

10. At-the-money implied volatility is sometimes used as a proxy for instantaneous volatility. However, the two are only identical when volatility is uncorrelated with the asset price, the market price of volatility risk is zero, and the time to maturity of the option is short.

Testing the Martingale Hypothesis

J. Carlos Escanciano and Ignacio N. Lobato

Abstract

This chapter examines testing the Martingale difference hypothesis (MDH) and related statistical inference issues. The earlier literature on testing the MDH was based on linear measures of dependence, such as sample autocorrelations; for example, the classic Box–Pierce portmanteau test and the variance ratio test. In order to account for the existing nonlinearity in economic and financial data, two directions have been entertained. First, to modify these classical approaches by taking into account possible nonlinear dependence. Second, to use more sophisticated statistical tools such as those based on empirical process theory or the use of generalized spectral analysis. This chapter discusses these developments and applies them to exchange rate data.

20.1 Introduction

Martingale testing has received enormous attention in econometrics. One of the main reasons is the efficient market hypothesis and the many ideas related to it. In addition, many economic theories examining dynamic contexts in which expectations are assumed to be rational lead to dependence restrictions of this kind in the underlying economic variables (see, e.g., Hall, 1978; Fama, 1991; LeRoy, 1989; Lo, 1997; Cochrane, 2005). These theories have prompted a great deal of research in macro- and financial economics which has stimulated a huge interest in developing suitable econometric techniques. This econometric research has grown around the theme of the lack of predictability of macro- or financial series, but this

topic has flourished in different branches, emphasized different methodological aspects, and appeared under different subject names.

When looking at asset prices, the idea of lack of predictability has been commonly referred to as the random walk hypothesis. Unfortunately, the term "random walk" has been used in different contexts to mean different statistical objects. For instance, in Campbell, Lo and MacKinlay's (1997) textbook, they distinguish three types of random walks according to the dependence structure of the increment series. Random walk 1 corresponds to independent increments, random walk 2 to mean-independent increments, and random walk 3 to uncorrelated increments. Of these three notions, the two most relevant to financial econometrics are the second and the third. The notion of random walk 1 is clearly rejected in financial data for many reasons, the most important being volatility: the lack of constancy of the variance of current asset returns conditional on lagged asset returns. Within this terminology, this chapter will focus basically on the idea of random walk 2, but we will also discuss some aspects associated with random walk 3. A martingale would correspond to random walk 2, and it plainly means that the best forecast of tomorrow's asset price is today's. The asset returns, which are unpredictable, are then said to form a martingale difference sequence. Since asset prices are not stationary, from a technical point of view it is simpler to handle asset returns, and instead of testing that prices follow a martingale, it is more common to test that returns follow a martingale difference sequence.

Given the huge literature that has developed, it is unavoidable that the present chapter reflects the authors' personal interests. It is important at the outset to stress what this chapter does *not* cover. We do not consider unit root tests, which is a topic covered in many references (see, e.g., Laudrup and Jansson, 2006). We do not address technical analysis, which assumes predictability and focuses on the best ways of constructing a variety of charts to forecast a series. We do not consider out-of-sample prediction tests because they assume particular models under the alternative (see Inoue and Kilian, 2004; Clark and West, 2006). We do not examine chaos tests, which are motivated by deterministic nonlinear models (see references in Barnett and Serletis, 2000; Chan and Tong, 2002). What we address is called conditional mean independence testing in the statistical literature.

The outline of the chapter is as follows. Section 20.2 contains the preliminary definitions and an overview of the data that we will employ to illustrate the different techniques. Section 20.3 studies martingale difference tests based on linear measures of dependence both in the time and frequency domains. Section 20.4 is devoted to tests based on nonlinear measures of dependence. Section 20.5 discusses briefly some hypotheses related to the martingale difference hypothesis and Section 20.6 concludes.

20.2 Preliminaries

The martingale difference hypothesis (MDH) plays a central role in economic models where expectations are assumed to be rational. The underlying statistical object

of interest is the concept of a martingale or, alternatively, the concept of a martingale difference sequence (m.d.s.). Mathematically speaking, we say that X_t forms a martingale, with respect to its natural filtration, when $E\left[X_t \mid X_{t-1}, X_{t-2}, \ldots\right] = X_{t-1}$ almost surely (*a.s.*). As stated in the introduction, from a technical point of view, it is simpler to work with the first differences, $Y_t = X_t - X_{t-1}$, and we say that Y_t follows an mds when $E\left[Y_t \mid Y_{t-1}, Y_{t-2}, \ldots\right] = 0$ *a.s.* More generally, we state that the MDH holds when, for a real-valued stationary time series $\{Y_t\}_{t=-\infty}^{\infty}$, the following conditional moment restriction holds *a.s.*:

$$E\left[Y_t \mid Y_{t-1}, Y_{t-2}, \ldots\right] = \mu, \quad \mu \in \mathbb{R}. \tag{20.1}$$

The MDH slightly generalizes the notion of m.d.s. by allowing the unconditional mean of Y_t to be non-zero and unknown. The MDH states that the best predictor, in the sense of least mean square error, of the future values of a time series, given the past and current information set, is just the unconditional expectation. The MDH is called conditional mean independence in the statistical literature, and it implies that past and current information are of no use for forecasting future values of an m.d.s. In section 20.5 we discuss extensions of this basic version of the MDH.

As noted in the introduction, there is a vast empirical and theoretical literature on the MDH. In order to systematize part of this literature, we start by introducing the following definitions. Let $I_t = \{Y_t, Y_{t-1}, \ldots\}$ be the information set at time t and let $\mathcal{F}_t$ be the σ-field generated by I_t. The following equivalence is then fundamental because it formalizes the characteristic property of an m.d.s.: Y_t is linearly unpredictable given any linear or nonlinear transformation of the past, $w(I_{t-1})$, i.e.,

$$E[Y_t \mid I_{t-1}] = \mu \text{ a.s., } \mu \in \mathbb{R} \iff E[(Y_t - \mu)w(I_{t-1})] = 0, \tag{20.2}$$

for any $\mathcal{F}_{t-1}$-measurable weighting function $w(\cdot)$ (such that the moment exists). Equation (20.2) is fundamental to understanding the motivation and main features behind many tests of the MDH. There are two challenging features present in the definition of an m.d.s.: first, the information set at time t, I_t, will typically include the infinite past of the series; second, the number of functions $w(\cdot)$ is also infinite. We will classify the extant theoretical literature on testing the MDH according to what types of functions $w(\cdot)$ are employed. Section 20.3 analyzes the case where linear $w(\cdot)$ are employed, that is, the use of tests based on linear measures of dependence. Section 20.4 analyzes the case where an infinite number of nonlinear *w*'s are employed, that is, the use of tests based on nonlinear measures of dependence. In both sections, we divide the extensive literature according to whether the tests account for a finite number of lags or not, that is, whether they assume that $w(I_{t-1}) = w(Y_{t-1}, ..., Y_{t-P})$ for some $P \geq 1$ or not.

We shall illustrate some of the available methods for testing the MDH by applying them to exchange rate returns. The martingale properties of exchange rate returns have been studied previously by many authors, leading to mixed conclusions. For instance, Bekaert and Hodrick (1992), Escanciano and Velasco (2006a, 2006b), Fong and Ouliaris (1995), Hong and Lee (2003), Kuan and Lee (2004), LeBaron (1999), Levich and Thomas (1993), Liu and He (1991), McCurdy and Morgan (1988) and

Sweeney (1986) all find evidence against the MDH for nominal or real exchange rates at different frequencies, whereas Diebold and Nason (1990), Fong, Koh and Ouliaris (1997), Hsieh (1988, 1989, 1993), McCurdy and Morgan (1987) and Meese and Rogoff (1983a, 1983b) find little evidence against the MDH. Here we consider data that consists of four daily and weekly exchange rate returns against the US dollar: the euro (Euro), the Canadian dollar (Can), the pound sterling (Pound) and the Japanese yen (Yen). The daily data is taken from January 1, 2004, to August 17, 2007, with a total of 908 observations. For the weekly data, we consider the returns on Wednesdays from January 14, 2000, to August 17, 2007, with a total of 382 observations. The daily noon buying rates in New York City certified by the Federal Reserve Bank of New York for customs and cable transfers purposes are obtained from http://www.federalreserve.gov/Releases/h10/hist. In Figures 20.1 and 20.2 we have plotted the evolution of these four daily and weekly exchange rates, respectively, and, similar to previous analyzes, the two main features of these plots are their unpredictability and their volatility. Table 20.1 provides summary statistics for the most relevant aspects of the marginal distribution of the data. Similar to most financial series, the main feature from Table 20.1 is kurtosis that, in line with previous studies, is larger for daily than for weekly data. Note that skewness is moderate and slightly negative for daily data. As has been observed repeatedly before, the marginal distribution of weekly data is closer to the normal distribution than that of daily data.

20.3 Tests based on linear measures of dependence

Recall the m.d.s. definition in equation (20.2) that should hold for any function $w(\cdot)$. The simplest approach is to consider linear functions, such as $w(I_{t-1}) = Y_{t-j}$,

Data from January 4, 2004, to August 17, 2007.

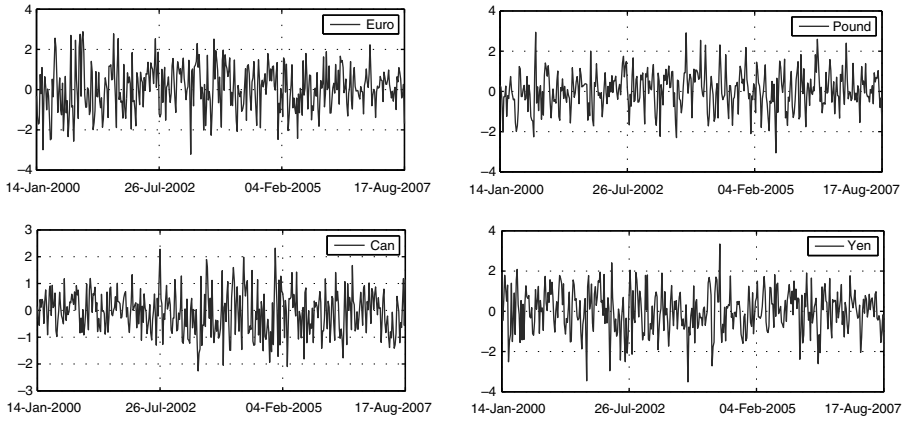

Figure 20.2 Weekly returns of the euro, Canadian dollar (Can), the pound sterling (Pound) and the Japanese yen (Yen) against the US dollar
Data from January 14, 2000, to August 17, 2007.

Table 20.1 Summary statistics of exchange rates returns

	Daily				*Weekly*			
	Euro	*Pound*	*Can*	*Yen*	*Euro*	*Pound*	*Can*	*Yen*
n	908	908	908	908	382	382	382	382
Mean	0.0076	0.0113	−0.0213	0.0068	0.0738	0.0552	−0.0832	0.0352
Median	0.0000	0.0221	−0.0080	0.0279	0.0781	0.0763	−0.0864	0.0141
SD	0.5423	0.5332	0.5036	0.5670	1.3539	1.1407	0.9410	1.2525
Skewness	−0.1263	−0.0976	−0.0196	−0.3763	0.0540	0.0545	0.0846	−0.2945
Kurtosis	3.7602	3.4927	3.1345	5.0746	3.0555	2.9649	2.8875	3.0895
Maximum	1.9358	2.0930	1.5129	2.4519	4.4680	3.4830	2.8128	3.1835
Minimum	−2.0355	−2.1707	−1.7491	−2.7859	−3.1636	−3.2307	−2.7067	−4.3058

for some $j \geq 1$. Hence, a necessary (but not sufficient, in general) condition for the the MDH to hold is that the time series is uncorrelated, i.e.,

$$\gamma_j = Cov(Y_t, Y_{t-j}) = E[(Y_t - \mu)Y_{t-j}] = 0 \qquad \text{for all } j \geq 1, \tag{20.3}$$

where γ_j denotes the autocovariance of order j. In principle, one should test that all autocovariances or autocorrelations are zero. However, the most employed tests just consider that a finite number of autocorrelations are zero. As commented in the introduction, we will address these two cases separately.

Notice that the early literature, which includes some distinguished references such as Yule (1926), Bartlett (1955), Grenander and Rosenblatt (1957) or Durbin and Watson (1950), essentially assumed Gaussianity and, hence, identified three concepts: lack of serial correlation, m.d.s., and independence. In the time series literature the term "white noise" is commonly used to denote an uncorrelated

series that can present some form of dependence. Obviously, a white-noise series is neither necessarily independent nor m.d.s., since dependence can be reflected in other aspects of the joint distribution such as higher-order moments. The distinction between these three concepts has been stressed recently in econometrics. In fact, during the last few years a variety of models designed to reflect nonlinear dependence have been studied in the econometrics literature. For instance, in empirical finance, ARCH and bilinear models have been widely studied (see Bera and Higgins, 1993, 1997, and Weiss, 1986, for a comparison). These models are suitable for reflecting the nonlinear dependence structure found in many financial series.

Tests for white noise have been proposed both in the time domain and in the frequency domain. The time domain has mainly, but not exclusively, focused on a finite number of lags, while the frequency domain has been more suitable for addressing the infinite-dimensional case.

20.3.1 Tests based on a finite-dimensional conditioning set

In the time domain the most popular test (apart from the Durbin–Watson, which is designed to test for lack of first-order serial correlation using regression residuals) has been the Box–Pierce (Box and Pierce, 1970) portmanteau Q_p test. The Q_p test is designed for testing that the first p autocorrelations of a series (possibly residuals) are zero. The number p can be considered to be fixed or to grow with the sample size n. In this section we will assume that p is fixed.

Suppose that we observe raw data $\{Y_t\}_{t=1}^n$. Then γ_j can be consistently estimated by the sample autocovariance:

$$\widehat{\gamma}_j = (n-j)^{-1} \sum_{t=1+j}^{n} (Y_t - \overline{Y})(Y_{t-j} - \overline{Y}),$$

where $\overline{Y}$ is the sample mean, and we also introduce $\widehat{\rho}_j = \widehat{\gamma}_j/\widehat{\gamma}_0$ to denote the jth-order autocorrelation. The Q_p statistic is just:

$$Q_p = n\sum_{j=1}^{p} \widehat{\rho}_j^2,$$

but it is commonly implemented via the Ljung and Box (1978) modification:

$$LB_p = n(n+2)\sum_{j=1}^{p} (n-j)^{-1} \widehat{\rho}_j^2.$$

Note that Q_p (or LB_p) only takes into account the linear dependence up to the lag p. When p is considered fixed, the Q_p test statistic applied to independent data follows a χ_p^2 asymptotic null distribution, since the asymptotic covariance matrix of the first p autocorrelations of an independent series is the identity matrix. Hence, it is useful to write $Q_p = \left(\sqrt{n}\widehat{\rho}\right)' I^{-1} \left(\sqrt{n}\widehat{\rho}\right)$, where $\widehat{\rho} = (\widehat{\rho}_1, ..., \widehat{\rho}_p)'$.

Note, however, that when the series present some kind of nonlinear dependence, such as conditional heteroskedasticity, this asymptotic null covariance matrix is no longer the identity. In fact, denoting $\rho = (\rho_1, ..., \rho_p)'$, for a general time series the asymptotic distribution of $\sqrt{n}(\widehat{\rho} - \rho)$ is $N(0, T)$, where the $p \times p$ matrix T has as (i, j)th element (see, e.g., Romano and Thombs, 1996),

$$\gamma_0^{-2}(c_{ij} - \rho_i c_{0j} - \rho_j c_{0i} + \rho_i \rho_j c_{00}),$$

where, for $i, j = 0, 1, ..., p$,

$$c_{ij} = \sum_{d=-\infty}^{\infty} \Big\{ E\Big[(Y_t - \mu)(Y_{t-i} - \mu)(Y_{t+d} - \mu)(Y_{t+d-j} - \mu)\Big] - E\big[(Y_t - \mu)(Y_{t-i} - \mu)\big] E\Big[(Y_{t+d} - \mu)(Y_{t+d-j} - \mu)\Big] \Big\}.$$

Under alternative assumptions the matrix T can be simplified and this will lead to several modified versions of the Box–Pierce statistic. When this matrix is still diagonal, as happens under m.d.s. and additional moment restrictions, which, for instance, are satisfied by Gaussian GARCH models and many stochastic volatility models, the natural approach is to robustify the Q_p by standardizing it by a consistent estimate of its asymptotic variance, i.e.,

$$Q_p^* = n \sum_{j=1}^{p} \frac{\widehat{\rho}_j^2}{\tau_j},$$

where:

$$\tau_j = \frac{1}{\widehat{\gamma}_0^2} \sum_{t=1+j}^{n} (Y_t - \overline{Y})^2 (Y_{t-j} - \overline{Y})^2.$$

We have followed Lobato, Nankervis and Savin's (2001) notation and denoted the robustified Q_p by Q_p^*. This statistic has appeared in different versions (see, e.g., Diebold, 1986; Lo and MacKinlay, 1989; Robinson, 1991; Cumby and Huizinga, 1992; Bollerslev and Wooldridge, 1992; Bera and Higgins, 1993). The Q_p^* statistic (or its Ljung–Box analog) should be routinely computed for financial data instead of the standard Q_p (or the LB_p). However, this is not typically the case (see Lobato, Nankervis and Savin, 2001, for details).

For the general case, the asymptotic covariance matrix of the first p autocorrelations is not a diagonal matrix. Hence, for this general case both the Q_p and the Q_p^* tests are invalid. However, under m.d.s. the matrix T can be greatly simplified so that its *ij*-th element takes the form $E[(Y_t - \mu)^2 (Y_{t-i} - \mu)(Y_{t-j} - \mu)]$, which can easily be estimated using its sample analog. This is the approach followed by Guo and Phillips (2001). For the general case, which includes m.d.s. and non-m.d.s. processes, the asymptotic covariance matrix of the first p autocorrelations is a complicated non-diagonal matrix. Hence, for this general case, the literature has proposed the following two modifications of the Q_p test. The first is to modify the

Q_p statistic by introducing a consistent estimator of the asymptotic null covariance matrix of the sample autocorrelations, $\widehat{T}$, so that the modified Q_p statistic retains the χ^2_p asymptotic null distribution. Lobato, Nankervis and Savin (2002) define this statistic as $\widetilde{Q}_p = \left(\sqrt{n}\widehat{\rho}\right)' \widehat{T}^{-1} \left(\sqrt{n}\widehat{\rho}\right)$. The main drawback of this approach is that, in order to construct $\widehat{T}$, a bandwidth parameter has to be introduced (see *ibid.*, for details). This approach works for general dependence structures that allow for the asymptotic covariance matrix of the first p autocorrelations to take any form. The second modification has been studied by Horowitz *et al.* (2006), who employ a bootstrap procedure to estimate consistently the asymptotic null distribution of the Q_p test for the general case. They compare two bootstrap approaches, a single and a double blocks-of-blocks bootstrap, and their final recommendation is to employ a double blocks-of-blocks bootstrap after prewhitening the time series. This solution presents a similar problem, though, namely that the researcher has to choose arbitrarily a block length number. The previous papers considered raw data, but Francq, Roy and Zakoïan (2005) have addressed the use of the Q_p statistic with residuals. They propose to estimate the asymptotic null distribution of the Q_p test statistic for the general weak dependent case. However, their approach still requires the selection of p, and of several additional arbitrary numbers necessary to estimate consistently the needed asymptotic critical values.

These references represent an effort to address the problem of testing for m.d.s. using standard linear measures (autocorrelations) but allowing for nonlinear dependence. Lobato (2001) represents an alternative approach with a similar spirit. The target is to avoid the problem of introducing a user-chosen number and the idea is to construct an asymptotically distribution free statistic. Although this approach delivers tests that handle nonlinear dependence and control properly the Type I error in finite samples, its main theoretical drawback is its inefficiency in terms of local power.

A related statistic, which has been commonly employed in the empirical finance literature (see Cochrane, 1988; Lo and MacKinlay, 1989), is the variance ratio, which takes the form:

$$VR_p = 1 + 2\sum_{j=1}^{p-1}(1 - \frac{j}{p})\widehat{\rho}_j.$$

Under independence, $\sqrt{np}(VR_p - 1)$ is asymptotically distributed as $N(0, 2(p-1))$. Although this test can also be robustified and can be powerful on some occasions, it presents the serious theoretical limitation of being inconsistent. For instance, González and Lobato (2003) considered a moving average of order 2 (MA(2)) process $y_t = e_t - 0.4597e_{t-1} + 0.10124e_{t-2}$. For this process $VR_3 = 0$, in spite of the first two autocorrelations being non-zero. The problem with variance ratio statistics resides in the possible existence of compensations between autocorrelations with different signs, and this may affect power severely. Related to variance ratio (VR) tests, Nankervis and Savin (2007) have proposed a robustified version of Andrews and Ploberger's (1996) test that appears to have very good finite sample power with common empirical finance models. In related work, Delgado and Velasco (2007)

have recently considered a large class of directional tests based on linear combinations of autocorrelations. Their tests are shown to be optimal in certain known local alternative directions and are asymptotically equivalent to Lagrange multiplier tests. Finally, we mention Kuan and Lee (2004), who propose a correlation-based test for the MDH that, instead of using lagged values of Y_t as the function $w(\cdot)$, employs some other arbitrary $w(\cdot)$. This test shares with all the tests analyzed in this section the problem of inconsistency, derived from not using a whole family of functions $w(\cdot)$.

20.3.2 Tests based on an infinite-dimensional conditioning set

The approach presented in the previous sub-section lays naturally in the time domain since a finite number of autocorrelations are tested. However, when the infinite past is considered, the natural framework for performing inference is the frequency domain. The advantage of the frequency domain is the existence of one object, namely the spectral density, that contains the information contained in all the autocovariances. Hence, in the frequency domain, the role previously taken by autocorrelations is now carried by the spectral density function. Define the spectral density $f(\lambda)$ implicitly by:

$$\gamma_k = \int_{\Pi} f(\lambda) \exp(ik\lambda) d\lambda \quad k = 0, 1, 2, \ldots,$$

where $\Pi = [-\pi, \pi]$. Define also the periodogram as $I(\lambda) = |w(\lambda)|^2$, where $w(\lambda) = n^{-1/2} \sum_{t=1}^{n} x_t \exp(it\lambda)$. Although the periodogram is an inconsistent estimator of the spectral density, it can be employed as a building block to construct a consistent estimator. The integral of the spectral density is called the spectral distribution, which, under the MDH, is linear in λ.

For this infinite lag case, the MDH implies as the null hypothesis of interest that $\gamma_k = 0$ for all $k \neq 0$, and equivalently, in terms of the spectral density, the null hypothesis states that $f(\lambda) = \gamma_0/2\pi$ for all $\lambda \in \Pi$.

The advantage of the frequency domain is that the problem of selecting p, which was present in the previous sub-section, does not appear because the null hypothesis is stated in terms of *all* autocorrelations, as summarized by the spectral density or distribution. The classical approach in the frequency domain involves the standardized cumulative periodogram, i.e.,

$$Z_n(\lambda) = \sqrt{T} \left(\frac{\sum_{j=1}^{[\lambda T/\pi]} I(\lambda_j)}{\sum_{j=1}^{T} I(\lambda_j)} - \frac{\lambda}{\pi} \right),$$

where $\lambda_j = 2\pi j/n$, $j = 1, 2, ..., n/2$, are called the Fourier frequencies. Based on $Z_n(\lambda)$, the two classical test statistics are the Kolmogorov–Smirnov:

$$\max_{j=1,\ldots,T} \left| Z_n(\lambda_j) \right|,$$

and the Cramér–von Mises:

$$\frac{1}{T}\sum_{j=1,}^{T} Z_n(\lambda_j)^2.$$

These test statistics have been commonly employed (see Bartlett, 1955; Grenander and Rosenblatt, 1957) because, when the series y_t is not only white noise but also independent (or m.d.s. with additional moment restrictions), it can be shown that the process $Z_n(\lambda)$ converges weakly in $D[0,\pi]$ (the space of cadlag functions in $D[0,\pi]$) to the Brownian bridge process (see Dahlhaus, 1985). Hence, asymptotic critical values are readily available for the independent case. In fact, Durlauf (1991) has shown that the independence assumption can be relaxed to conditional homoskedastic m.d.s. For the m.d.s. case with conditional heteroskedasticity (and some moment conditions), Deo (2000) slightly modified this statistic so that the standardized cumulative periodogram retained its convergence to the Brownian bridge. Deo's test can be interpreted as a continuous version of the robustified Box–Pierce statistic, Q_p^*. Notice that, in Deo's set-up, there is no need to introduce any user-chosen number since, under the stated assumptions (see condition A in *ibid.*, p. 293), the autocorrelations are asymptotically independent. As Deo comments, his assumption (vii) is mainly responsible for the diagonality of the asymptotic null covariance matrix of the sample autocorrelations. However, for many common models, such as GARCH models with asymmetric innovations, EGARCH models and bilinear models, Deo's condition (vii) does not hold and the autocorrelations are not asymptotically independent under the null hypothesis. Hence, for the general case, Deo's test is not asymptotically valid. Deo's Cramér–von Mises test statistic can also be written in the time domain as:

$$DEO_n := n\sum_{j=1}^{n-1} \frac{\widehat{\rho}_j^2}{\tau_j}\left(\frac{1}{j\pi}\right)^2.$$

More general weighting schemes for the sample autocovariances $\widehat{\rho}_j$ than the ones considered here are possible. Under the null hypothesis of m.d.s. and some additional assumptions (see Deo, 2000),

$$DEO_n \xrightarrow{d} \int_0^1 B^2(t)dt \text{ as } n \longrightarrow \infty,$$

where $B(t)$ is the standard Brownian bridge on [0,1]. The 10%, 5% and 1% asymptotic critical values can be obtained from Shorack and Wellner (1986, p. 147) and are 0.347, 0.461 and 0.743, respectively. For extensions of this basic approach see also Paparoditis (2000) and Delgado, Hidalgo and Velasco (2005), among others.

Under general weak dependent assumptions (see Dahlhaus, 1985), the asymptotic null distribution of the process $Z_n(\lambda)$ is no longer the Brownian bridge but, in fact, converges weakly in $D[0,\pi]$ to a zero mean Gaussian process with covariance given by:

$$\frac{\pi G(\pi)}{F(\pi)^2}\left\{\frac{G(\lambda\wedge\mu)}{G(\pi)}+\frac{F(\lambda)F(\mu)}{F(\pi)^2}-\frac{F(\lambda)G(\mu)}{F(\pi)G(\pi)}-\frac{F(\mu)G(\lambda)}{F(\pi)G(\pi)}\right.$$
$$\left.+\frac{F_4(\lambda,\mu)}{G(\pi)}+\frac{F_4(\pi,\pi)}{G(\pi)}\frac{F(\lambda)F(\mu)}{F(\pi)^2}-\frac{F_4(\mu,\pi)}{G(\pi)}\frac{F(\lambda)}{F(\pi)}-\frac{F_4(\lambda,\pi)}{G(\pi)}\frac{F(\mu)}{F(\pi)}\right\},$$

where $F(\lambda)$ denotes the spectral distribution function, $F(\lambda)=\int_0^\lambda f(\omega)d\omega$, $G(\lambda)=\int_0^\lambda f(\omega)^2 d\omega$, and $F_4(\lambda,\mu)=\int_0^\lambda\int_0^\mu f_4(\omega,-\omega,-\theta)d\omega d\theta$, where $f_4(\lambda)$, with $\lambda\in\Pi^{q-1}$, denotes the fourth-order cumulant spectral density (see expression (2.6.2) in Brillinger, 1981, p. 25). The important message from the previous complicated covariance is that the asymptotic null distribution depends on the nature of the data generating process of y_t. Therefore, no asymptotic critical values are available. Chen and Romano (1999, p. 628) propose estimating the asymptotic distribution by means of either the block bootstrap or the sub-sampling technique. Unfortunately, these bootstrap procedures require the selection of some arbitrary number and, in a general framework, no theory is available about their optimal selection. Alternative bootstrap procedures which do not require the selection of a user-chosen number, such as resampling the periodogram as in Franke and Hardle (1992) or Dahlhaus and Janas (1996), will not estimate consistently the asymptotic null distribution because of the fourth-order cumulant terms.

Lobato and Velasco (2004) considered the statistic:

$$M_n=\frac{T^{-1}\sum_{j=1}^T I(\lambda_j)^2}{\left(T^{-1}\sum_{j=1}^T I(\lambda_j)\right)^2}-1,$$

under general weak dependence conditions. This statistic was previously considered by Milhøj (1981), who employed M_n as a general goodness-of-fit statistic for time series. Milhøj informally justified the use of this statistic for testing the adequacy of linear time series models but, since he identified white noise with independent and identically distributed (i.i.d.) (see *ibid.*, p. 177), his analysis does not automatically apply in general contexts. Beran (1992) and Deo and Chen (2000) have also employed the M_n statistic as a goodness-of-fit test for Gaussian processes. Statistical inference is especially simple with M_n, since its asymptotic null distribution is normal even after parametric estimation. We note that the continuous version of M_n can be expressed in the time domain as a statistic proportional to $\sum_{j=0}^{n-1}\widehat{\rho}_j^2$, which shows the difficulty of deriving the asymptotic properties in the time domain since the $\widehat{\rho}_j$ may not be asymptotically independent.

In the time domain, Hong (1996) has considered p as growing with n and, hence, has been able to derive a consistent test in the time domain for the case of regression residuals. In this framework p can be interpreted as a bandwidth number that needs to grow with n, so his test can handle the fact that the null hypothesis implies an infinite number of autocovariances. Hong (1996) restricted attention to the independent case while Hong and Lee (2003) have extended Hong's procedure to allow for conditional heteroskedasticity. However, notice that their framework still restricts the sample autocorrelations to be asymptotically independent.

An alternative solution recently explored by Escanciano and Lobato (2007) consists of modifying the Box–Pierce statistic using an adaptive Neyman test that takes the form:

$$AQ_n = Q_{\widetilde{p}}^*,$$

where:

$$\widetilde{p} = \min\{m : 1 \leq m \leq p_n; L_m \geq L_h, h = 1, 2, \ldots, p_n\}, \tag{20.4}$$

and where:

$$L_p = Q_p^* - \pi(p, n, q).$$

p_n is an upper bound that grows slowly to infinity with n, and:

$$\pi(p, n, q) = \begin{cases} p \log n, & \text{if} \quad \max_{1 \leq j \leq p_n} \left| \dfrac{\widehat{\rho}_j^2}{\tau_j} \right| \leq \sqrt{q \log n} \\ 2p, & \text{if} \quad \max_{1 \leq j \leq p_n} \left| \dfrac{\widehat{\rho}_j^2}{\tau_j} \right| > \sqrt{q \log n}, \end{cases}$$

where q is some fixed positive number. We denote this automatic portmanteau test AQ_n. Our choice of q is 2.4 and is motivated by an extensive simulation study in Inglot and Ledwina (2006) and from simulations in Escanciano and Lobato (2007). Small values of q result in the use of Akaike's criterion, while large $q's$ lead to choosing Schwarz's criterion. Moderate values, such as 2.4, provide a "switching effect" which combines the advantages of the two selection rules: when the alternative is of high frequency (that is, when the only significant autocorrelations are at large lags j), Akaike is used whereas, if the alternative is of low-frequency (i.e., if the first autocorrelations are different from zero), Schwarz is chosen. The adaptive test is an improvement with respect to the traditional Box–Pierce and Hong approaches because the AQ_n test is more powerful and less sensitive to the selection of the bandwidth number p_n than these approaches and, more importantly, it avoids the estimation of the complicated variance-covariance matrix T since its asymptotic distribution is χ_1^2 for general m.d.s. processes.

Summarizing, testing the MDH using linear measures of dependence presents two challenging features. The first aspect is that the null hypothesis implies that an infinite number of autocorrelations are zero. This feature has been addressed successfully in the frequency domain under severe restrictions on the dependence structure of the process. The second feature is that the null hypothesis allows the time series to present some form of dependence beyond the second moments. This dependence entails that the asymptotic null covariance matrix of the sample autocorrelations is not diagonal, so that it has n^2 non-zero terms (contrary to Durlauf, 1991, and Deo, 2000, who consider a diagonal matrix, which has only n non-zero elements). This aspect has been handled by introducing some arbitrary user-chosen numbers whose selection complicates statistical inference.

However, all these tests are suitable for testing for lack of serial correlation but not necessarily for the MDH and, in fact, they are not consistent against non-martingale difference sequences with zero autocorrelations. This happens when

only nonlinear dependence is present, as is commonly the case with financial data, e.g., exchange rates dynamics. These tests are inconsistent because they only employ information contained in the second moments of the process.

To circumvent this problem we could take into account higher-order moments, as in Hinich and Patterson (1992). They proposed using the bispectrum, i.e., the Fourier transform of the third-order cumulants of the process, but again, this test is not consistent against non-martingale difference sequences with zero third-order cumulants.

In Table 20.2 we report the robust (to conditional heteroskedasticity) version of the first five autocorrelations, the Ljung and Box (1978) test, which is a corrected Q^*_p statistic, which we call LB^*_p, Deo's (2000) modification of Durlauf's test statistic, and the Escanciano and Lobato (2007) test based on AQ_n, to check whether or not our exchange rates changes are uncorrelated. (For further evidence of linear independence, see Figures 20.3–20.10 in section 20.4.2.) Table 20.2 is in agreement with previous findings that have shown that exchange rates have no linear dependence (see, e.g., Table 2 in Hsieh, 1989; Bera and Higgins, 1997; Hong and Lee, 2003, and references therein):

20.4 Tests based on nonlinear measures of dependence

Arguably, testing for the MDH is a challenging problem since, in order to verify it, we must check that a very large class of transformations of the past does not help to predict the current value of the series (see (20.2)). An important step, through the development of consistent tests, was made when econometricians realized that it is not necessary to take a very *large* class of functions in (20.2), but just a convenient parametric class of functions, satisfying certain properties. Domínguez and Lobato (2003) called this methodology the global approach and Escanciano (2007a) called

it the integrated approach. Most of this section will be devoted to a careful study of this approach.

Note, however, that there exists an alternative methodology that is based on the direct estimation of the conditional expectation $E[Y_t|\widetilde{Y}_{t,P}]$, where $\widetilde{Y}_{t,P} = (Y_{t-1}, ..., Y_{t-P})'$ for some finite P. This approach can be called the smoothing approach (since smoothing numbers are required for this non-parametric estimation) or a local approach (see Domínguez and Lobato, 2003). Tests within the local approach have been proposed by Wooldridge (1992), Yatchew (1992), Horowitz and Härdle (1994), Zheng (1996), Fan and Huang (2001), Horowitz and Spokoiny (2001) and Guerre and Lavergne (2005), to mention just a few (see Hart, 1997, for a comprehensive review of the local approach when $P = 1$). Among these tests based on local methods, the test recently proposed by Guay and Guerre (2006) seems to be especially convenient for testing the MDH for two reasons. First, it has been justified for time series under conditional heteroskedasticity of unknown form. Second, it is an adaptive data-driven test. Their test combines a chi-square statistic, based on nonparametric Fourier series estimators for $E[Y_t \mid \widetilde{Y}_{t,P}]$, coupled with a data-driven choice for the number of components in the estimator. To construct their test a nonparametric estimator of the unknown conditional variance is needed. Notice that a relevant practical problem of the local approach arises when P is large or even moderate. The problem is motivated by the sparseness of the data in high-dimensional spaces, which leads most test statistics to suffer considerable bias, even for large sample sizes. In the next sub-section, we will consider an approach that helps to alleviate this problem.

This section focuses on integrated tests. We divide the extensive literature within this integrated approach according to whether the tests consider functions of a finite number of lags or not, i.e., whether $w(I_{t-1}) = w(\widetilde{Y}_{t,P})$ for some $P \geq 1$ or not. We stress at the outset that the main advantage of the tests considered in this section is that they are consistent for testing the MDH (at least when the information set has a finite number of variables), contrary to the tests considered in section 20.3. The main disadvantage is that their asymptotic null distributions are, in general, not standard, which means that no critical values are readily available. In this situation, the typical solution is to employ the bootstrap to estimate these distributions.

20.4.1 Tests based on a finite-dimensional conditioning set

The problem of testing over all possible weighting functions can be reduced to testing the orthogonality condition over a parametric family of functions (see, e.g., Stinchcombe and White, 1998). Although the parametric class still has to include an infinite number of elements, the complexity of the class to be considered is substantially simplified and makes it possible to test for the MDH.

The methods that we review in this sub-section use $w(I_{t-1}) = w_0(\widetilde{Y}_{t,P}, x)$ in (20.2), where, as stated above, $\widetilde{Y}_{t,P} = (Y_{t-1}, ..., Y_{t-P})'$ and w_0 is a known function indexed by a parameter x. That is, these methods check for any form of predictability from the lagged P values of the series. The test statistics are based on a "distance" of the sample analogue of $E[(Y_t - \mu)w_0(\widetilde{Y}_{t,P}, x)]$ from zero.

The exponential function $w_0(\widetilde{Y}_{t,P}, x) = \exp(ix'\widetilde{Y}_{t,P})$, $x \in \mathbb{R}$, was first considered in Bierens (1982, 1984, 1990) (see also Bierens and Ploberger, 1997). One version of the Cramér–von Mises (CvM) test of Bierens (1984) leads to the test statistic:

$$CvM_{n,\exp,P} = n^{-1}\widehat{\sigma}^{-2}\sum_{t=1}^{n}\sum_{s=1}^{n}(Y_t - \overline{Y})(Y_s - \overline{Y})\exp\left(-\frac{1}{2}\left|\widetilde{Y}_{t,P} - \widetilde{Y}_{s,P}\right|^2\right),$$

where:

$$\widehat{\sigma}^2 = \frac{1}{n}\sum_{t=1}^{n}(Y_t - \overline{Y})^2.$$

Indicator functions $w_0(\widetilde{Y}_{t,P}, x) = 1(\widetilde{Y}_{t,P} \leq x)$, $x \in \mathbb{R}$, were used in Stute (1997) and Koul and Stute (1999) for model checks of regressions and autoregressions, respectively, and in Domínguez and Lobato (2003) for the MDH problem.

Domínguez and Lobato (2003), extending to the multivariate case the results of Koul and Stute (1999), considered the CvM and Kolmogorov–Smirnov (KS) statistics, respectively:

$$CvM_{n,P} \quad : \quad = \frac{1}{\widehat{\sigma}^2 n^2}\sum_{j=1}^{n}\left[\sum_{t=1}^{n}(Y_t - \overline{Y})1(\widetilde{Y}_{t,P} \leq \widetilde{Y}_{j,P})\right]^2,$$

$$KS_{n,P} \quad : \quad = \max_{1\leq i\leq n}\left|\frac{1}{\widehat{\sigma}\sqrt{n}}\sum_{t=1}^{n}(Y_t - \overline{Y})1(\widetilde{Y}_{t,P} \leq \widetilde{Y}_{i,P})\right|.$$

As mentioned above, an important problem of the local approach (also shared by other methods) arises in the case where P is large or even moderate. The sparseness of the data in high-dimensional spaces implies severe biases to most test statistics. This is an important practical limitation for most tests considered in the literature because these biases still persist in fairly large samples. Motivated by this problem, Escanciano (2007a) proposed the use of $w_0(\widetilde{Y}_{t,P}, x) = 1(\beta'\widetilde{Y}_{t,P} \leq u)$, where $x = (\beta, u) \in \mathbb{S}^d \times \mathbb{R}$, with $\mathbb{S}^d = \{\beta \in \mathbb{R}^d : |\beta| = 1\}$, and defined CvM tests based on this choice. We denote by $PCVM_{n,P}$ the resulting CvM test in Escanciano. Also recently, Lavergne and Patilea (2007) proposed a dimension-reduction bootstrap consistent test for regression models based on nonparametric kernel estimators of one-dimensional projections. Their proposal falls in the category of local-based methods, though.

As mentioned earlier, the asymptotic null distribution of integrated tests based on $w_0(\widetilde{Y}_{t,P}, x)$ depends on the data-generating process in a complicated way. Therefore, critical values for the test statistics cannot be tabulated for general cases. One possibility, only explored in the literature for the case $P = 1$ by Koul and Stute (1999), consists of applying the so-called Khmaladze's transformation (Khmaladze, 1981) to get asymptotically distribution free tests. Extensions to $P > 1$ are not available yet. Alternatively, we can approximate the asymptotic null distributions by bootstrap methods. The most relevant bootstrap procedure for testing the MDH has been the wild bootstrap introduced in Wu (1986) and Liu (1988). For example, this

$PCVM_{n,3}$	0.248	0.438	0.790	0.664	0.746	0.443	0.566	0.414

approach has been employed in Domínguez and Lobato (2003) and Escanciano and Velasco (2006a, 2006b) to approximate the asymptotic distribution of integrated MDH tests. The asymptotic distribution is approximated by replacing $(Y_t - \overline{Y})$ with $(Y_t - \overline{Y})(V_t - \overline{V})$, where $\{V_t\}_{t=1}^n$ is a sequence of independent random variables (RVs) with zero mean, unit variance, bounded support and also independent of the sequence $\{Y_t\}_{t=1}^n$. Here, $\overline{V}$ is the sample mean of $\{V_t\}_{t=1}^n$. The bootstrap samples are obtained by resampling from the distribution of V_t. A popular choice for $\{V_t\}$ is a sequence of i.i.d. Bernoulli variates with $P(V_t = 0.5(1-\sqrt{5})) = (1+\sqrt{5})/2\sqrt{5}$, and $P(V_t = 0.5(1+\sqrt{5})) = 1 - (1+\sqrt{5})/2\sqrt{5}$.

We have applied several tests within the integrated methodology to our exchange rate data. In Table 20.3 we report the wild bootstrap empirical values. In our application we have considered the values $P = 1$ and $P = 3$ for the number of lags used in $CvM_{n,\exp,P}$, $CvM_{n,P}$, $KS_{n,P}$ and $PCVM_{n,P}$. Our results favor the MDH for all exchange rates at both frequencies, weekly and daily, with the exception of the daily euro for $P = 1$. Surprisingly enough, we obtain contradictory results for this exchange rate when $P = 3$. These contradictory results have been previously documented in, e.g., Escanciano and Velasco (2006a), and they may be due to a lack of power of the tests for the $P = 3$ case.

Although the consideration of an omnibus test, like those discussed in this section, is naturally the first idea when there is no a priori information about directions in the alternative hypothesis, it is worth noting that omnibus tests present an important limitation: despite their capability to detect deviations from the null in any direction, it is well-known that they only have reasonable nontrivial local power against very few orthogonal directions (see Janssen, 2000, and Escanciano, 2008, for theoretical explanations and bounds for the number of orthogonal directions).

A possible solution for overcoming the "lack" of power of omnibus tests is provided by the so-called Neyman smooth tests. They were first proposed by Neyman (1937) in the context of goodness-of-fit of distributions and, since then, there has been a plethora of research documenting their theoretical and empirical

Table 20.4 Testing the MDH of exchange rates returns
Bootstrap *P*-values. Data-driven tests

properties. In the context of MDH testing, a recent data-driven smooth test has been proposed by Escanciano and Mayoral (2007). Their test is based on the principal components of the marked empirical processes resulting from the choice $w_0(\widetilde{Y}_{t,1}, x) = 1(Y_{t-1} \leq x)$ with $x \in \mathbb{R}$. This test is an extension to nonlinear dependence of order one, i.e., for $P = 1$, of the test based on AQ_n. As shown by these authors, this test possesses excellent local power properties and compares favorably to omnibus tests and other competing tests. The test statistic is:

$$T_{n,\widetilde{p}} = \sum_{j=1}^{\widetilde{p}} \widehat{\epsilon}_{j,n}^2, \tag{20.5}$$

with $\widetilde{p}$ as in (20.4), but with $T_{n,p}$, defined by (20.5), replacing Q_p^* there, and where $\widehat{\epsilon}_{j,n}$ are the sample principal components of a certain CvM test (the reader is referred to Escanciano and Mayoral, 2007, for details). The asymptotic null distribution of $T_{n,\widetilde{p}}$ is a χ_1^2.

We have applied the adaptive data-driven test based on $T_{n,\widetilde{p}}$ to our exchange rate data. The results are reported in Table 20.4 and support our previous conclusions. Only the MDH for the daily euro exchange rate is rejected at 1% with $T_{n,\widetilde{p}}$.

20.4.2 Tests based on an infinite-dimensional information set

The aforementioned statistics test the MDH by conditioning on a finite-dimensional information set and, therefore, may miss some dependence structure in the conditional mean at omitted lags. In principle, maximum power could be achieved by using the correct lag-order P of the alternative. However, prior information on the conditional mean structure is usually not available.

There have been some proposals considering infinite-dimensional information sets. First, de Jong (1996) generalized Bierens' test to time series, and although his test had the appealing property of considering an increasing number of lags as the sample size increases, it required numerical integration with dimension equal to the sample size, which makes this test unfeasible in applications where the sample size is usually large, e.g., financial applications. Second, Domínguez and Lobato (2003) suggest constructing a test statistic as a weighted average of all the test statistics established for a fixed number of lags. However, Domínguez and Lobato did not analyze the test any further, nor the selection of the measure to weight the different statistics.

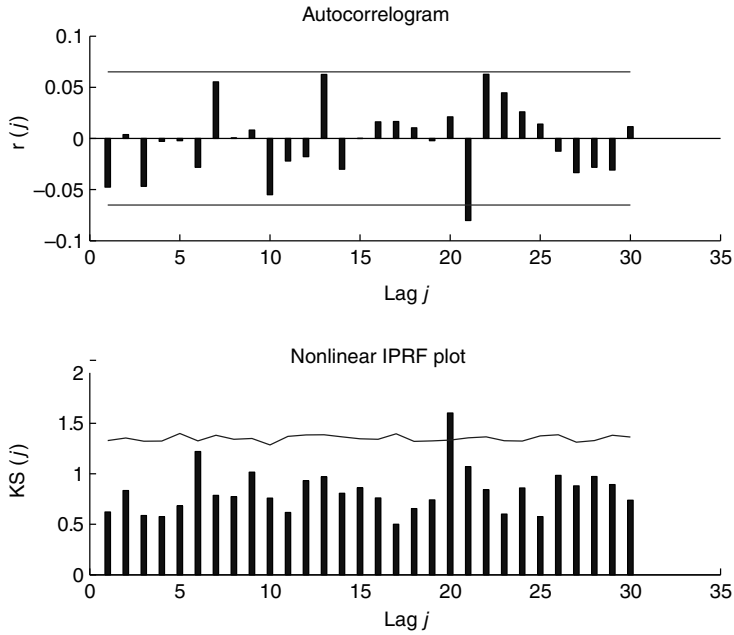

Figure 20.3 IPRF for the daily euro
Top graph is the heteroskedasticity robust autocorrelation plot. Bottom graph is the IPRF plot.

Using a different methodology based on the generalized spectral density approach of Hong (1999), Hong and Lee (2003) proposed an MDH bootstrap test (see also Hong and Lee, 2005). Tests based on the generalized spectral density involve three choices: a kernel, a bandwidth parameter, and an integrating measure; and, in general, statistical inferences are sensitive to these choices. This fact motivated Escanciano and Velasco (2006a, 2006b) to propose testing the MDH by means of a generalized spectral distribution function.

The generalized spectral approach is based on the fact that the MDH implies that:

$$H_0 : \gamma_{j,w}(x) = 0 \quad \forall j \geq 1, \text{ for all } x, \tag{20.6}$$

where $\gamma_{j,w}(x) = E[(Y_t - \mu)w_0(Y_{t-j}, x)]$ and where $w_0(Y_{t-j}, x)$ is any of the parametric functions of the previous section. The generalized spectral approach of Hong is based on the choice $w_0(Y_{t-j}, x) = \exp(ixY_{t-j})$. Escanciano and Velasco (2006a) considered the latter choice, while Escanciano and Velasco (2006b) used $w_0(Y_{t-j}, x) = 1(Y_{t-j} \leq x)$, and called the measure $\gamma_{j,ind}(x) = E[(Y_t - \mu)1(Y_{t-j} \leq x)]$ the integrated pairwise autoregression function (IPAF). The name follows from the fact that:

$$\gamma_{j,ind}(x) = E[(Y_t - \mu)1(Y_{t-j} \leq x)] = \int_{-\infty}^{x} E[Y - \mu \mid Y_{t-j} = z]F(dz),$$

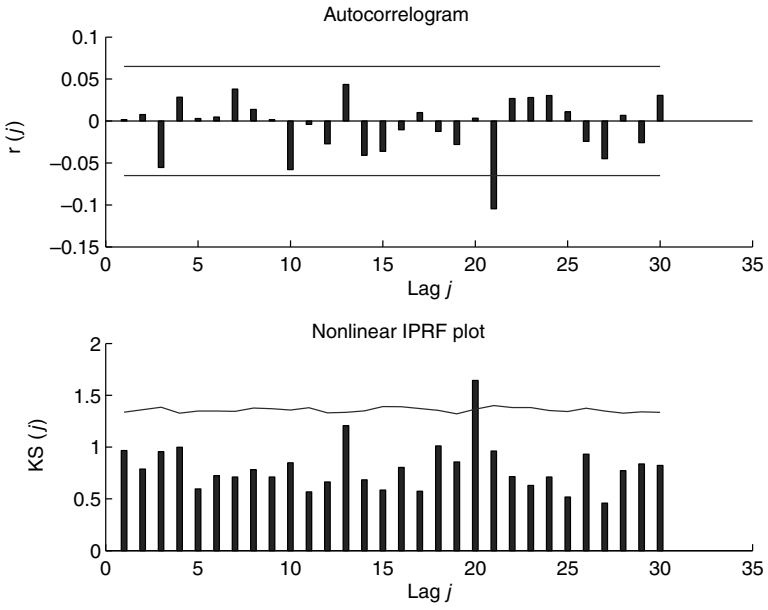

Figure 20.4 IPRF for the daily pound

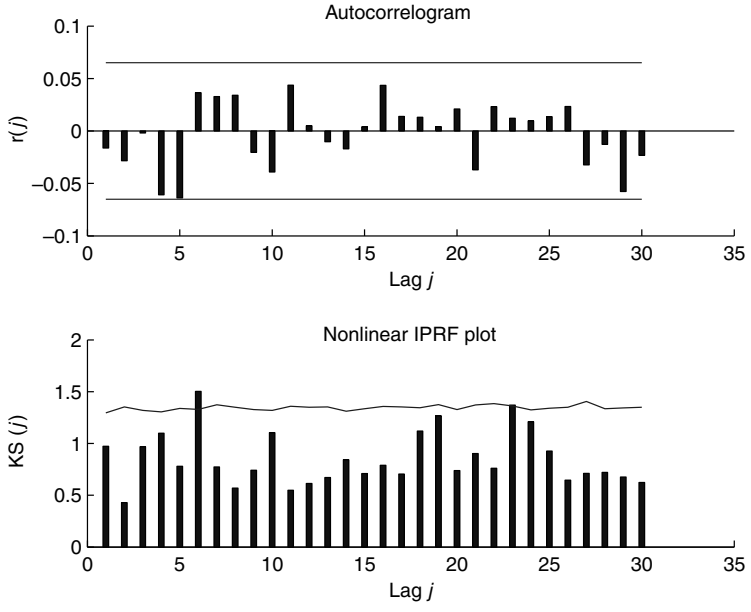

Figure 20.5 IPRF for the daily Can
Top graph is the heteroskedasticity robust autocorrelation plot. Bottom graph is the IPRF plot.

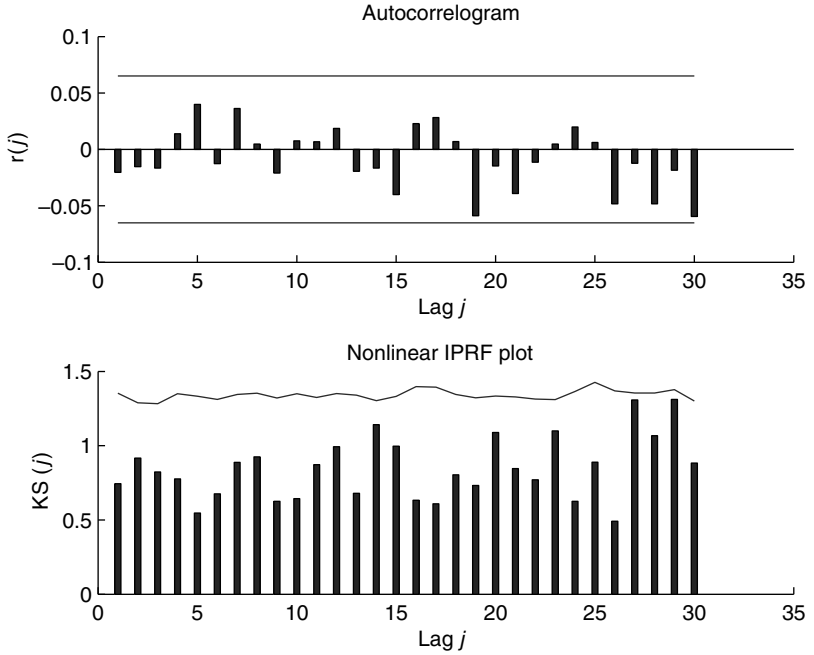

Figure 20.6 IPRF for the daily yen
Top graph is the heteroskedasticity robust autocorrelation plot. Bottom graph is the IPRF plot.

where F is the cumulative distribution function (c.d.f.) of Y_t. The measure $\gamma_{j,w}(x)$ can be viewed as a generalization of the usual autocovariance to measure the conditional mean dependence in a nonlinear time series framework. It can easily be estimated from a sample. For example, the IPAF can be estimated by:

$$\widehat{\gamma}_{j,ind}(x) = \frac{1}{n-j}\sum_{t=1+j}^{n}(Y_t - \overline{Y})1(Y_{t-j} \leq x). \tag{20.7}$$

Moreover, as proposed by Escanciano and Velasco (2006b), nonlinear correlograms can be used to formally assess the nonlinear dependence structure in the conditional mean of the series. These authors define the KS test statistic as:

$$KS(j) := \sup_{x\in[-\infty,\infty]^d}\left|(n-j)^{\frac{1}{2}}\widehat{\gamma}_{j,ind}(x)\right| = \max_{1+j\leq t\leq n}\left|(n-j)^{\frac{1}{2}}\widehat{\gamma}_{j,ind}(Y_{t-j})\right|.$$

The asymptotic quantiles of $KS(j)$ under the MDH can be approximated via a wild bootstrap approach. With these bootstrap critical values we can calculate uniform confidence bands for $\widehat{\gamma}_j(x)$ and the significance of $\gamma_j(x)$ can be tested. The plot of a standardization of $KS(j)$ against the lag parameter $j \geq 1$ can be viewed as a generalization of the usual autocovariance plot in linear dependence to nonlinear conditional mean dependence. Escanciano and Velasco (2006b) call this plot the integrated pairwise regression function (IPRF) plot.

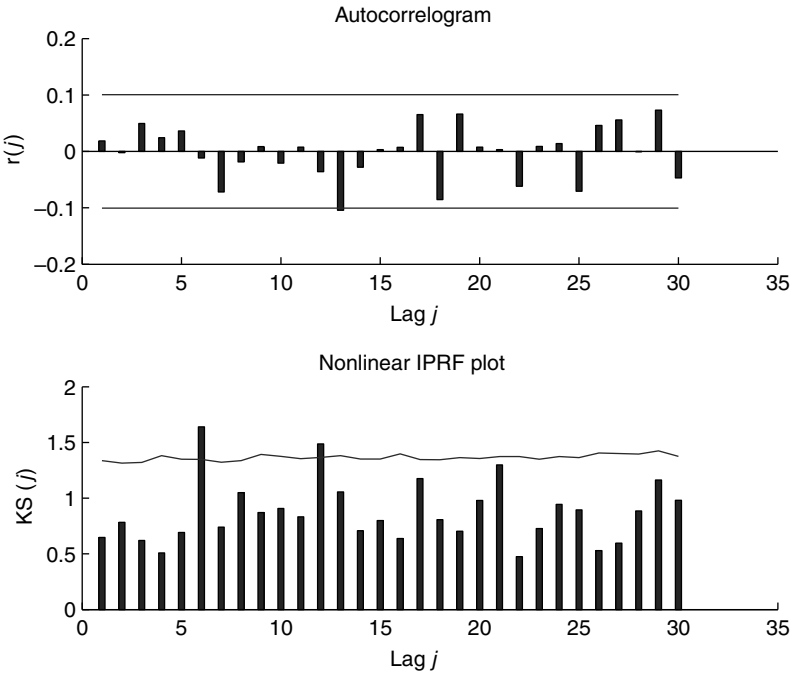

Figure 20.7 IPRF for the weekly euro
Top graph is the heteroskedasticity robust autocorrelation plot. Bottom graph is the IPRF plot.

In Figures 20.3–20.10 we plot the IPRF for our exchange rate returns. The common feature of these graphs is the lack of dependence in the exchange rates, both linear and nonlinear. Only a few isolated statistics seem to be significant, but the evidence is very weak. It seems that the IPRF supports the MDH for these datasets.

We now describe a generalized spectral approach to enable us to consider simultaneously all the nonlinear measures of dependence $\{\gamma_{j,w}(\cdot)\}$. Define $\gamma_{-j,w}(\cdot) = \gamma_{j,w}(\cdot)$ for $j \geq 1$, and consider the Fourier transform of the functions $\gamma_{j,w}(x)$,

$$f_w(\varpi, x) = \frac{1}{2\pi} \sum_{j=-\infty}^{\infty} \gamma_{j,w}(x) e^{-ij\varpi} \quad \forall \varpi \in [-\pi, \pi]. \tag{20.8}$$

Note that $f_w(\varpi, x)$ is able to capture pairwise non-martingale difference alternatives with zero autocorrelations. Under the MDH, the condition $f_{0,w}(\varpi, x) = (2\pi)^{-1}\gamma_0(x)$ holds, i.e., the generalized spectral density $f_w(\varpi, x)$ is flat in ϖ. Hong (1999) proposed the estimators:

$$\widehat{f}_w(\varpi, x) = \frac{1}{2\pi} \sum_{j=-n+1}^{n-1} \left(1 - \frac{|j|}{n}\right)^{\frac{1}{2}} k\left(\frac{j}{p}\right) \widehat{\gamma}_{j,\exp}(x) e^{-ij\varpi},$$

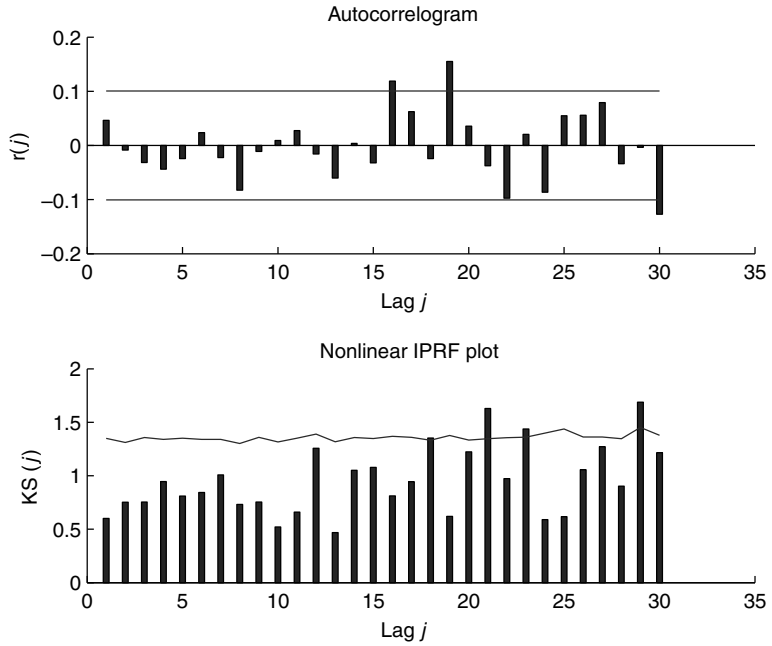

Figure 20.8 IPRF for the weekly pound
Top graph is the heteroskedasticity robust autocorrelation plot. Bottom graph is the IPRF plot.

and:

$$\widehat{f}_{0,w}(\varpi, x) = \frac{1}{2\pi}\widehat{\gamma}_{0,w}(x),$$

to test the MDH, where $k(\cdot)$ is a symmetric kernel and p a bandwidth parameter. He considered a standardization of an L_2-distance using a weighting function $W(\cdot)$:

$$L^2_{2,n}(p) = \frac{\pi}{2}\int_{\mathbb{R}}\int_{-\pi}^{\pi} n\left|\widehat{f}_w(\varpi, x) - \widehat{f}_{0,w}(\varpi, x)\right|^2 W(dx)d\varpi \tag{20.9}$$

$$= \sum_{j=1}^{n-1}(n-j)k^2\left(\frac{j}{p}\right)\int_{\mathbb{R}}\left|\widehat{\gamma}_{j,w}(x)\right|^2 W(dx).$$

Under the null of MDH and some additional assumptions, Hong and Lee (2005) showed that a convenient standardization of $L^2_{2,n}(p)$ converges to a standard normal random variable. The centering and scaling factors in this standardization depend on the higher dependence structure of the series.

Alternatively, the generalized spectral distribution function is:

$$H_w(\lambda, x) = 2\int_0^{\lambda\pi} f_w(\varpi, x)d\varpi \qquad \lambda \in [0, 1],$$

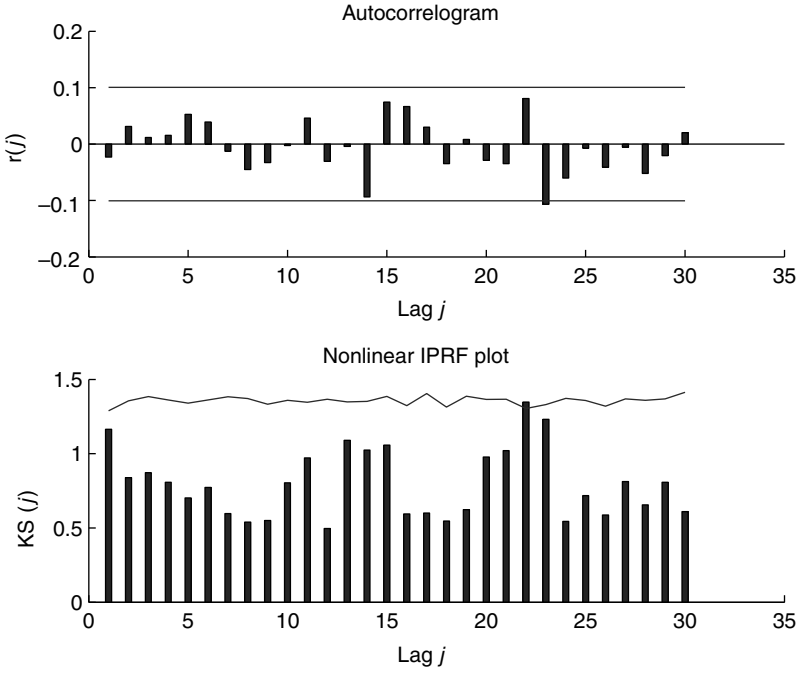

Figure 20.9 IPRF for the weekly Can
Top graph is the heteroskedasticity robust autocorrelation plot. Bottom graph is the IPRF plot.

which, after some algebra, boils down to:

$$H_w(\lambda, x) = \gamma_{0,w}(x)\lambda + 2\sum_{j=1}^{\infty}\gamma_{j,w}(x)\frac{\sin j\pi\lambda}{j\pi}. \tag{20.10}$$

Tests can be based on the sample analogue of (20.10), i.e.:

$$\widehat{H}_w(\lambda, x) = \widehat{\gamma}_{0,w}(x)\lambda + 2\sum_{j=1}^{n-1}(1 - \frac{j}{n})^{\frac{1}{2}}\widehat{\gamma}_{j,w}(x)\frac{\sin j\pi\lambda}{j\pi},$$

where $(1 - \frac{j}{n})^{\frac{1}{2}}$ is a finite sample correction factor. The effect of this correction factor is to put less weight on very large lags, for which we have less sample information. Note that under the MDH, $H_w(\lambda, x) = \gamma_0(x)\lambda$, so that tests for MDH can be constructed based on the discrepancy between $\widehat{H}_w(\lambda, x)$ and $\widehat{H}_{0,w}(\lambda, x) := \widehat{\gamma}_0(x)\lambda$. That is, we can consider the process:

$$S_{n,w}(\lambda, x) = \left(\frac{n}{2}\right)^{\frac{1}{2}}\{\widehat{H}_w(\lambda, x) - \widehat{H}_{0,w}(\lambda, x)\} = \sum_{j=1}^{n-1}(n-j)^{\frac{1}{2}}\widehat{\gamma}_{j,w}(x)\frac{\sqrt{2}\sin j\pi\lambda}{j\pi}, \tag{20.11}$$

to test for the MDH.

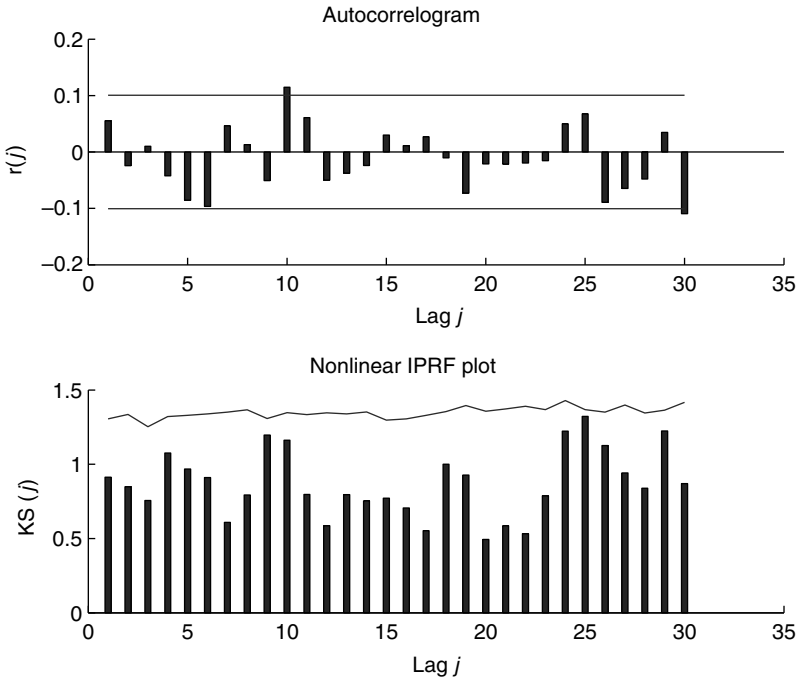

Figure 20.10 IPRF for the weekly yen
Top graph is the heteroskedasticity robust autocorrelation plot. Bottom graph is the IPRF plot.

In order to evaluate the distance of $S_n(\lambda, x)$ from zero, a norm has to be chosen. One norm considered in practice is the Cramér–von Mises norm:

$$D^2_{n,w} = \int_{\mathbb{R}} \int_0^1 \left| S_{n,w}(\lambda, x) \right|^2 W(dx) d\lambda = \sum_{j=1}^{n-1} (n-j) \frac{1}{(j\pi)^2} \int_{\mathbb{R}} \left| \widehat{\gamma}_{j,w}(x) \right|^2 W(dx), \quad (20.12)$$

where $W(\cdot)$ is a weighting function satisfying some mild conditions. $D^2_{n,w}$ has the attractive convenience of being free of choosing any smoothing parameter or kernel, and it has been documented to deliver tests with good power properties (cf. Escanciano and Velasco, 2006a, 2006b).

Among the members of this class of test statistics, the most common choices are:

$$D^2_{n,\exp} = \widehat{\sigma}^{-2} \sum_{j=1}^{n-1} (n-j) \frac{1}{(j\pi)^2} \sum_{t=j+1}^{n} \sum_{s=j+1}^{n} (Y_t - \overline{Y}_{n-j})(Y_s - \overline{Y}_{n-j}) \exp(-0.5(Y_{t-j} - Y_{s-j})^2),$$

and:

$$D^2_{n,ind} = \widehat{\sigma}^{-2} \sum_{j=1}^{n-1} \frac{(n-j)}{n(j\pi)^2} \sum_{t=1}^{n} \widehat{\gamma}^2_{j,ind}(X_t),$$

Table 20.5 Testing the MDH of exchange rates returns
Bootstrap *P*-values. Generalized spectral tests

	Daily				*Weekly*			
	Euro	*Pound*	*Can*	*Yen*	*Euro*	*Pound*	*Can*	*Yen*
$D^2_{n,\exp}$	0.023	0.450	0.680	0.913	0.670	0.123	0.360	0.586
$D^2_{n,ind}$	0.016	0.343	0.640	0.923	0.800	0.253	0.526	0.524

where $\widehat{\gamma}_{j,ind}$ is given in (20.7). The test statistic $D^2_{n,\exp}$ is based on $w_0(Y_{t-j}, x) = \exp(ixY_{t-j})$ and the standard normal c.d.f. as the weighting function $W(\cdot)$, whereas $D^2_{n,ind}$ is based on $w_0(Y_{t-j}, x) = 1(Y_{t-j} \leq x)$ and the empirical c.d.f. as the function W.

We have applied these two generalized spectral distribution based tests to our exchange rate data. The results are reported in Table 20.5 and support our previous conclusions. Only the MDH for the daily euro exchange rate is rejected.

20.5 Related hypotheses

In this chapter we have considered testing the MDH which, in statistical terms, just implies that the mean of an economic time series is independent of its past. The procedures studied in this chapter can be straightforwardly applied to testing the following generalization of the MDH:

$$H_0 : E[Y_t \mid X_{t-1,}X_{t-2,}...] = \mu, \quad \mu \in \mathbb{R},$$

where Y_t is a measurable real-valued transformation of X_t and $\mu = E[Y_t]$. This null hypothesis, which is referred to as the generalized MDH, contains many interesting testing problems as special cases. For instance, when Y_t is a power transformation of X_t, this null hypothesis implies constancy of conditional moments. The leading case in financial applications is where $Y_t = X_t^2$, because when X_t follows an m.d.s., this null hypothesis means that there is no volatility in the series X_t, i.e., X_t is conditionally homoskedastic. The cases $Y_t = X_t^3$ or $Y_t = X_t^4$ would, respectively, test for no dynamic structure in the third moment (conditionally constant skewness) and fourth moment (conditionally constant kurtosis) (see, e.g., Bollerslev, 1987; Engle and González-Rivera, 1991). Another relevant case is when $Y_t = 1(X_t > c)$, $c \in \mathbb{R}^d$. In this case, the null hypothesis represents no directional predictability (see, e.g., Linton and Whang, 2007). Another situation of interest occurs when the null hypothesis is the equality of the regression curves of two random variables, X_{1t} and X_{2t}, say; in this case, $Y_t = X_{1t} - X_{2t}$, $\mu = 0$ (see Ferreira and Stute, 2004, for a recent reference).

Note also that most of the procedures considered in this chapter are also applicable for testing the null hypothesis that a general dynamic nonlinear model is

correctly specified. In this situation, the null hypothesis of interest establishes that:

$$\exists \theta_0 : E[\psi(Y_t, X_t, \theta_0) \mid X_t] = 0,$$

where ψ is a given function, Y_t is a vector of endogenous variables and X_t is a vector of exogenous variables. Test statistics can be constructed along the lines described in this chapter. The main theoretical challenge in this framework is the way of handling the estimation of the parameters. There are basically three alternative approaches. First, to estimate the asymptotic null distribution of the relevant test statistic by estimating its spectral decomposition (e.g., Horowitz, 2006; Carrasco, Florens and Renault, 2007). Second, to use the bootstrap to estimate this distribution (see Wu, 1986; Stute, González-Manteiga and Presedo-Quindmil, 1998). Third, to transform the test statistic via martingalization to yield an asymptotically distribution-free test statistic.

Finally, in this chapter we have considered testing for m.d.s. instead of testing for a martingale. Recall that X_t is a martingale, with respect to its natural filtration, when $E\left[X_t \mid X_{t-1}, X_{t-2}, \ldots\right] = X_{t-1}$ *a.s.* Testing for a martingale presents the additional challenge of handling non-stationary variables. Park and Whang (2005) considered testing that a first-order Markovian process follows a martingale by testing that the first difference of the process, conditionally on the last value, has zero mean, i.e.,

$$E(X_t - X_{t-1} \mid X_{t-1}) = 0 \ a.s. \tag{20.13}$$

Hence they allow for a singular non-stationary conditioning variable. This restrictive Markovian framework has the advantage of leading to test statistics which are asymptotically distribution free and, hence, they do not need to transform their statistics or to use bootstrap procedures to obtain critical values. Similarly, note that many of the procedures described in section 20.4 also lead to asymptotically distribution free tests in this restrictive framework. As shown in Escanciano (2007b), the extension to the multivariate conditioning case in (20.13) leads to non-pivotal tests and some resampling procedure is necessary.

20.6 Conclusions

This chapter has presented a general panoramic of the literature of testing for the MDH. This research started at the beginning of the last century by developing tests for serial correlation and experienced renewed interest recently because of the nonlinear dependence present in economic and, especially, financial series. The initial statistical tools were based on linear dependence measures such as autocorrelations or the spectral density function. These tools were initially motivated by the observation that economic time series follow normal distributions. Since the last 25 years has stressed the non-normal behavior of financial series, the statistics and econometrics literature has followed two alternative approaches. The first's target was to robustify the well-established linear measures to allow for non-linear dependence. This approach has the advantage of simplicity, since it leads typically to standard asymptotic null distributions. However, its main limitation is that it

cannot detect nonlinear dependence. The second approach considered nonlinear measures of dependence. Its advantage is that it is more powerful, its disadvantage is that asymptotic null distributions are non-standard. Nowadays, this feature is hardly a drawback because the increasing availability of computing resources has allowed the implementation of bootstrap procedures, which can estimate the asymptotic null distributions with relative ease.

The definition of a martingale involves the information set of the agent that typically contains the infinite past of the economic series. This feature implies that, in practice, it is practically impossible to construct a test which, although it may be consistent theoretically, has power for any possible violation of the null hypothesis. The *pairwise* approach, which admittedly does not deliver consistent tests, nevertheless leads to tests with reasonable power for common alternatives. Another sensible possibility for reducing this dimensionality problem is to consider alternatives of a single-index structure, i.e., where the conditioning set is given by a univariate, possibly unknown, projection of the infinite-dimensional information set. More research is clearly needed in this direction.

In this chapter we have illustrated the different methodologies with exchange rate data that typically satisfy the MDH, as we have seen. Stock market data are not such a clear-cut case. Rejecting the MDH leads to the challenge of selecting a proper model. In this respect, data-driven adaptive tests are informative, since they provide an alternative model in the case of rejection. Notably, the principal component analysis provided in Escanciano and Mayoral (2007) represents a clear, theoretically well-motivated approach that, coupled with an effective choice for the number of components, can help in this selection process.

Acknowledgments

We are very grateful to Terry Mills for a careful reading of a previous version of this chapter. Autoregressive Conditional Duration Models[1]

Ruey S. Tsay

Abstract

This chapter studies the autoregressive conditional duration model. It discusses properties and statistical inference of the model. It also considers some extensions to handle nonlinear durations and interventions. For applications, we apply the model to daily range of the log price of Apple stock and find that adopting the decimal system for the US stock price on January 29, 2001, significantly reduces price volatility.

21.1 Introduction

The autoregressive conditional duration (ACD) model was proposed by Engle and Russell (1998) to model irregularly spaced financial transaction data. It has attracted much interest among researchers and practitioners ever since, and has found many applications outside of modeling transaction data. Duration is commonly defined as the time interval between consecutive events, e.g., the time interval between two transactions of a stock on the New York Stock Exchange or the difference between arrival times of two customers at a service station. The duration between two consecutive transactions in finance is important, for it may signal the arrival

of new information concerning the underlying asset. A cluster of short durations corresponds to active trading and, hence, an indication of the existence of new information.

Since duration is necessarily non-negative, the ACD model has also been used to model time series that consist of positive observations. An example is the daily range of the log price of an asset. The range of an asset price during a trading day can be used to measure its price volatility (e.g., Parkinson, 1980). Therefore, studying range can serve as an alternative approach to volatility modeling. Chou (2005) considers a conditional autoregressive range (CARR) model and shows that his CARR model can improve volatility forecasts for the weekly log returns of the Standard & Poor 500 index over some commonly used volatility models. The CARR model is essentially an ACD model.

In this chapter, we shall introduce the ACD model, discuss its properties, and address issues of statistical inference concerning the model. We then demonstrate its applications via some real examples. We also consider some extensions of the model, including nonlinear duration models and intervention analysis. Using the daily range of the log price of Apple stock, our ACD application shows that adopting the decimal system for US stock prices on January 29, 2001, significantly reduces the volatility of the stock price.

21.2 Duration models

Duration models in finance are concerned with time intervals between trades. For a given asset, longer durations indicate lack of trading activities, which in turn signify a period of no new information. On the other hand, arrival of new information often results in heavy trading and, hence, leads to shorter durations. The dynamic behavior of durations thus contains useful information about market activities. Furthermore, since financial markets typically take a period of time to uncover the effect of new information, active trading is likely to persist for a period of time, resulting in clusters of short durations. Consequently, durations might exhibit characteristics similar to those of asset volatility. Considerations like this lead to the development of duration models. Indeed, to model the durations of intraday trading, Engle and Russell (1998) use an idea similar to that of the generalized autoregressive conditional heteroskedastic (GARCH) models to propose an ACD model and show that the model can successfully describe the evolution of time durations for (heavily traded) stocks. Since intraday transactions of a stock often exhibit certain diurnal patterns, adjusted time durations are used in ACD modeling. We shall discuss methods for adjusting the diurnal pattern later. Here we focus on introducing the ACD model.

Let t_i be the time, measured with respect to some origin, of the ith event of interest with t_0 being the starting time. The ith duration is defined as:

$$x_i = t_i - t_{i-1}, \quad i = 1, 2, \ldots.$$

For simplicity, we ignore, at least for now, the case of zero durations so that $x_i > 0$ for all i. The ACD model postulates that x_i follows the model:

$$x_i = \psi_i \epsilon_i, \tag{21.1}$$

where $\{\epsilon_i\}$ is a sequence of independent and identically distributed (i.i.d.) random variables with $E(\epsilon_i) = 1$ and positive support, and ψ_i satisfies:

$$\psi_i = \alpha_0 + \sum_{j=1}^{p} \alpha_j x_{i-j} + \sum_{\nu=1}^{q} \beta_\nu \psi_{i-\nu}, \tag{21.2}$$

where p and q are non-negative integers and α_j and β_ν are constant coefficients. Since x_i is positive, it is common to assume that $\alpha_0 > 0$, $\alpha_j \geq 0$ and $\beta_\nu \geq 0$ for $j \in \{1, \ldots, p\}$ and $\nu \in \{1, \ldots, q\}$. Furthermore, the zeros of the polynomial $\alpha(L) = 1 - \sum_{j=1}^{g} (\alpha_j + \beta_j) L^j$ are outside the unit circle, where L denotes the lag operator, $g = \max\{p, q\}$, and $\alpha_j = 0$ for $j > p$ and $\beta_j = 0$ for $j > q$.

Let F_h be the σ-field generated by $\{\epsilon_h, \epsilon_{h-1}, \ldots\}$. It is easy to see that $E(x_i|F_{i-1}) = \psi_i E(\epsilon_i|F_{i-1}) = \psi_i$. Thus, ψ_i is the conditional expected duration of the next transaction given F_{i-1}. Since ϵ_i has a positive support, it may assume the standard exponential distribution. This results in an exponential ACD model. For ease of reference, we shall refer to the model in equations (21.1)–(21.2) as an EACD(p, q) model when ϵ_i follows the standard exponential distribution.

21.2.1 Properties of the EACD model

We start with the simple EACD(1,1) model:

$$x_i = \psi_i \epsilon_i, \quad \psi_i = \alpha_0 + \alpha_1 x_{i-1} + \beta_1 \psi_{i-1}. \tag{21.3}$$

Taking the expectation of the model, we obtain:

$$E(x_i) = E(\psi_i \epsilon_i) = E[\psi_i E(\epsilon_i|F_{i-1})] = E(\psi_i),$$
$$E(\psi_i) = \alpha_0 + \alpha_1 E(x_{i-1}) + \beta_1 E(\psi_{i-1}).$$

Under the weak stationarity assumption, $E(x_i) = E(x_{i-1})$, so that:

$$\mu_x \equiv E(x_i) = E(\psi_i) = \frac{\alpha_0}{1 - \alpha_1 - \beta_1}.$$

Consequently, $0 \leq \alpha_1 + \beta_1 < 1$ for a weakly stationary process $\{x_i\}$. Next, making use of the fact that $E(\epsilon_i) = 1$ and $E(\epsilon_i^2) = 2$, we have $E(x_i^2) = 2E(\psi_i^2)$. Again, under weak stationarity:

$$E(\psi_i^2) = \frac{\mu_x^2 [1 - (\alpha_1 + \beta_1)^2]}{1 - 2\alpha_1^2 - \beta_1^2 - 2\alpha_1\beta_1}, \tag{21.4}$$

$$\text{Var}(x_i) = \frac{\mu_x^2 (1 - \beta_1^2 - 2\alpha_1\beta_1)}{1 - 2\alpha_1^2 - \beta_1^2 - 2\alpha_1\beta_1}. \tag{21.5}$$

From these results, for the EACD(1,1) model to have a finite variance, we need $1 > 2\alpha_1^2 + \beta_1^2 + 2\alpha_1\beta_1$. Similar results can be obtained for the general EACD(p, q) model, but the algebra involved becomes tedious.

Forecasts from an EACD model can be obtained using a procedure similar to that of a GARCH model, which in turn is similar to that of a stationary autoregressive moving average (ARMA) model. Again, consider the simple EACD(1,1) model and suppose that the forecast origin is $i = h$. For a one-step-ahead forecast, the model states that $x_{h+1} = \psi_{h+1}\epsilon_{h+1}$ with $\psi_{h+1} = \alpha_0 + \alpha_1 x_h + \beta_1 \psi_h$. Let $x_h(1)$ be the one-step-ahead forecast of x_{h+1} at the origin h. Then:

$$x_h(1) = E(x_{h+1}|F_h) = E(\psi_{h+1}\epsilon_{h+1}) = \psi_{h+1},$$

which is known at the origin $i = h$. The associated forecast error is $e_h(1) = x_{h+1} - x_h(1) = \psi_{h+1}(\epsilon_{h+1} - 1)$. The conditional variance of the forecast error is then ψ^2_{h+1}. For multi-step-ahead forecasts, we use $x_{h+j} = \psi_{h+j}\epsilon_{h+j}$ so that, for $j = 2$,

$$\begin{aligned}\psi_{h+2} &= \alpha_0 + \alpha_1 x_{h+1} + \beta_1 \psi_{h+1} \\ &= \alpha_0 + (\alpha_1 + \beta_1)\psi_{h+1} + \alpha_1 \psi_{h+1}(\epsilon_{h+1} - 1).\end{aligned}$$

Consequently, the two-step-ahead forecast is:

$$x_h(2) = E(\psi_{h+2}\epsilon_{h+2}) = \alpha_0 + (\alpha_1 + \beta_1)\psi_{h+1} = \alpha_0 + (\alpha_1 + \beta_1)x_h(1),$$

and the associated forecast error is:

$$e_h(2) = \alpha_0(\epsilon_{h+2} - 1) + \alpha_1 \psi_{h+1}(\epsilon_{h+2}\epsilon_{h+1} - 1) + \beta_1 \psi_{h+1}(\epsilon_{h+2} - 1).$$

In general, we have:

$$x_h(m) = \alpha_0 + (\alpha_1 + \beta_1)x_h(m-1), \quad m > 1.$$

This is exactly the recursive forecasting formula of an ARMA(1,1) model with autoregressive (AR) polynomial $1 - (\alpha_1 + \beta_1)L$. By repeated substitutions, we can rewrite the forecasting formula as:

$$x_h(m) = \frac{\alpha_0[1 - (\alpha_1 + \beta_1)^{m-1}]}{1 - \alpha_1 - \beta_1} + (\alpha_1 + \beta_1)^{m-1} x_h(1).$$

Since $\alpha_1 + \beta_1 < 1$, we have:

$$x_h(m) \to \frac{\alpha_0}{1 - \alpha_1 - \beta_1}, \quad \text{as} \quad m \to \infty,$$

which says that, as expected, the long-term forecasts of a stationary series converge to its unconditional mean as the forecast horizon increases.

Let $\eta_j = x_j - \psi_j$. It is easy to show that $E(\eta_j) = 0$ and $E(\eta_j \eta_t) = 0$ for $t \neq j$. The variables $\{\eta_j\}$, however, are not identically distributed. Using $\psi_j = x_j - \eta_j$, we can rewrite the EACD(p, q) model in equation (21.2) as:

$$x_i = \alpha_0 + \sum_{j=1}^{g} (\alpha_j + \beta_j) x_{i-j} + \eta_i - \sum_{j=1}^{q} \beta_j \eta_{i-j},$$

where $g = \max\{p, q\}$ and it is understood that $\alpha_j = 0$ for $j > p$ and $\beta_j = 0$ for $j > q$. This is in the form of an ARMA(g, q) model with AR polynomial $1 - \sum_{j=1}^{g}(\alpha_j + \beta_j)L^j$. Consequently, some properties of EACD models can be inferred from those of ARMA models.

21.2.2 Estimation of EACD models

Suppose that $\{x_1, \ldots, x_n\}$ represents a realization of an EACD(p, q) model. The parameter $\boldsymbol{\theta} = (\alpha_0, \alpha_1, \ldots, \alpha_p, \beta_1, \ldots, \beta_q)'$ can be estimated by the conditional likelihood method. Again, let $g = \max\{p, q\}$. The likelihood function of the data is:

$$f(\boldsymbol{x}_n|\boldsymbol{\theta}) = f(\boldsymbol{x}_g|\boldsymbol{\theta}) \times \prod_{i=g+1}^{n} f(x_i|\boldsymbol{x}_{i-1}, \boldsymbol{\theta}),$$

where $\boldsymbol{x}_j = (x_1, \ldots, x_j)'$. Since the joint distribution of $\boldsymbol{x}_g$ is complicated and its influence on the overall likelihood function is diminishing as n increases, we adopt the conditional likelihood method by ignoring $f(\boldsymbol{x}_g|\boldsymbol{\theta})$. This results in using the conditional likelihood estimates. Since $f(x_i|F_{i-1}, \boldsymbol{\theta}) = \frac{1}{\psi_i}\exp(-x_i/\psi_i)$, the conditional log-likelihood function of the data then becomes:

$$\ell(\boldsymbol{\theta}|\boldsymbol{x}_n) = -\sum_{i=t_o+1}^{n}\left[\ln(\psi_i) + \frac{x_i}{\psi_i}\right]. \tag{21.6}$$

The usual asymptotics of maximum likelihood estimates apply when the process $\{x_i\}$ is weakly stationary.

21.2.3 Additional ACD models

The EACD model has several nice features. For instance, it is simple in theory and in ease of estimation. But the model also encounters some weaknesses. For example, the use of the exponential distribution implies that the model has a constant hazard function. In the statistical literature, the hazard function (or intensity function) of a random variable X is defined by:

$$h(x) = \frac{f(x)}{S(x)},$$

where $f(x)$ and $S(x)$ are the probability density function and the survival function of X, respectively. The survival function of X is given by:

$$S(x) = P(X > x) = 1 - P(X \leq x) = 1 - \text{CDF}(x), \quad x > 0,$$

which gives the probability that a subject, which follows the distribution of X, survives at the time x. Under the EACD model, the distribution of the innovations is standard exponential so that the hazard function of ϵ_i is 1. As mentioned before, transaction duration in finance is inversely related to trading intensity, which in turn depends on the arrival of new information, making it hard to justify that the hazard function of duration is constant over time.

To overcome this weakness, alternative innovational distributions have been proposed in the literature. Engle and Russell (1998) entertain the Weibull distribution for ϵ_i and Zhang, Russell and Tsay (2001) consider the generalized Gamma distribution. The probability density function of a standardized Weibull random variable X is:

$$f(x|\alpha) = \begin{cases} \alpha \left[\Gamma\left(1+\frac{1}{\alpha}\right)\right]^{\alpha} x^{\alpha-1} \exp\left\{-\left[\Gamma\left(1+\frac{1}{\alpha}\right)y\right]^{\alpha}\right\}, & \text{if } x \geq 0, \\ 0 & \text{otherwise,} \end{cases} \tag{21.7}$$

where the α is referred to as the shape parameter and $\Gamma(.)$ is the usual Gamma function. The mean and variance of X are $E(X) = 1$ and $\text{Var}(X) = \Gamma(1+2/\alpha)/[\Gamma(1+1/\alpha)]^2 - 1$. The hazard function of X is:

$$h(x|\alpha) = \alpha \left[\Gamma\left(1+\frac{1}{\alpha}\right)\right]^{\alpha} x^{\alpha-1}.$$

Consequently, if $\alpha > 1$, the hazard function is a monotonously increasing function of x. If $0 < \alpha < 1$, then the hazard function is a monotonously decreasing function of x.

The probability density function of a generalized Gamma random variable X with $E(X) = 1$ is:

$$f(x|\alpha,\kappa) = \begin{cases} \frac{\alpha x^{\kappa\alpha-1}}{\lambda^{\kappa\alpha}\Gamma(\kappa)} \exp\left[-\left(\frac{x}{\lambda}\right)^{\alpha}\right], & \text{if } x > 0, \\ 0 & \text{otherwise,} \end{cases} \tag{21.8}$$

where $\lambda = \Gamma(\kappa)/\Gamma(\kappa+1/\alpha)$ with $\alpha > 0$ and $\kappa > 0$. Both α and κ are shape parameters so that the hazard function of X becomes more flexible than that of a Weibull distribution.

If ϵ_i of a duration model follows the standardized Weibull distribution with probability density function $f(x|\alpha)$ in equation (21.7), the conditional density function of x_i given F_{i-1} is:

$$f(x,\alpha) = \alpha \left[\Gamma\left(1+\frac{1}{\alpha}\right)\right]^{\alpha} \frac{x_i^{\alpha-1}}{\psi_i^{\alpha}} \exp\left\{-\left[\frac{\Gamma\left(1+\frac{1}{\alpha}\right)x_i}{\psi_i}\right]^{\alpha}\right\}, \tag{21.9}$$

which can be used to obtain the conditional log-likelihood function of the data for estimation.

If ϵ_i of a duration model follows the generalized Gamma distribution with $E(\epsilon_i) = 1$ in equation (21.8), the conditional density function of x_i given F_{i-1} is:

$$f(x_i|\alpha,\kappa) = \frac{\alpha x_i^{\kappa\alpha-1}}{(\psi_i\lambda)^{\kappa\alpha}\Gamma(\kappa)} \exp\left[-\left(\frac{x_i}{\psi_i\lambda}\right)^{\alpha}\right], \tag{21.10}$$

where, again, $\lambda = \Gamma(\kappa)/\Gamma(\kappa+1/\alpha)$. This density function can be used to perform conditional maximum likelihood estimation of the model.

In what follows, we refer to the duration model in equations (21.1)–(21.2) as the WACD(p,q) or GACD(p,q) model if the innovation ϵ_i follows the standardized Weibull or generalized Gamma distribution, respectively.

21.2.4 Quasi-maximum likelihood estimates

In real applications, the true distribution function of the innovation ϵ_i of a duration model is unknown. One may, for simplicity, employ the conditional likelihood function of an EACD model in equation (21.6) to perform parameter estimation. The resulting estimates are called the quasi-maximum likelihood estimates (QMLE). Engle and Russell (1998) show that, under some regularity conditions, QMLE of a duration model are consistent and asymptotically normal. They are, however, not efficient when the innovations are not exponentially distributed.

21.2.5 Model checking

Let $\hat{\psi}_i$ be the fitted value of the conditional expected duration of an ACD model. We define $\hat{\epsilon}_i = x_i/\hat{\psi}_i$ as the *standardized innovation* or *standardized residual* of the model. If the fitted ACD model is adequate, then $\{\hat{\epsilon}_i\}$ should behave as an i.i.d. sequence of random variables with the assumed distribution. We can use this standardized residual series to perform model checking. In particular, if the fitted model is adequate, both series $\{\hat{\epsilon}_i\}$ and $\{\hat{\epsilon}_i^2\}$ should have no serial correlations. The Ljung–Box statistics can be used to check the serial correlations of these two series. Large values of the Ljung–Box statistics indicate model inadequacy.

In addition, the quantile-to-quantile (QQ) plot of the standardized residuals against the assumed distribution of the innovations can be used to check the validity of the distributional assumption. For instance, under the WACD models, $\hat{\epsilon}_i$ should be close to the standardized Weibull distribution with shape parameter $\hat{\alpha}$. A deviation from the straight line of the QQ-plot suggests that the distributional assumption needs further improvement.

21.3 Some simple examples

In this section, we demonstrate the application of ACD models by considering two real examples.

Example 1 Consider the adjusted transaction durations of IBM stock from November 1 to November 7, 1990. The original durations are time intervals between two consecutive trades measured in seconds. Overnight intervals and zero durations were ignored. The adjustment is made to take care of the diurnal pattern of daily trading activities. The series consists of 3,534 observations and was used in Example 5.4 of Tsay (2005). Figure 21.1(a) shows the adjusted durations and Figure 21.2(a) gives the sample autocorrelation functions of the data. The autocorrelations are not large in magnitude, but they clearly indicate serial dependence in the data.

For illustration, we entertain EACD(1,1), WACD(1,1) and GACD(1,1) models for the IBM transaction durations. The estimated parameters of the three models are given in Table 21.1. The estimates of the ACD equation are rather stable for all three models, consistent with the theory that the estimates based on the exponential likelihood function are QMLE. Figure 21.1(b) shows the standardized innovations and

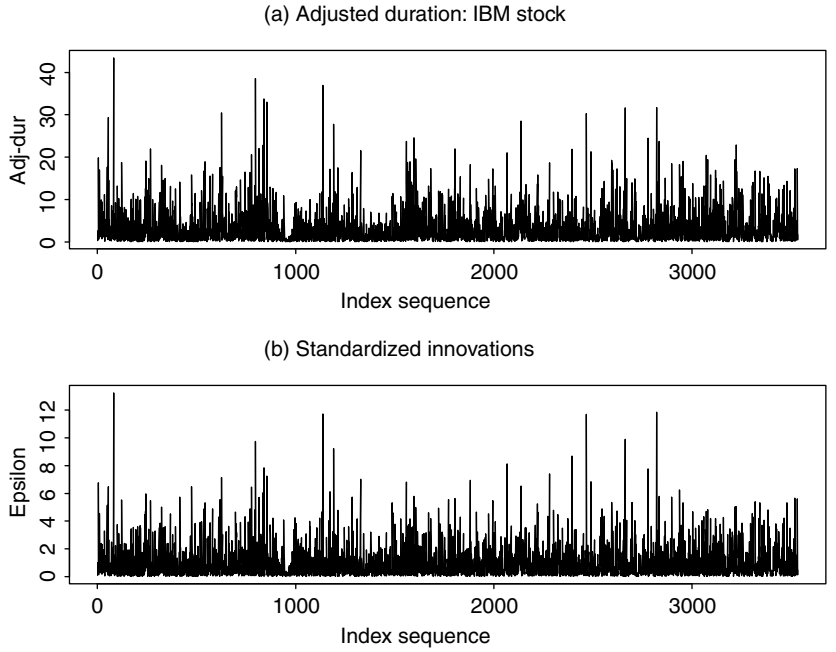

Figure 21.1 Time plots of the IBM transaction durations from November 1 to November 7, 1990: (a) adjusted durations; (b) standardized innovations of a WACD(1,1) model

Figure 21.2(b) gives the sample autocorrelation function (ACF) of the standardized innovations for the fitted WACD(1,1) model. The innovations appear to be random and their ACFs fail to indicate any serial dependence. Indeed, the Ljung–Box statistics for the standardized innovations and the squared innovations are insignificant, so that the fitted models are adequate for describing the dynamic dependence of the adjusted durations.

Figure 21.3 shows the QQ-plot of the standardized residuals versus a Weibull distribution with shape parameter 0.88 and scale parameter 1. The quantiles of the Weibull distribution are generated using a random sample of 30,000 observations. A straight line is imposed on the plot to aid interpretation. From the plot, except for a few large residuals, the assumption of a Weibull distribution seems reasonable. In this particular example, the GACD(1,1) model also fits the data well. We chose the WACD(1,1) model for its simplicity.

Finally, for the WACD(1,1) model, the estimated shape parameter α is less than 1, indicating that the hazard function of the adjusted durations is monotonously decreasing. This seems reasonable for the adjusted durations of the heavily traded IBM stock.

Example 2 In this example, we apply the ACD model to stock volatility modeling. Consider the daily range of the log price of Apple stock from January 4, 1999, to

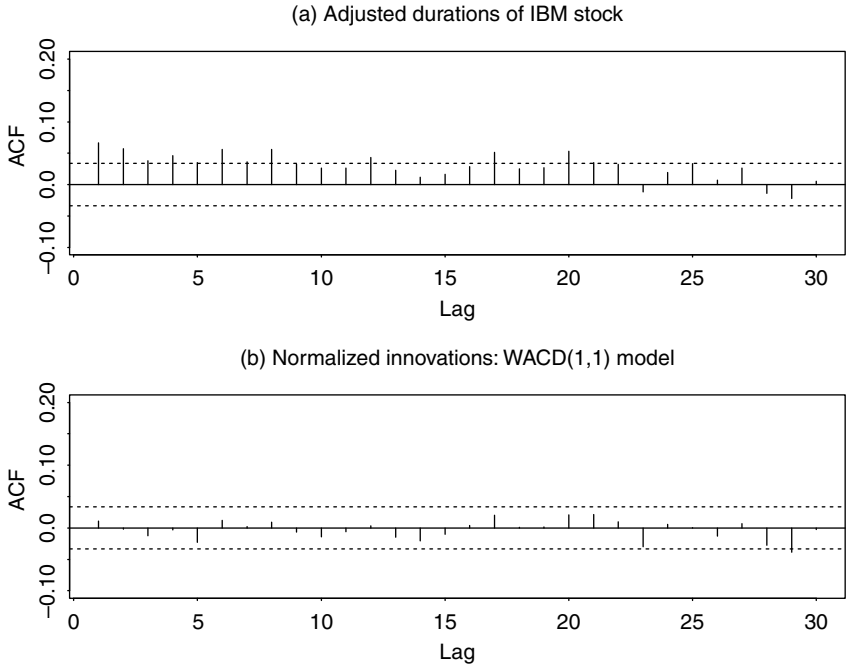

Figure 21.2 The sample autocorrelation function of IBM transaction durations from November 1 to November 7, 1990: (a) ACF of the adjusted durations; (b) ACF of the standardized residual series of a WACD(1,1) model

Table 21.1 Estimation results of EACD(1,1), WACD(1,1) and GACD(1,1) models for the IBM transaction durations of Example 1

Model	*Parameters*					*Checking*	
	α_0	α_1	β_1	α	κ	$Q(10)$	$Q^*(10)$
EACD	0.129	0.056	0.905			4.55	5.48
	(0.037)	(0.009)	(0.018)			(0.92)	(0.86)
WACD	0.125	0.056	0.906	0.880		3.85	5.51
	(0.040)	(0.010)	(0.019)	(0.012)		(0.92)	(0.85)
GACD	0.111	0.056	0.912	0.407	4.016	4.62	5.53
	(0.040)	(0.010)	(0.019)	(0.040)	(0.730)	(0.92)	(0.85)

Notes: The adjusted durations are from November 1 to November 7, 1990, with 3,534 observations. The standard errors of the estimates are in parentheses. The *p*-values of the Ljung–Box statistics are also in parentheses with $Q(10)$ and $Q^*(10)$ for standardized residual series and its squared process, respectively.

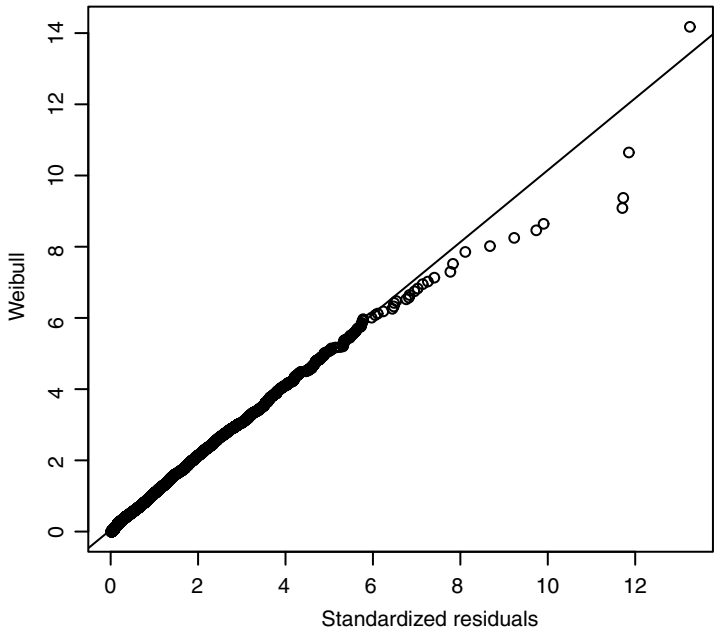

Figure 21.3 QQ-plot of the standardized residuals of the WACD(1,1) model versus a Weibull distribution
The Weibull quantiles are generated from a random sample of 30,000 observations using the shape parameter 0.88 and scale parameter 1.0.

November 20, 2007. The data are obtained from Yahoo Finance and consist of 2,235 observations. The range has been used in the literature as a robust alternative to volatility modeling (see Chou, 2005, and the references therein). Apple stock had two-for-one splits on June 21, 2000, and February 28, 2005, both during the sample period, but for simplicity we make no adjustments for the splits. Also, stock prices in the US markets switched from the tick size 1/16 of a dollar to the decimal system on January 29, 2001. Such a change affected the daily range of stock prices. We shall return to this point later. The sample mean, standard deviation, minimum and maximum of the range of log prices are 0.0407, 0.0218, 0.0068 and 0.1468, respectively. The sample skewness and excess kurtosis are 1.3 and 2.13, respectively. Figure 21.4(a) shows the time plot of the range series. The volatility seems to be increasing from 2000 to 2001, then deceasing to a stable level after 2002. It seems to increase somewhat at the end of the series. Figure 21.5(a) shows the sample ACF of the daily range series. The sample ACFs are highly significant and decay slowly.

Again, we fit the EACD(1,1), WACD(1,1), and GACD(1,1) models to the daily range series. The estimation results, along with the Ljung–Box statistics for the standardized residual series and its squared process, are given in Table 21.2. Again, the parameter estimates for the duration equation are stable for all three models, except for the constant term of the EACD model, which appears to be

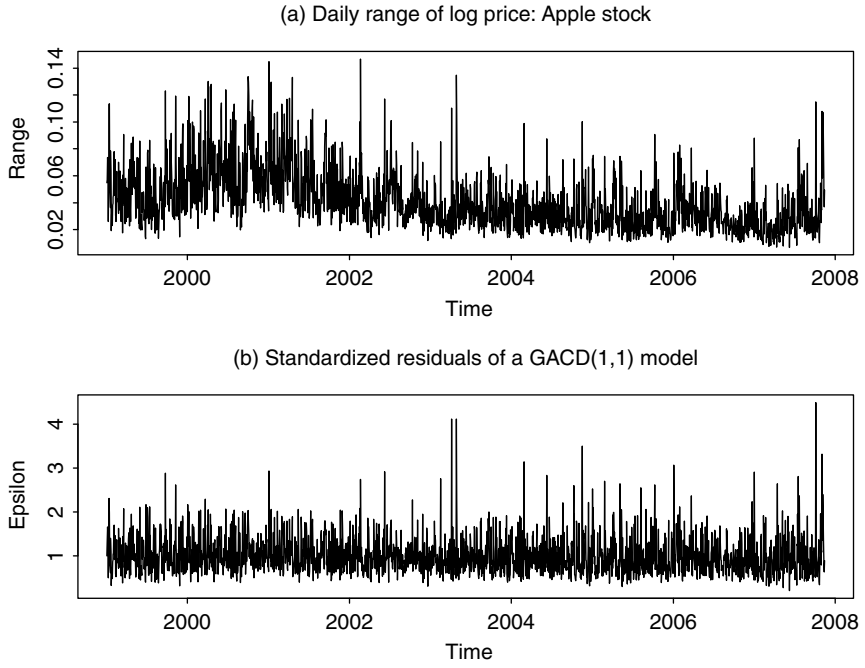

Figure 21.4 Time plots of the daily range of log price of Apple stock from January 4, 1999, to November 20, 2007: (a) observed daily range; (b) standardized residuals of a GACD(1,1) model

statistically insignificant at the usual 5% level. Indeed, in this particular instance, the EACD(1,1) model fares slightly worse than the other two ACD models. Between the WACD(1,1) and GACD(1,1) models, we slightly prefer the GACD(1,1) model, because it fits the data better and is more flexible. Figure 21.6 shows the QQ-plots of the standardized residuals versus the assumed innovation distribution for the GACD(1,1) and WACD(1,1). The plots indicate that further improvement in the distributional assumption is needed for the daily range, but they support the preference of the GACD(1,1) model.

Figure 21.5(b) shows the sample ACFs of the standardized residuals of the fitted GACD(1,1) model. From the plot, the standardized residuals do not have significant serial correlations, even though the lag-1 sample ACF is slightly above its two standard-error limit. We shall return to this point later when we introduce nonlinear ACD models. Figure 21.4(b) shows the time plot of the standardized residuals of the GACD(1,1) model. The residuals do not show any pattern of model inadequacy. The mean, standard deviation, minimum and maximum of the standardized residuals are 0.203, 4.497, 0.999, and 0.436, respectively.

It is interesting to see that the estimates of the shape parameter α are greater than 1 for both WACD(1,1) and GACD(1,1) models, indicating that the hazard function of the daily range is monotonously increasing. This is consistent with the idea

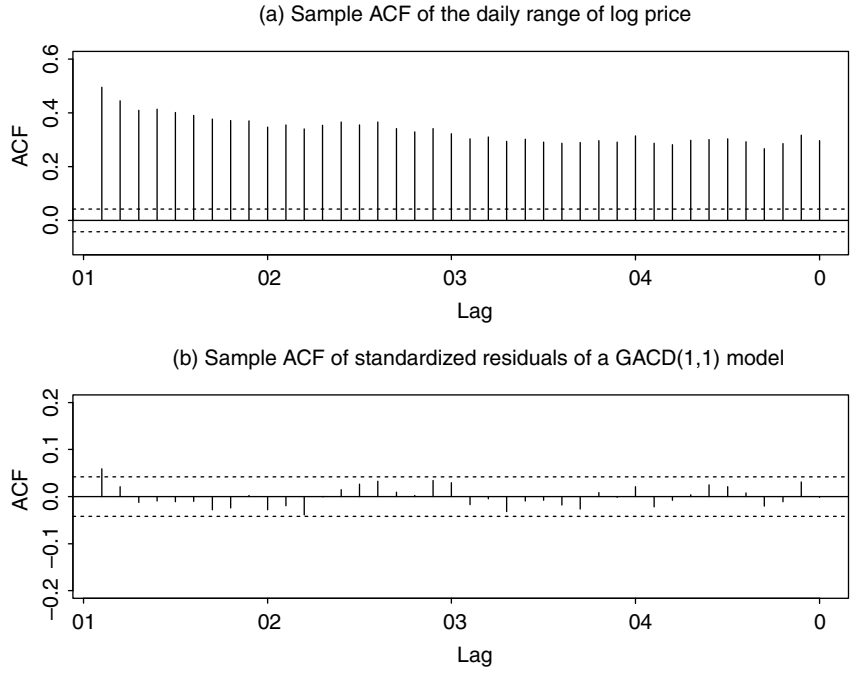

Figure 21.5 The sample autocorrelation function of the daily range of log price of Apple stock from January 4, 1999 to November 20, 2007: (a) ACF of daily range; (b) ACF of the standardized residual series of a GACD(1,1) model

of volatility clustering, for a large volatility tends to be followed by another large volatility. This phenomenon is different from that of the transaction durations in Example 1 for which $\hat{\alpha}$ is less than 1.

21.4 The diurnal pattern

In this section, we discuss a simple method to adjust the diurnal pattern of intradaily trading activities. Figure 21.7(a) shows the trade durations of General Motors (GM) stock from December 1 to December 5, 2003. Again, for simplicity, zero durations are ignored. Figure 21.7(b) shows the time intervals from the market opening (9.30 a.m. Eastern time) to the transaction time. The four vertical drops of the intervals signify the five trading days. From parts (a) and (b) of the figure, the diurnal pattern of trading activities is clearly seen. Specifically, except for a few outliers, the trade durations exhibit a cap-shape pattern within a trading day, namely the durations are in general shorter at the beginning and closing of the market, and longer around the middle of a trading day. One must consider such a diurnal pattern in modeling the transaction durations.

Table 21.2 Estimation results of EACD(1,1), WACD(1,1) and GACD(1,1) models for the daily range of log price of Apple stock from January 4, 1999, to November 20, 2007

	(0.0003)	(0.015)	(0.021)	(0.031)		(0.189)	(0.464)
GACD	0.0010	0.133	0.843	1.622	2.104	14.62	11.21
	(0.0002)	(0.015)	(0.019)	(0.029)	(0.040)	(0.147)	(0.341)

Notes: The sample size is 2,235. The standard errors of the estimates are in parentheses. The *p*-values of the Ljung–Box statistics are also in parentheses with $Q(10)$ and $Q^*(10)$ for standardized residual series and its squared process, respectively.

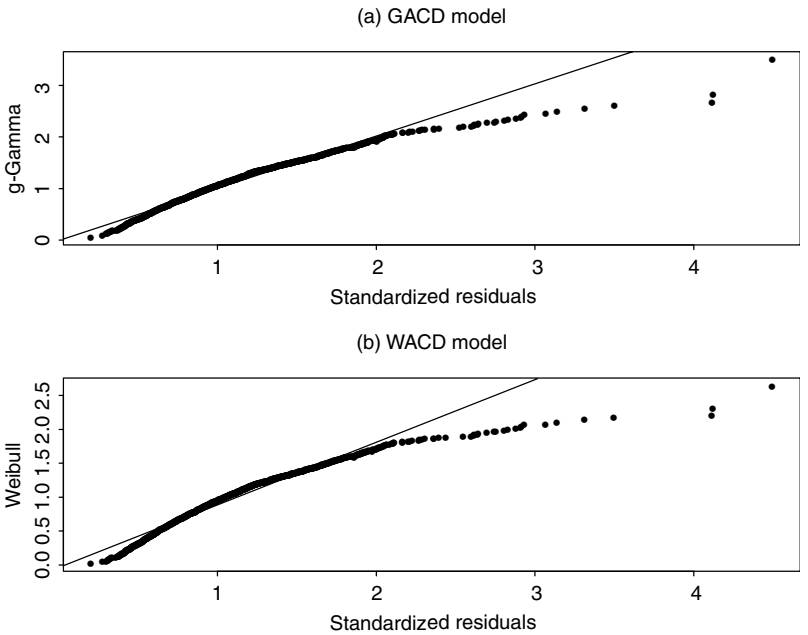

Figure 21.6 QQ-plots for the standardized residuals of ACD models for the daily range of log price of Apple stock from January 4, 1999, to November 20, 2007: (a) GACD(1,1) model; (b) WACD(1,1) model

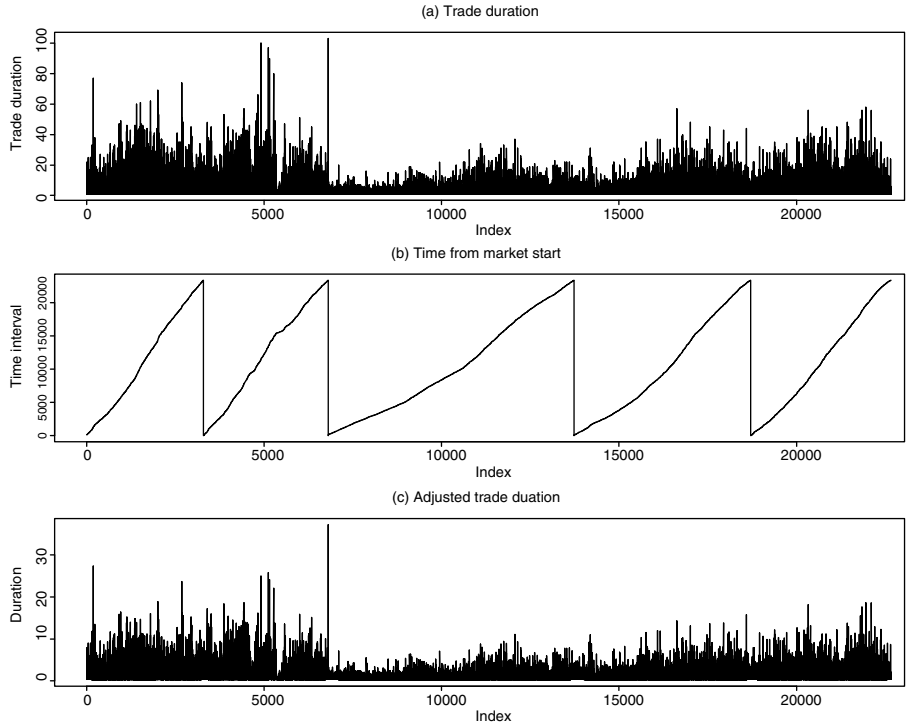

Figure 21.7 Time plots of durations for the General Motors stock from December 1 to December 5, 2003: (a) observed trade durations (positive only); (b) transaction times measured in seconds from midnight; (c) adjusted trade durations

There are many ways to remove the diurnal pattern of transaction durations. Engle and Russell (1998) and Zhang, Russell and Tsay (2001) use some simple exponential functions of time, and Tsay (2005) constructs some deterministic functions of time of the day to adjust the diurnal pattern. Let $f(t_i)$ be the mean value of the diurnal pattern at time t_i, measured from midnight. Then, define:

$$x_i = \frac{z_i}{f(t_i)}, \tag{21.11}$$

to be the adjusted duration, where z_i is the observed duration between the ith and $(i-1)$th transactions. We construct $f(t_i)$ using two simple time functions. Define:

$$O(t_i) = \begin{cases} t_i - 34200 & \text{if } t_i < 43200 \\ 0 & \text{otherwise,} \end{cases} \qquad C(t_i) = \begin{cases} 57600 - t_i & \text{if } t_i \geq 43200 \\ 0 & \text{otherwise,} \end{cases} \tag{21.12}$$

where t_i is the time of the ith transaction measured in seconds from midnight and 34200, 43200, and 57600 denote, respectively, the market opening, noon, and market closing times measured in seconds. Figures 21.8(b) and (c) show the

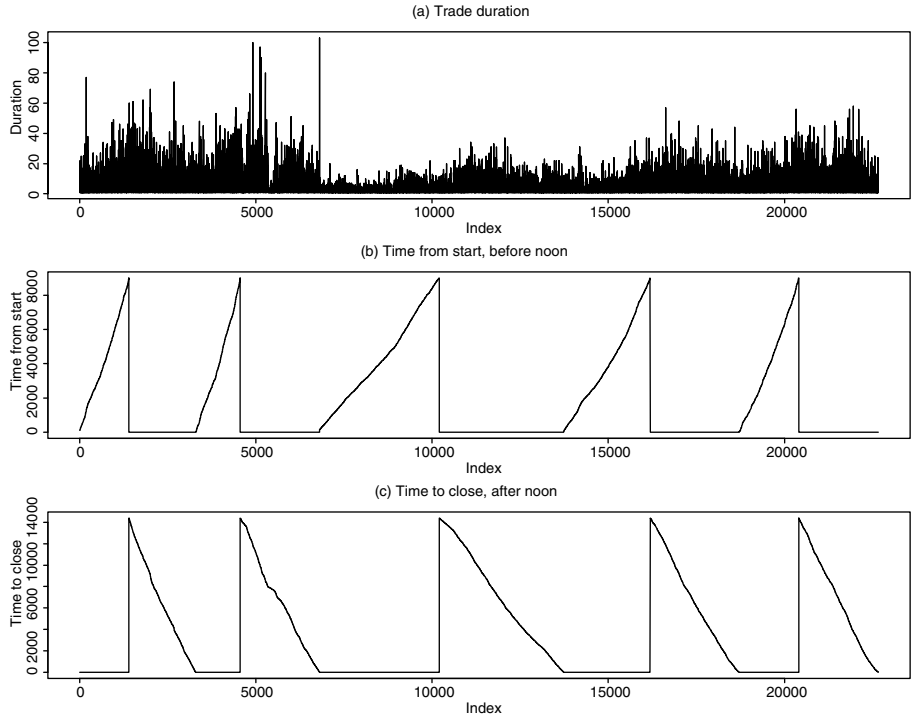

Figure 21.8 Time plots of durations for the G.M. stock from December 1 to December 5, 2003; (a) observed trade durations (positive only); (b) and (c) the time function $O(t_i)$ and time function $C(t_i)$ of equation (21.12)

time plots of $O(t_i)$ and $C(t_i)$ of the GM stock transactions. Figure 21.8(a) shows the observed trade durations as in Figure 21.7(a). From the plots, the use of $O(t_i)$ and $C(t_i)$ is justified.

Consider the multiple linear regression:

$$\ln(z_i) = \beta_0 + \beta_1 o(t_i) + \beta_2 c(t_i) + e_i, \tag{21.13}$$

where $o(t_i) = O(t_i)/10000$ and $c(t_i) = C(t_i)/10000$. Let $\hat{\beta}_i$ be the ordinary least squares estimates of the above linear regression. The residual is then given by:

$$\hat{e}_i = \ln(z_i) - \hat{\beta}_0 - \hat{\beta}_1 o(t_i) - \hat{\beta}_2 c(t_i).$$

The adjusted durations then become:

$$\hat{x}_i = \exp(\hat{e}_i). \tag{21.14}$$

For the GM stock transactions, the estimates of the β_i are 1.015(0.012), 0.133(0.028) and 0.313(0.016), respectively, where the numbers in parentheses denote standard errors. All estimates are statistically significant at the usual 1% level. Note that

the residuals of the regression in equation (21.13) are serially correlated. Thus, the standard errors shown above underestimate the true ones. A more appropriate estimation method of the standard errors is to apply the Newey and West (1987) correction. The adjusted standard errors are 0.018, 0.044 and 0.027, respectively. These standard errors are larger, but all estimates remain statistically significant at the 1% level.

Figure 21.7(c) shows the time plot of the adjusted durations for the GM stock. Compared with part (a), the diurnal pattern of the trade durations is largely removed.

21.5 Nonlinear duration models

The linear duration models discussed in the previous sections are parsimonious in their parameterization and useful in many situations. However, in financial applications, the sample size can be large and the linearity assumption of the model might become an issue. Indeed, our limited experience indicates that some nonlinear characteristics are often observed in transaction durations and daily ranges of log stock prices. For instance, Zhang, Russell and Tsay (2001) showed that simple threshold autoregressive duration models can improve the analysis of stock transaction durations. In this section, we consider some simple nonlinear duration models and demonstrate that they can improve upon the linear ACD models.

21.5.1 The threshold autoregressive duration model

A simple nonlinear duration model is the threshold autoregressive conditional duration (TACD) model. The nonlinear threshold autoregressive (TAR) model was proposed in the time series literature by Tong (1978) and has been widely used ever since (see, e.g., Tong, 1990; Tsay, 1989). A simple two-regime TACD(2;p, q) model for x_i can be written as:

$$x_i = \begin{cases} \psi_i \epsilon_{1i} & \text{if } x_{t-d} \le r, \\ \psi_i \epsilon_{2i} & \text{if } x_{t-d} > r, \end{cases} \tag{21.15}$$

where d is a positive integer, x_{t-d} is the threshold variable, r is a threshold, and:

$$\psi_i = \begin{cases} \alpha_{10} + \sum_{v=1}^{p} \alpha_{1v} x_{i-v} + \sum_{v=1}^{q} \beta_{1v} \psi_{i-v} & \text{if } x_{t-d} \le r, \\ \alpha_{20} + \sum_{v=1}^{p} \alpha_{2v} x_{i-v} + \sum_{v=1}^{q} \beta_{2v} \psi_{i-v} & \text{if } x_{t-d} > r, \end{cases}$$

where $\alpha_{j0} > 0$ and α_{jv} and β_{jv} satisfy the conditions of the ACD model stated in equation (21.2) for $j = 1$ and 2. Here j denotes the regime. The innovations $\{\epsilon_{1i}\}$ and $\{\epsilon_{2i}\}$ are two independent i.i.d. sequences. They can follow the standard exponential, standardized Weibull, or standardized generalized Gamma distribution as before. For simplicity, we shall refer to the resulting models as the TEACD, TWACD, and TGACD model, respectively. The TACD model is a piecewise linear model in

the space of x_{i-d}, and it is nonlinear when some of the parameters in the two regimes are different. The model can be extended to have more than two regimes. In what follows, we assume $p = q = 1$ in our discussion, because ACD(1,1) models fare well in many applications.

The TACD model appears to be simple, and it is indeed easy to use. However, its theoretical properties are very involved. For instance, the stationarity condition stated in equation (21.15) is only sufficient. The necessary condition of stationarity would depend on d and the parameters and deserves further investigation.

A key step in specifying a TACD model for a given time series is the identification of the threshold variable and the threshold, i.e., specifying d and r. The choice of d is relatively simple because $d \in \{1, \ldots, d_0\}$ for some positive integer d_0. For stock transaction durations, $d = 1$ is a reasonable choice as trading activities tend to be highly serially correlated. For the threshold r, a simple approach is to use empirical quantiles. Let $x_{<q>}$ be the qth quantile of the observed durations $\{x_i | i = 1, \ldots, n\}$. We assume that $r \in \{x_{<q>} | q = 60, 65, 70, \ldots, 95\}$. For each candidate $x_{<q>}$, estimate the TACD(2;1,1) model:

$$\psi_i = \begin{cases} \alpha_{10} + \alpha_{11} x_{i-1} + \beta_{11} \psi_{i-1} & \text{if } x_{t-1} \leq x_{<q>}, \\ \alpha_{20} + \alpha_{21} x_{i-1} + \beta_{21} \psi_{i-1} & \text{otherwise,} \end{cases}$$

and evaluate the log-likelihood function of the model at the maximum likelihood estimates. Denote the resulting log-likelihood value by $\ell(x_{<q>})$. The threshold is then selected by:

$$\hat{r} = x_{<q_o>} \quad \text{such that} \quad \ell(x_{<q_o>}) = \max_q \{\ell(x_{<q>}) | q = 60, 65, 70, \ldots, 95\}.$$

21.5.2 Example

In this sub-section, we revisit the series of daily ranges of the log price of Apple stock from January 4, 1999, to November 20, 2007. The standardized innovations of the GACD(1,1) model of section 21.3 have a marginally significant lag-1 autocorrelation. This serial correlation also occurs for the EACD(1,1) and WACD(1,1) models. Here we employ a two-regime threshold WACD(1,1) model to improve the fit. Preliminary analysis of the TWACD models indicates that the major difference in the parameter estimates between the two regimes is the shape parameter of the Weibull distribution. Thus, we focus on a TWACD(2;1,1) model with different shape parameters for the two regimes.

Table 21.3 gives the maximized log-likelihood function of a TWACD(2;1,1) model for $d = 1$ and $r \in \{x_{<q>} | q = 60, 65, \ldots, 95\}$. From the table, the threshold 0.04753 is selected, which is the 70th percentile of the data. The fitted model is:

$$x_i = \psi_i \epsilon_i, \quad \psi_i = 0.0013 + 0.1539 x_{i-1} + 0.8131 \psi_{i-1},$$

where the standard errors of the coefficients are 0.0003, 0.0164 and 0.0215, respectively, and ϵ_i follows the standardized Weibull distribution as:

$$\epsilon_i \sim \begin{cases} W(2.2756) & \text{if } x_{i-1} \leq 0.04753, \\ W(2.7119) & \text{otherwise,} \end{cases}$$

Table 21.3 Selection of the threshold of a TWACD(2;1,1) model for the daily range of the log price of Apple stock from January 4, 1999, to November 20, 2007

Quantile	60	65	70	75	80	85	90	95
$r \times 100$	4.03	4.37	4.75	5.15	5.58	6.16	7.07	8.47
$\ell(r) \times 10^3$	6.073	6.076	6.079	6.076	6.078	6.074	6.072	6.066

Note: The threshold variable is x_{i-1}.

where the standard errors of the two shape parameters are 0.0394 and 0.0717, respectively.

Figure 21.9(a) shows the time plot of the conditional expected duration for the fitted TWACD(2;1,1) model, i.e., $\hat{\psi}_i$, whereas Figure 21.9(b) gives the residual ACFs for the fitted model. All residual ACFs are within the two-standard-error limits. Indeed, we have $Q(1) = 4.01(0.05)$, $Q(10) = 9.84(0.45)$ for the standardized residuals and $Q^*(1) = 0.83(0.36)$ and $Q^*(10) = 9.35(0.50)$ for the squared series of the standardized residuals, where the number in parentheses denotes p-value. Note that the threshold variable x_{i-1} is also selected based on the value of the log-likelihood function. For instance, the log-likelihood function of the TWACD(2;1,1) model assumes the value 6.069×10^3 and 6.070×10^3, respectively, for $d = 2$ and 3 when the threshold is 0.04753. These values are lower than that when $d = 1$.

21.6 The use of explanatory variables

High-frequency financial data are often influenced by external events, e.g., an increase or drop in interest rates by the US Federal Open Market Committee or a jump in the oil price. Applications of ACD models in finance are often faced with the problem of outside interventions. To handle the effects of external events, the intervention analysis of Box and Tiao (1975) can be used. In this section, we consider intervention analysis in ACD modeling. We use the daily range series of Apple stock as an example. Here the intervention is the change in tick size of the US stock markets.

On January 29, 2001, all stock prices on the US markets switched to the decimal system. Before the switch, tick sizes of US stocks went through several transitions, from 1/8 to 1/16 to 1/32 of a dollar. The observed daily range is certainly affected by the tick size.

Let t_o be the time of intervention. For Apple stock, $t_o = 522$, which corresponds to January 26, 2001, the last trading day before the change in tick size. Since more observations in the sample are after the intervention, we define the indicator variable:

$$I_i^{(t_o)} = \begin{cases} 1 & \text{if } i \le t_o, \\ 0 & \text{otherwise,} \end{cases}$$

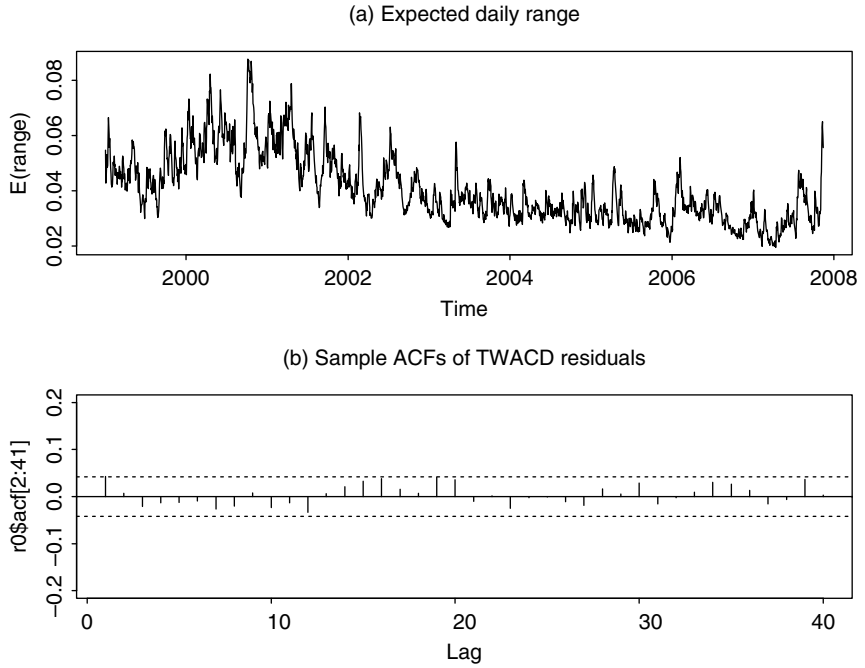

Figure 21.9 Model fitting for the daily range of the log price of Apple stock from January 4, 1999, to November 20, 2007: (a) the conditional expected durations of the fitted TWACD(2;1,1) model; (b) the sample ACF of the standardized residuals

to signify the absence of intervention. Since a larger tick size tends to increase the observed daily price range, it is reasonable to assume that the conditional expected range would be higher before the intervention. A simple intervention model for the daily range of Apple stock is then given by:

$$x_i = \psi_i \begin{cases} \epsilon_{1i} & \text{if } x_{i-1} \le 0.04753, \\ \epsilon_{2i} & \text{otherwise,} \end{cases}$$

where ψ_i follows the model:

$$\psi_i = \alpha_0 + \gamma I_i^{(t_o)} + \alpha_1 x_{i-1} + \beta_1 \psi_{i-1}, \tag{21.16}$$

where γ denotes the decrease in expected duration due to the decimalization of stock prices. In other words, the expected durations before and after the intervention are:

$$\frac{\alpha_0 + \gamma}{1 - \alpha_1 - \beta_1} \quad \text{and} \quad \frac{\alpha_0}{1 - \alpha_1 - \beta_1},$$

respectively. We expect $\gamma > 0$.

The fitted duration equation for the intervention model is:

$$\psi_i = 0.0021 + 0.0011 I_i^{(522)} + 0.1595 x_{i-1} + 0.7828 \psi_{i-1},$$

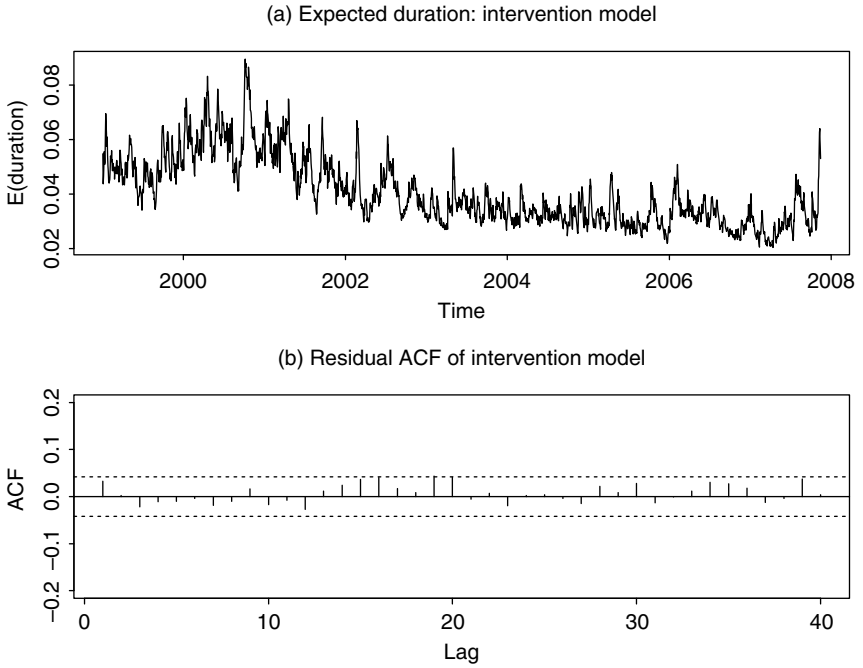

Figure 21.10 Model fitting for the daily range of the log price of Apple stock from January 4, 1999, to November 20, 2007: (a) the conditional expected durations of the fitted TWACD(2;1,1) model with intervention; (b) the sample ACF of the corresponding standardized residuals

where the standard errors of the estimates are 0.0004, 0.0003, 0.0177, and 0.0264, respectively. The estimate $\hat{\gamma}$ is significant at the 1% level. For the innovations, we have:

$$\epsilon_i \sim \begin{cases} W(2.2835) & \text{if } x_{i-1} \leq 0.04753, \\ W(2.7322) & \text{otherwise.} \end{cases}$$

The standard errors of the two estimates of the shape parameter are 0.0413 and 0.0780, respectively. Figure 21.10(a) shows the expected durations of the intervention model and Figure 21.10(b) shows the ACF of the standardized residuals. All residual ACFs are within the two standard error limits. Indeed, for the standardized residuals, we have $Q(1) = 2.37(0.12)$ and $Q(10) = 6.24(0.79)$. For the squared series of the standardized residuals, we have $Q^*(1) = 0.34(0.56)$ and $Q^*(10) = 6.79(0.75)$. As expected, $\hat{\gamma} > 0$ so that the decimalization indeed reduces the expected value of the daily range. This simple analysis shows that, as expected, adopting the decimal system reduces the volatility of Apple stock.

Note that a general intervention model that allows for changes in the dynamic dependence of the expected duration can be used, even though our analysis only allows for a change in the expected duration. Of course, more flexible models are harder to estimate and understand.

21.7 Conclusion

In this chapter, we introduced the autoregressive conditional duration models and discussed their properties and statistical inference. Among many applications, we used the model to study the daily volatility of stock prices and found that, for Apple stock, adopting the decimal system on January 29, 2001, indeed significantly reduces the price volatility.

Note

1. The estimation of all ACD models in this chapter is carried out by the FMINCON function in Matlab.

The Econometrics of Exchange Rates

Efthymios G. Pavlidis, Ivan Paya and David A. Peel

Abstract

We provide a selective overview of the econometric methods employed in modeling some of the key relationships which determine the behavior of exchange rates and the efficacy of models employed to forecast them.

22.1 Introduction

The purpose of this chapter is to provide a selective overview of the econometric methods employed in the modeling of exchange rates. Given space constraints, we can only give very brief outlines of the underlying economic theory, which is well covered in, e.g., Taylor (1995), Obstfeld and Rogoff (1996), and Sarno and Taylor (2002).

Whilst always an important focus of applied work, econometric developments, in conjunction with new high-quality datasets and the move to generalized floating exchange rates in 1973, have generated a vast number of empirical papers in the last couple of decades. Perhaps the major change in emphasis over this period has been the application of nonlinear rather than linear methods. These nonlinear models are based on theoretical models that embody factors such as transactions costs, limits to arbitrage and heterogeneity of expectations of market participants (see, e.g., Dumas, 1992; De Grauwe *et al.*, 1993; Shleifer and Vishny, 1997).

An essential building block of many macroeconomic models is that purchasing power parity (PPP) holds in the long run. PPP states that the nominal exchange rate between two currencies should be equal to the ratio of aggregate price levels between the two countries, so that a unit of currency of one country will have the same purchasing power in a foreign country. The first empirical studies employing unit root tests in the late 1980s were consistent in their failure to reject the unit root hypothesis for major real exchange rates (e.g., Taylor, 1988; Mark, 1990). Subsequent research employing longer time series datasets or panel methods suggested that the early non-rejections of the unit root hypothesis was due to low power of the corresponding test (Lothian and Taylor, 1996). However, the implied speeds of adjustment of the real exchange rate in these studies was implausibly slow, typically with half-life in the range of three to five years. Rogoff (1996, p. 647) summarized this position as follows, "How can one reconcile the enormous short-term volatility of real exchange rates with the extremely slow rate at which shocks appear to damp out?"

Perhaps the most important explanation of the Rogoff puzzle is that real exchange rates can be described by a nonlinear data-generating process (DGP) that exhibits a region of unit root or near unit root behavior near the equilibrium real exchange rate. Nonlinear models that capture this type of behavior are the threshold autoregressive model of Tong (1983), and the exponential smooth transition autoregressive model of Ozaki (1978). Econometric testing requires appropriate tests for nonlinearity, where the null can be a stationary linear process or a non-stationary linear process. In addition, the error process can exhibit heteroskedasticity due to changes in regime (e.g., fixed to floating, or different monetary regimes), as well as time-varying volatility. Consequently, the tests have to allow for this feature and critical values have been obtained by either Monte Carlo or bootstrap methods. Because many other empirical tests of aspects of exchange rate behavior employ these tests, we initially consider the econometric tests of PPP in section 22.2.

Average daily global turnover in foreign exchange market transactions was estimated at around $2.7 trillion in 2006. In an efficient speculative market, prices should fully reflect publicly available information so that it should not be possible for a trader to earn systematic abnormal returns. However, empirical estimates show that the spot exchange rate next period moves on average in the opposite direction to that currently predicted by the forward premium, the so-called forward bias puzzle. In section 22.3.1 we consider econometric tests of the covered interest parity condition and, in section 22.3.2, the uncovered interest parity condition and the various explanations of the forward bias puzzle.

If expectations are forward looking then the exchange rate regime in place, as well as the anticipation of the implementation of future exchange rate regimes, will impact on the behavior of the exchange rate. An important example of such policy arrangements are "target zones." Within this framework the authorities intervene to attempt to keep the exchange rate within a band. The recent experience of European currencies between 1979 and 1998 under the European Monetary System (EMS) is one such example.[1] In section 22.4 we consider some of the econometric testing of target zone models.

As with other asset markets, researchers have examined whether exchange rates exhibit rational speculative bubbles.[2] In section 22.5 we briefly discuss some of the more recent developments in the area.

Section 22.6 covers the issue of exchange rate forecasting. In a seminal paper, Meese and Rogoff (1983a) compared the out-of-sample forecasts produced by various exchange rate models with forecasts produced by a random walk (RW) model. On the basis of the root mean square criterion, they concluded that none of the various asset-market exchange rate models they considered outperformed a simple RW. Since then a plethora of papers have been published on this issue. We give an overview of developments. Finally, section 22.7 provides a brief conclusion of the major issues to emerge in this chapter.

22.2 Real exchange rates

The PPP hypothesis states that domestic prices in two countries should be the same when converted to a common currency. Let us define the log real exchange rate as $y_t = s_t - p_t + p_t^*$, where s_t is the logarithm of the spot exchange rate (the domestic price of foreign currency), p_t is the logarithm of the domestic price level and p_t^* the logarithm of the foreign price level.

Initial empirical studies of PPP consisted of fitting a univariate autoregressive model for the real exchange rate, $y_t = \sum_{i=1}^{p} \beta_i y_{t-i} + \varepsilon_t$. In the 1980s many empirical studies were unable to reject the unit root null hypothesis for y_t using standard unit root tests such as the augmented Dickey–Fuller (ADF) and Phillips–Perron (PP) (Taylor, 1988; Mark, 1990). In the light of these results, the first econometric issue addressed in the literature was the power of the ADF and PP tests in a linear framework. Lothian and Taylor (1996) undertook the following simulation. They generate a stationary AR(1) process calibrated with empirical estimates on data for 100 years of the dollar–pound real exchange rate as $y_t = 0.87 y_{t-1} + \varepsilon_t$.[3]

The power of both ADF and PP tests was around 45% for a sample size of 100. Caner and Kilian (2001) did a similar experiment but with the null of stationarity. They employ the Kwiatkowski *et al.* (1992) (KPSS) and Leybourne and McCabe (1994) tests. They found that, if real exchange rates were a linear autoregressive process with half-life of about three to five years ($\beta = 0.5^{(1/60)} = 0.9885$ for monthly data, and $\beta = 0.5^{(1/20)} = 0.9659$ for quarterly), they would reject the null of stationarity with about 60% probability for quarterly data and 40% for monthly data. Together, these results pointed out a serious problem with unit root and stationarity tests due to their lack of power and size, respectively.[4]

A number of authors have employed a multivariate cointegration methodology to test for a long-run relationship between exchange rates and foreign and domestic price levels in the recent floating exchange rate period (MacDonald, 1993; Baum *et al.*, 2001). The cointegrating relationship is usually specified as:

$$s_t = \alpha + \beta_1 p_t^* + \beta_2 p_t + u_t. \tag{22.1}$$

The standard empirical findings employing these methods are that cointegration cannot be rejected but the assumption of proportionality and symmetry between the nominal exchange rate and domestic and foreign prices ($\beta_1 = -\beta_2 = 1$) is not supported by the data.[5]

Theoretical analysis of purchasing power parity deviations demonstrate how transactions costs or the sunk costs of international arbitrage induce nonlinear but mean reverting adjustment of the real exchange rate (see, e.g., Dumas, 1992; Sercu *et al.*, 1995; O'Connell and Wei, 1997). Whilst globally mean reverting, these nonlinear processes have the property of exhibiting near unit root behavior for small deviations from PPP, since small deviations are left uncorrected if they are not large enough to cover transactions costs or the sunk costs of international arbitrage. The nonlinearity postulated can be captured by a set of parametric nonlinear autoregressive models. We can classify this set of nonlinear models according to the way the real exchange rate switches between regimes: first, with smooth transition models; second, with threshold autoregressive models.

22.2.1 Smooth transition (STR) models

Consider the following STR model:

$$y_t = \beta' \widetilde{y}_t + \phi' \widetilde{y}_t F(z_{t-d}; \gamma, c) + u_t, \tag{22.2}$$

where $\widetilde{y}_t = (1, y_{t-1}, \ldots, y_{t-p}, w_{t-1}, \ldots, w_{t-q})$, with w_t a vector of exogenous variables, and u_t is a white-noise sequence with mean zero and variance σ_u^2. If $\widetilde{y}_t = (1, y_{t-1}, \ldots, y_{t-p})$, the model is called a smooth transition autoregressive (STAR). We will concentrate on this case hereafter as results can easily be generalized to the STR. The variable z_{t-d} is the transition variable, the one that drives the dependent variable to move between regimes. We will consider the case that $z_{t-d} = y_{t-d}$. The STAR model can then be written as:

$$y_t = \beta_0 + \sum_{j=1}^{p} \beta_j y_{t-j} + \left(\phi_0 + \sum_{j=1}^{q} \phi_j y_{t-j} \right) F(y_{t-d}; \gamma, c) + u_t. \tag{22.3}$$

The variable y_{t-d} (though in general it could be a vector) is assumed to be stationary and ergodic and, for $d \in 1, 2, \ldots, d_{\max}$ with d the delay parameter, must satisfy $1 \leq d \leq r$ for $r = \max(p, q)$. We will only consider the case $p = q$. We are interested in the special case of a unit root in the linear polynomial, $\sum_{j=1}^{p} \beta_j = 1$. The function $F(\cdot)$ is at least fourth-order, continuously differentiable with respect to γ. There are two common forms of the STAR model. The one we will discuss here in detail is the exponential STAR (ESTAR) model of Granger and Teräsvirta (1993), in which transitions between a continuum of regimes are assumed to occur smoothly.[6] The transition function $F(\cdot)$ of the ESTAR model is:

$$F(y_{t-d}; \gamma, c) = [1 - \exp(-\gamma(y_{t-d} - c)^2)]. \tag{22.4}$$

This transition function is symmetric around $(y_{t-d} - c)$ and admits the limits:

$$\begin{aligned} F(\cdot; \gamma) &\rightarrow 1 \text{ as } |y_{t-d} - c| \rightarrow +\infty, \\ F(\cdot; \gamma) &\rightarrow 0 \text{ as } |y_{t-d} - c| \rightarrow 0. \end{aligned}$$

Parameter γ can be seen as the transition speed of the function $F(\cdot)$ towards 1 (or 0) as the deviation grows larger (smaller). The variable y_t moves between an AR of the form $y_t = \beta_0 + \phi_0 + \sum_{j=1}^{p}(\beta_j + \phi_j)y_{t-j} + u_t$ when $F(\cdot)$ is 1 and a unit root, $y_t = \beta_0 + \sum_{j=1}^{p} \beta_j y_{t-j} + u_t$, when the variable is in "equilibrium," $F(\cdot) = 0$. If $\phi_j = -\beta_j$ $\forall j$, the variable y_t would be an AR process that moves between a white noise and a unit root depending on the size of the deviation, $|y_{t-d} - c|$.[7] Unlike in a linear model, the speed of adjustment of these nonlinear models will depend on the size of the deviation from PPP. They can exhibit strong persistence and near unit root behavior.[8] Recent empirical work (e.g., Michael *et al.*, 1997; Taylor *et al.*, 2001; Paya *et al.*, 2003; Paya and Peel, 2006a) has employed monthly real exchange rates for the interwar and post-war float as well as a two-century span of annual rates and showed that the ESTAR model provides a parsimonious fit to the data.

22.2.1.1 Linearity testing against STR

When testing for the existence of the nonlinear part of (22.2) an identification problem arises. The null hypothesis of linearity corresponds to $H_0 : \phi' = 0$. Under H_0, the parameters γ and c could take any value as they are not identified under the null. Alternatively, if the null hypothesis was $H_0 : \gamma = 0$, then parameters ϕ and c would not be identified under the null. In these cases it would not be possible to differentiate between a linear or nonlinear process (see Davies, 1977).[9] This problem is solved by taking a Taylor series approximation of $F(\cdot)$ with respect to γ evaluated at $\gamma = 0$. This method was introduced by Luukkonen *et al.* (1988) and adopted by Teräsvirta (1994). A third-order Taylor expansion of the logistic function would yield:

$$y_t = \beta' \widetilde{y}_t + \frac{1}{4}\gamma \phi' \widetilde{y}_t (y_{t-d} - c) + \frac{1}{48}\gamma^3 \phi' \widetilde{y}_t (y_{t-d} - c)^3. \tag{22.5}$$

In the case of the exponential function a first-order Taylor approximation yields:

$$y_t = \beta' \widetilde{y}_t + \gamma \phi' \widetilde{y}_t (y_{t-d} - c)^2. \tag{22.6}$$

A researcher might not know which STAR model the data follows and a sensible first step would be to have a general linearity test that will include both alternative models. Teräsvirta (1994) proposes a modeling cycle consisting of the following stages:

1. Specification of a linear model.
2. Testing for linearity, $H_{L,0} : \gamma = 0$. Combining (22.5) and (22.6) and recombining in terms of identified parameters, the regression equation becomes:

$$y_t = \beta_1^{'}\tilde{y}_t + \beta_2^{'}\bar{y}_t y_{t-d} + \beta_3^{'}\bar{y}_t y_{t-d}^2 + \beta_4^{'}\bar{y}_t y_{t-d}^3 + u_t, \tag{22.7}$$

   where $\bar{y}_t = (y_{t-1}, \ldots, y_{t-p})$. The linearity test has null hypothesis $H_{L,0} : \beta_2^{'} = \beta_3^{'} = \beta_4^{'} = 0$ and the original hypothesis can be tested by applying the Lagrange multiplier (LM) principle. The appropriate transition variable lag in the STR model can be determined without specifying the form of the transition function. We can compute the F-statistic for $H_{L,0}$ for various values of d (and different z_t variables) and select the one for which the p-value of the test is smallest.
3. Selecting the transition function. The choice between ESTAR and LSTAR models can be based on the following sequence of null hypotheses:

$$\begin{aligned} H_{03} &: \ \beta_4 = 0, \\ H_{02} &: \ \beta_3 = 0 \mid \beta_4 = 0, \\ H_{01} &: \ \beta_2 = 0 \mid \beta_3 = \beta_4 = 0. \end{aligned}$$

   If the p-value for the F-test of H_{02} is smaller than that for H_{01} and H_{03} then we select the ESTAR family, otherwise we choose the LSTAR family.

While Teräsvirta (1994) uses a third-order Taylor expansion of the logistic function and a first-order expansion for the exponential function, Escribano and Jordä (1999) (EJ) augment the regression equation with a second order expansion of the exponential function:[10]

$$y_t = \beta_1^{'}\tilde{y}_t + \beta_2^{'}\bar{y}_t y_{t-d} + \beta_3^{'}\bar{y}_t y_{t-d}^2 + \beta_4^{'}\bar{y}_t y_{t-d}^3 + \beta_5^{'}\bar{y}_t y_{t-d}^4 + v_t. \tag{22.8}$$

EJ claim that this procedure improves the power of both the linearity test and the selection procedure test. The null hypothesis of linearity corresponds to $H_0 : \beta_2^{'} = \beta_3^{'} = \beta_4^{'} = \beta_5^{'} = 0$. Under this null the LM test is asymptotically χ^2. The selection procedure between ESTAR and LSTAR is as follows:

1. Test the null $H_0 : \beta_3^{'} = \beta_5^{'} = 0$ with an F-test (F_E).
2. Test the null $H_0 : \beta_2^{'} = \beta_4^{'} = 0$ with an F-test (F_L).
3. If the p-value of F_E is lower than F_L then select an ESTAR. Choose an LSTAR otherwise.

If the errors display heteroskedasticity, Granger and Teräsvirta (1993) suggest ways of making the testing procedure more robust.[11] However, Lundbergh and

Teräsvirta (1998) conclude that conditional heteroskedasticity may result in severe size distortions and that the robust version of Granger and Teräsvirta (1993) appears to have very low power.[12] Pavlidis *et al.* (2007) investigate the performance of possible alternatives to improve the properties (size and power) of linearity LM tests using heteroskedasticity consistent covariance matrix estimators (HCCME) and the wild bootstrap.[13] They show that in the case of the LM linearity tests, the fixed-design wild bootstrap appears to improve tests both in terms of size and size-adjusted power.

However, besides the functional form of the real exchange rate, a major concern in the PPP literature is that real exchange rates follow a RW. Kapetanios *et al.* (2003a) (KSS) develop a test with a linear unit root null against the alternative of a stationary ESTAR. Their test is also based on a Taylor approximation of the nonlinear autoregressive model. For simplicity, assuming $p = 1$, $d = 1$, $\beta_1 = 1$, $\phi_1 = -\beta_1$, $c = 0$, then (22.3) becomes:

$$y_t = y_{t-1} + \left[1 - \exp\left(-\gamma y_{t-1}^2\right)\right](-y_{t-1}) + u_t. \tag{22.9}$$

Using the first-order Taylor expansion (22.6) in this particular case:

$$y_t = y_{t-1} - \delta(y_{t-1})(y_{t-1})^2 \Rightarrow \Delta y_t = \delta y_{t-1}^3 + u_t. \tag{22.10}$$

Under the null hypothesis of linearity, $H_0 : \gamma = 0$, $\Delta y_t = u_t$. KSS also consider the more general case where model (22.9) includes deterministic components. To ease notation, let $y_t^* = y_t - \hat{c}' x_t$ where $x_t = (1, t)$, and $\hat{c}'$ denotes least squares estimates. Then we can rewrite equation (22.10) as:

$$\Delta y_t^* = \sum_{j=1}^{p} a_j \Delta y_{t-j}^* + \delta y_{t-1}^{*3} + u_t, \tag{22.11}$$

where lags of the dependent variable address the issue of possible error autocorrelation. Testing for $\delta = 0$ against $\delta < 0$ corresponds to testing the null hypothesis. The t-statistic for the null of a linear unit root is given by:

$$t_{NL}(\hat{c}') = \frac{\hat{\delta}}{s.e(\hat{\delta})}, \tag{22.12}$$

where $s.e(\hat{\delta})$ denotes the standard error of $\hat{\delta}$. The asymptotic distribution of (22.12) is not standard but converges weakly to a complicated functional of Brownian motions.[14] Asymptotic critical values for the $t_{NL}(\hat{c}')$ statistics have been tabulated via stochastic simulation. KSS use quarterly data for bilateral real exchange rates for 11 OECD countries against the dollar covering the period 1957–98. While the ADF test was unable to reject the null of a unit root in any of the rates, the KSS test rejected the null in favor of an ESTAR in six cases, thus giving support to PPP.[15]

The linearity tests reviewed so far test the null of linear stationarity or a linear unit root process against a globally stationary nonlinear process in levels. Harvey and Leybourne (2007) (HL) develop a testing procedure for the null of linearity

against nonlinearity. Rejection of the null is therefore indicative of nonlinearity and not that the DGP follows a different linear process.

The HL test consists of two steps. First is the test of linearity. Second, the order of integration of the linear or nonlinear process is determined. Consider the linearity test (22.7) described above for the case of the null of linear $I(0)$. In the case of an $I(1)$ variable, the Taylor expansion would become (considering the transition variable is y_{t-1}):

$$\Delta y_t = \varphi_0 \Delta y_{t-1} + \varphi_1 (\Delta y_{t-1})^2 + \varphi_1 (\Delta y_{t-1})^3 + \varepsilon_t.$$

In order to combine both possibilities, $I(0)$ and $I(1)$, HL propose the following regression model:

$$y_t = \alpha_0 + \alpha_1 y_{t-1} + \alpha_2 y_{t-1}^2 + \alpha_3 y_{t-1}^3 + \alpha_4 \Delta y_{t-1} + \alpha_5 (\Delta y_{t-1})^2 + \alpha_6 (\Delta y_{t-1})^3 + \varepsilon_t. \tag{22.13}$$

The null hypothesis of linearity would be $H_{0L} : \alpha_2 = \alpha_3 = \alpha_5 = \alpha_6 = 0$. The alternative hypothesis (nonlinearity) would be that at least one of those αs is different from zero. This test is carried out using the Wald statistic:

$$W_T = \frac{RSS_1 - RSS_0}{RSS_0 / T},$$

where the restricted residual sum of squares (RSS_1) comes from an ordinary least squares (OLS) regression of y_t on a constant, y_{t-1}, and Δy_{t-1}. As HL point out, the distribution of W_T under the null differs depending on whether the process followed by y_t is $I(0)$ or $I(1)$. In order to make the limiting distribution of W_T homogeneous under the null they multiply it with a correction that is the exponential of a weighted inverse of the absolute value of the ADF statistic:[16]

$$W_T^* = \exp\left(-b \left| DF_T \right|^{-1}\right) W_T, \tag{22.14}$$

where an expression for the value of b is provided such that, for a given significance level, the critical value of W_T^* coincides with that from a $\chi^2(4)$. They also prove that, under H_1, W_T^* is consistent at the rate $O_p(T)$.

The second step is to test whether the series is an $I(0)$ or an $I(1)$ process. HL use the Harris *et al.* (2003) statistic to distinguish between $I(0)$ or $I(1)$ processes regardless of whether nonlinearity is present or not. HL apply their testing methodology to the monthly real exchange rates of 15 European countries against the dollar and find evidence of PPP (linear $I(0)$ or nonlinear $I(0)$) in only two of them, Finland and the Netherlands. Notwithstanding, from a theoretical point of view, evidence that the real exchange rate follows a nonlinear $I(1)$ process would not be considered evidence in support of PPP.

22.2.1.2 Nonlinear STR estimation

Once the functional form of the real exchange rate has been determined using linearity testing, the next step is to review the nonlinear estimation procedure.[17]

The unrestricted ESTAR model considered here has the following form:

$$y_t^* = \sum_{j=1}^{p} \varphi_j y_{t-j}^* + \left(\sum_{j=1}^{p} \varphi_j^* y_{t-j}^* \right) \left[1 - \exp\left(-\gamma \left(y_{t-d}^* \right)^2 \right) \right] + u_t, \tag{22.15}$$

where y_t^* denotes de-meaned, detrended or in-deviation data.[18] In the estimation of the nonlinear model, γ is estimated by scaling it by the variance of the transition variable. This scaling is suggested for two reasons. One is to avoid problems in the convergence of the algorithm. Second, it makes it easier to compare speeds of adjustment across different studies (see Teräsvirta, 1994).[19]

Since the t-ratio of the estimated coefficient γ in (22.15) does not provide a valid significance test in the usual way, its critical values must be obtained by simulation.[20] The estimation technique can be nonlinear least squares (NLS) or maximum likelihood. Under the assumption that u_t is normally distributed, NLS is equivalent to maximum likelihood, otherwise, NLS estimates can be interpreted as quasi-maximum likelihood estimates. Wooldridge (1994) and Pötscher and Prucha (1997) discuss regularity conditions that allow consistent and asymptotically normal estimators.

The adequacy of the estimated STR model can be evaluated employing the LM-type diagnostic tests for the hypothesis of no error autocorrelation, (the customary portmanteau test has an unknown asymptotic null distribution), nonlinearity and parameter constancy of Eitrheim and Teräsvirta (1996). The last two tests address important issues of misspecification due to neglected nonlinearity and possible parameter instability.

The nonlinear models reported in empirical work have been estimated on data sampled at different levels of aggregation, namely monthly, quarterly and annual (see, e.g., Michael *et al.*, 1997; Taylor *et al.*, 2001; Taylor and Kilian, 2003; Paya *et al.*, 2003).[21] As noted by Taylor (2001), if the true DGP is nonlinear, the temporally aggregated data could exhibit misleading properties regarding the adjustment speeds if a linear model is estimated. Paya and Peel (2006c) complement this work by examining the effects of different levels of temporal aggregation of an ESTAR DGP on aggregate estimates of ESTAR models.[22] They show that ESTAR type nonlinearities are usually preserved under the temporal aggregation schemes examined. However, the dynamic structure of the best fitting models changes and tends to take the form researchers have found to fit well on actual data of the same frequency. Furthermore, comparison of the measured speed of response to shocks with models estimated on the temporally aggregated data and the true DGP shows that the measured speed of adjustment declines the more aggregated the data.

22.2.1.3 Time-varying equilibrium real exchange rate

A variety of theoretical models, such as those of Balassa (1964), Samuelson (1964), Lucas (1982), and Backus and Smith (1993), imply a non-constant equilibrium in the real exchange rate and estimates, including proxies for the equilibrium determinants, appear significant (see, e.g., Lothian and Taylor, 2000; Hegwood and Papell, 2002). Paya and Peel (2004, 2006a), employing various proxies, show the estimated

speeds of mean-reversion to be much faster than when it is assumed constant, with the half-life of shocks to the real exchange rate being less than two years.

However, Paya and Peel (2006a) also highlight the possibility of spurious relationships in nonlinear models if standard critical values are considered as valid when a persistent variable or vector of variables (x_t) are included as proxies for the equilibrium level of the real exchange rate in the ESTAR model:

$$y_t = \alpha + \delta x_t + \exp\left(-\gamma(y_{t-1} - \alpha - \delta x_{t-1})^2\right) \sum_{i=1}^{p} \beta_i (y_{t-i} - \alpha - \delta x_{t-i}) + u_t. \quad (22.16)$$

The bootstrap methodology is used to provide a better finite sample approximation to the distribution of a particular estimator in cases where classical asymptotic theory might not yield a reliable guide.[23] If the true DGP admits heteroskedasticity of unknown form, it cannot be replicated in the bootstrap DGP. The bootstrap method called the wild bootstrap solves this problem by using the following procedure (see, e.g., Wu, 1986; Mammen, 1993; Davidson and Flachaire, 2001).[24]

The null hypothesis is that the coefficients (δ) on the proxy variables for the equilibrium real exchange rate are zero. Accordingly, an "artificial"series for y_t ($\widehat{y}_t^b$) is simulated using previously estimated coefficients of the ESTAR model (22.16) and setting the coefficients of the equilibrium determinants (δ) equal to zero:

$$\widehat{y}_i^b = \widehat{\alpha} + \exp\left(-\widehat{\gamma}(y_{t-1} - \widehat{\alpha})^2\right) \sum_{i=1}^{p} \hat{\beta}_i (y_{t-i} - \widehat{\alpha}) + u_i^b, \quad (22.17)$$

where the $i = 1, \ldots, B$ are replications. The residuals u_i^b are obtained from bootstrapping the estimated residuals ($\widehat{u}_t$) obtained from the ESTAR model (22.16) which includes the equilibrium determinants.[25] In other words, every replication employs the actual residuals from regression (22.16) and creates a new series of residuals (u_i^b) based on $\widehat{u}_t$ as follows:

$$u_i^b = \widehat{u}_t \epsilon_i,$$

where ϵ_i is drawn from the following two-point distribution:

$$\epsilon_i = \begin{cases} -(\sqrt{5}-1)/2 & \text{with probability } p = \dfrac{(1+\sqrt{5})}{2\sqrt{5}}, \\ (\sqrt{5}+1)/2 & \text{with probability } (1-p). \end{cases}$$

The ϵ_i are mutually independent drawings from a distribution independent of the original data. The distribution has the properties that $E(\epsilon_i) = 0$, $E(\epsilon_i^2) = 1$, and $E(\epsilon_i^3) = 1$.[26] A consequence of these properties is that any heteroskedasticity in the estimated residuals ($\widehat{u}_t$) is preserved in the newly created residuals, u_i^b.[27]

This procedure provides an empirical distribution for $\widehat{\delta}$ and their associated standard errors. The idea in using B replications is to determine the appropriate t-values and F-statistic so we do not reject the null of $\widehat{\delta} = 0$. These critical values can then be used to determine whether the estimates of $\widehat{\delta}$ reject the null or not. Paya and Peel (2006a) find that the hypothesis that the real dollar–sterling rate follows an ESTAR process with time-varying equilibrium proxied by productivity differentials and/or wealth cannot be rejected at the usual significance level.[28]

22.2.2 Threshold autoregressive (TAR) models

If the transition between regimes is assumed abrupt rather than smooth the dynamics of PPP adjustment can be captured by the TAR model of Tong (1983). Empirical studies that use TAR models for deviations from PPP include Obstfeld and Taylor (1997) and Sarno *et al*. (2004a). One of the advantages of this methodology is the direct estimation of the transaction cost band or threshold band. For illustrative purposes we start by describing the estimation of a simple symmetric threshold TAR model of order one employed in some of the empirical work previously mentioned:[29]

$$y_t = \begin{cases} a_0 + a_1 y_{t-1} + u_t & \text{if } z_{t-d} \leq c, \\ b_0 + b_1 y_{t-1} + u_t & \text{if } z_{t-d} > c, \end{cases} \tag{22.18}$$

where z_{t-d} is the transition variable, in our case $z_{t-d} = y_{t-d}$.[30] The integer d is called the delay lag and is typically unknown, so it must be estimated. As we will shortly explain, the least squares principle allows d to be estimated along with the other parameters. Parameter c is the "threshold" that distinguishes two regimes: (i) transition variable z_{t-d} is below c (lower regime); (ii) transition variable z_{t-d} is above c (upper regime). Then, parameter vectors $\boldsymbol{\alpha} = (a_0, a_1)'$ and $\mathbf{b} = (b_0, b_1)'$ determine the response of the real exchange rate to changes in its last period's value.

If the threshold value, c, was known, then to test for threshold behavior all one needs is to test the hypothesis $H_0 : \boldsymbol{\alpha} = \mathbf{b}$. Unfortunately, the threshold value is typically unknown and, under the null hypothesis, parameter c is not identified. The second difficult statistical issue associated with TAR models is the sampling distribution of the threshold estimate. Hansen (1997) provides a bootstrap procedure to test H_0, develops an approximation to the sampling distribution of the threshold estimator free of nuisance parameters, and also develops a statistical technique that allows confidence interval construction for c.[31] In particular, we can write the TAR model (22.18) compactly as:

$$y_t = x_t(c)'\theta + u_t, \tag{22.19}$$

where $x_t(c) = (x_t' \mathbf{1}\{z_{t-d} \leq c\}, x_t' \mathbf{1}\{z_{t-d} > c\})'$ with $x_t = (1, y_{t-1})'$, $\mathbf{1}\{\cdot\}$ the indicator function and $\theta = (\boldsymbol{\alpha}', \mathbf{b}')'$. For a given value of c the least squares (LS) estimate of θ is:

$$\hat{\theta}(c) = \left(\sum x_t(c) x_t(c)' \right)^{-1} \left(\sum x_t(c) y_t \right),$$

with LS residuals $\widehat{u}(c)_t$ and LS residual variance $\sigma_T^2(c) = (1/T) \sum_{t=1}^{T} \hat{u}^2(c)_t$. Then the LS estimate of c is the value:

$$\hat{c} = \arg\min_{c \in C} \sigma_T^2(c), \tag{22.20}$$

where C is an interval (usually trimmed) that covers the sample range of the transition variable. Problem (22.20) can be solved by a direct search over C. The LS

estimate of θ is then $\hat{\theta} = \hat{\theta}(\hat{c})$. Furthermore, the LS principle allows the estimation of the, typically, unknown value d by extending problem (22.20) to a search across the discrete space $[1, \bar{d}]$.

The hypothesis $H_0 : \boldsymbol{\alpha} = \mathbf{b}$ is tested as follows. Let $\{e_t\}_{t=1}^{T}$ be an i.i.d. sequence of $N(0,1)$ draws. Regress e_t on x_t to obtain the residual variance $\hat{\sigma}_T^2$ and on $x_t(c)$ to obtain $\hat{\sigma}_T^2(c)$ and compute $F(c) = T(\hat{\sigma}_T^2 - \hat{\sigma}_T^2(c))/\hat{\sigma}_T^2(c)$. Then compute $F = \sup_{c \in C} F(c)$. Repeat the procedure n times and the asymptotic p-value of the test is given by the percentage of samples for which F exceeds the observed F_T. Hansen (1997) also provides critical values and a method to construct asymptotically valid confidence intervals.[32]

In the last decade the basic TAR model has been extended. New unit root tests against these TAR models have been used as tests for PPP. We detail below some of those tests that include TAR models but differ according to the nature of the transition variable (in levels or in differences), the symmetry or asymmetry of the bands, the autoregressive process within each region (unit root, stationary AR), and the number of regimes.

22.2.2.1 Unit root test versus TAR

Enders and Granger (1998) (EG) modify the Dickey–Fuller (DF) critical values of the F-statistic in order to have the right size to test the unit root null against TAR, or momentum-TAR (M-TAR) models. In particular, they consider the F-statistic of the null unit root hypothesis ($H_0 : \rho_1 = \rho_2 = 0$) in the following TAR model:

$$\Delta y_t = \begin{cases} \rho_1 y_{t-1} + u_t & \text{if } y_{t-1} \leq 0, \\ \rho_2 y_{t-1} + u_t & \text{if } y_{t-1} > 0, \end{cases} \tag{22.21}$$

and also for the M-TAR model:

$$\Delta y_t = \begin{cases} \rho_1 y_{t-1} + u_t & \text{if } \Delta y_{t-1} \leq 0, \\ \rho_2 y_{t-1} + u_t & \text{if } \Delta y_{t-1} > 0. \end{cases} \tag{22.22}$$

EG show that the power of their test improves relative to the standard ADF as the asymmetric adjustment becomes more pronounced.[33]

An alternative threshold unit root test is developed by Basci and Caner (2005) (BC). They consider the following M-TAR model:

$$\Delta y_t = \begin{cases} \theta_1' x_{t-1} + e_t & \text{if } |y_{t-1} - y_{t-m-1}| < \lambda, \\ \theta_2' x_{t-1} + e_t & \text{if } |y_{t-1} - y_{t-m-1}| \geq \lambda, \end{cases} \tag{22.23}$$

where $x_{t-1} = (y_{t-1}, 1, \Delta y_{t-1}, ..., \Delta y_{t-k})$ for $t = 1, 2, ..., T$. e_t is an i.i.d. error term, m represents the delay parameter and $1 \leq m \leq k$. It is possible to rewrite the model above as follows:

$$\Delta y_t = \theta_1' x_{t-1} \mathbf{1}_{\{|y_{t-1} - y_{t-m-1}| < \lambda\}} + \theta_2' x_{t-1} \mathbf{1}_{\{|y_{t-1} - y_{t-m-1}| \geq \lambda\}} + e_t. \tag{22.24}$$

The expression above is estimated using OLS for each $\lambda \in \Lambda$ and the OLS estimate[34] of σ^2 is then $\widehat{\sigma}^2(\lambda) = T^{-1} \sum_{t=1}^{T} \widehat{e}_t(\lambda)^2$. The estimated threshold parameter λ is the one that minimizes the error variance: $\widehat{\lambda} = \arg\min_{\lambda \in \Lambda} \widehat{\sigma}^2(\lambda)$. Testing linearity reduces to $H_0 : \theta_1 = \theta_2$. BC propose the following test:

$$\sup_{\lambda \in \Lambda} W_T(\lambda) = \sup_{\lambda \in \Lambda} T \left(\frac{\widehat{\sigma}_0^2}{\widehat{\sigma}^2(\widehat{\lambda})} - 1 \right), \tag{22.25}$$

where $\widehat{\sigma}_0^2$ is the residual variance from simple OLS estimation of the null linear model. Following Caner and Hansen (2001), BC resort to a bootstrap approximation of the distribution of W_T to obtain p-values. They tested the nonlinear behavior of 14 OECD real exchange rates and found that 11 of them display a unit root inside the band and mean reversion outside the band.[35]

This section has examined recent developments in linearity testing and the autoregressive modeling of real exchange rates. The overall conclusion is that nonlinear models provide considerably greater support for the PPP hypothesis and that the PPP puzzle is largely resolved by them.

22.3 International parity conditions

22.3.1 Covered interest parity (CIP)

In the absence of frictions such as transactions costs or limits to arbitrage funds, riskless arbitrage should ensure that the covered interest differential on assets of identical characteristics should be equal to zero. Employing the usual approximations, we have that:

$$i_t - i_t^* = f_t - s_t, \tag{22.27}$$

where i_t, i_t^* are the interest rates on the domestic and foreign assets concerned, f_t is the logarithm of the forward exchange rate (the rate at which the future exchange of currencies is agreed at time t) of the same term to maturity as the assets, and s_t is the spot exchange rate (domestic price of foreign currency).

Whether CIP holds is of interest for at least three reasons. First, absence of CIP, given its riskless nature in principle, would *ceteris paribus* imply that the efficient markets assumption approach to modeling exchange rates (or asset prices in general) had very serious limitations. Second, CIP forms a basis with uncovered interest arbitrage (see below) to determining the properties of the forward rate as a predictor of future movements in the spot rate. Uncovered interest arbitrage could hardly be expected to hold in the absence of CIP. Finally, it is assumed in numerous models that covered and uncovered parity hold. Many empirical tests of the covered interest rate condition have been undertaken.[36] Taylor (1987, 1989), unlike in most previous studies, employs high frequency contemporaneously sampled data for spot and forward dollar–sterling and dollar–Mark exchange rates and corresponding euro-deposit interest rates for a number of maturities and makes allowance for bid-ask spreads and brokerage costs in his calculations for the 1980s and selected

post-war periods. His evidence suggests that there are few profitable violations of CIP, even during periods of market uncertainty and turbulence, which contrasts with the results in earlier studies, thus illustrating the crucial role that appropriately sampled data can play.

A second method for testing CIP widely used in the early literature is to employ regression analysis and test whether $\alpha = 0$ and $\beta = 1$ in the regression:

$$f_t - s_t = \alpha + \beta(i_t - i_t^*) + u_t. \tag{22.28}$$

If CIP holds, on average we should obtain estimates of α and β differing insignificantly from zero and one, respectively. However, as noted by Taylor (1987), $\widehat{\alpha} = 0$ and $\widehat{\beta} = 1$ is a necessary but not a sufficient condition for CIP to hold. These restrictions could be met but the error term might be of such magnitude as to permit substantial arbitrage possibilities.

A more recent approach to modeling deviations from CIP is to employ univariate threshold models (see Balke and Wohar, 1998; Peel and Taylor, 2002).[37] The rationale of the univariate threshold model is, of course, to capture the transactions band that arbitrageurs face in reality. This method of analysis was explained in section 22.2. A complementary method is to model the dynamics of adjustment of each component of CIP by the threshold error correction model set out by Balke and Fomby (1997).

Peel and Taylor (2002) applied this model, as well as the univariate threshold model, to weekly data in the interwar period 1922–25. We outline their method for estimating the threshold error correction model. If we define the vector $X_t = (i_t, i_t^*, f_t - s_t)'$, the deviation from CIP, δ_t, may be viewed as an error correction term relating the three elements of X_t, since $\delta_t = f_t - s_t - (i_t - i_t^*)$. A simple first-order threshold vector error correction model (TVECM) may be written as:

$$\Delta X_t = \begin{cases} E_t & \text{if } |\delta_{t-1}| < \kappa, \\ \theta + \Gamma\delta_{t-1} + E_t & \text{if } \delta_{t-1} \geq \kappa, \\ -\theta + \Gamma\delta_{t-1} + E_t & \text{if } \delta_{t-1} \leq -\kappa, \end{cases} \tag{22.29}$$

where E_t is a (3×1) disturbance vector, and Γ and θ are (3×1) parameter vectors. Within the band, the error correction term has no effect on any of the variables and there is no tendency to adjust toward CIP. However, once outside the band, we expect at least one of the elements in Γ to be non-zero. In that case, one or more of $f_t - s_t$, i_t, and i_t^* adjust toward CIP so that δ_t also adjusts. The statistical significance and relative size of the estimated elements of Γ, the error correction parameters, should give an indication of the relative speeds of adjustment of the components of CIP to large deviations from CIP.

If we define the indicator variables $\mathbf{1}(|\delta_{t-1}| < \kappa)$, $\mathbf{1}(\delta_{t-1} \geq \kappa)$ and $\mathbf{1}(\delta_{t-1} \leq -\kappa)$, each of which takes the value unity when the inequality indicated in parentheses is satisfied, and zero otherwise, the TVECM may be written as a set of dummy variable regressions:

$$\Delta X_t = \mathbf{1}(\delta_{t-1} \geq \kappa)\theta - \mathbf{1}(\delta_{t-1} \leq -\kappa)\theta + [1 - \mathbf{1}(|\delta_{t-1}| < \kappa]\Gamma\delta_{t-1} + E_t. \tag{22.30}$$

Estimation may be carried out by nonlinear least squares through a grid search over κ. However, given the need to form an overall objective function from three sets of residuals, it is easier in the multivariate case to employ maximum likelihood estimation. The concentrated log-likelihood function for this system, for known κ, is:

$$L(\theta, \Gamma, \Sigma, \kappa) = \frac{-T}{2}\left(3\left\{1 + \ln(2\pi)\right\} + \ln\left|\widehat{\Sigma}\right|\right), \tag{22.31}$$

where $\widehat{\Sigma} = (1/T)\Sigma^{T} E_t E_t'$ is the maximum likelihood estimator of the covariance matrix (see Davidson and MacKinnon, 1993, p. 316). This is maximized through a grid search over κ with (22.30) estimated using a full information maximum likelihood (FIML) estimator at each point in the grid. If $\widehat{L}(h)$ is the maximized log-likelihood conditional on a bandwidth parameter h, the resulting estimator of κ may be expressed as:

$$\widehat{\kappa} = \arg\max_{h \in H} \widehat{L}(h),$$

where $H = [0, \max|\delta_t|]$ is the range of the grid search. Hypotheses concerning the parameters can then be tested using an LR statistic defined as $\lambda' = 2(\widehat{L} - \widetilde{L})$, where $\widehat{L}$ denotes the value of the maximized log-likelihood and $\widetilde{L}$ denotes the maximized log-likelihood with the relevant restrictions imposed. Empirical marginal significance levels for this statistic can be calculated using methods set out in Hansen (1997) and explained in section 22.2.2. The results reported by Peel and Taylor were consistent with the conjectures of Keynes (1923) and Einzig (1937). Arbitrage only occurred when significant deviations from CIP occurred and the adjustment back to the implied arbitrage bounds was fairly persistent due to the microstructure faced by arbitragers. Estimation of these threshold (or ESTAR) error correction mechanisms would be of interest in other areas such as PPP.

In the absence of a new study employing high-quality data of the type employed by Taylor in the 1980s, it would appear reasonable to assume that restrictions on arbitrage funds and the ability to make near riskless trades instantaneously implies that CIP holds within a very small transactions band.

However, before we discuss the uncovered condition there is one feature of the nonlinear work applied to CIP that needs comment and has applicability to nonlinear models more generally. Whilst the nonlinear assumption is well motivated, the economic arguments of arbitrage apply to a particular data frequency. For instance, currently we might expect deviations from the arbitrage bound to occur near instantaneously. In the 1920s the appropriate period might have been hours, (possibly days or a week). Unfortunately, if the data frequency available is not that of the DGP then the estimates of a nonlinear model may generate misleading results as to the period of dynamic adjustment or the impact of shocks, as discussed in the context of PPP above. Paya and Peel (2007b) show that systematic sampling from the true DGP, where they employ every *k*th observation from the true DGP, can lead to seriously biased estimates of speeds of adjustment. Estimation of nonlinear models on data sampled at a different frequency to the economic decision would appear to be a serious problem in the evaluation of nonlinear models.[38]

22.3.2 Uncovered interest parity (UIP)

In the absence of frictions an agent should be indifferent between holding domestic or foreign assets of identical type. The return from the foreign asset over a given holding period is its return plus or minus the return from exchange rate changes over the holding period. The latter component is risky so that risk averse agents will require a risk premium. Employing interest rates as the asset's return, the UIP condition is given by:

$$i_t - i_t^* = E_t s_{t+n} - s_t + rp_t, \tag{22.32}$$

where $E_t s_{t+n}$ is the expectation at time t of the exchange rate in n periods time, the time to maturity of the interest rates, conditional on all information available at time t. The uncovered parity condition in conjunction with the covered parity condition imply that:

$$f_t = E_t s_{t+n} + rp_t, \tag{22.33}$$

and assuming rational expectations we obtain:

$$s_{t+n} = f_t - rp_t + \epsilon_{t+n}, \tag{22.34}$$

where ϵ_{t+n} is the rational expectations forecast error, which can follow up to an $n-1$ order moving average error process (see Hansen and Hodrick, 1980). Early tests of the properties of the forward rate were based on testing the hypothesis that $\beta = 1$ in the following OLS regression:

$$s_{t+n} = \alpha + \beta f_t + u_t. \tag{22.35}$$

The estimates of β were typically close to unity. However, the early research, naturally, was unaware that if s_t and f_t are integrated variables, so that (22.35) is a cointegration regression, the t-ratio is not asymptotically standard normal.

A number of different estimation techniques have been employed to estimate (22.35) which remedy this deficiency. For example, Hai *et al.* (1997) estimate α and β with the dynamic OLS (DOLS) and dynamic generalized least squares (DGLS) cointegration vector estimators of Stock and Watson (1993). Moore and Copeland (1995) employ the fully modified maximum likelihood procedure (FM-OLS) of Phillips and Hansen (1990), which treats equation errors in a general semi-parametric way to estimate α and β. Phillips *et al.* (1996), building on Phillips (1995), estimate the coefficients employing the fully modified least absolute deviations (FM-LAD) estimator.[39]

A comparison by Phillips of the FM-LAD estimates of α and β with those obtained from FM-OLS and OLS on interwar data suggests it can make a major difference to the magnitude and significance of the estimated coefficients. The properties of the FM-LAD estimator appear to us to make it a prime candidate for use in many areas of finance, e.g., the relationship between asset prices and fundamentals and tests of bubbles (see section 22.5). It appears to us a neglected contribution.

Overall, the estimates of β do not appear to differ significantly from unity.[40] The estimates of α do appear to differ from zero but this, of course, could be the influence of a stationary, non-zero mean risk-premium. However, an estimate of

β that does not differ significantly from unity does not imply that markets are efficient or expectations are formed rationally. It is also consistent with a variety of non-rational expectations processes.

Orthogonality tests are a standard method for testing the rationality of expectations. Consider the following specifications:

$$s_{t+n} - s_t = \lambda + \theta(f_t - s_t) + v_{t+n}, \tag{22.36}$$

$$s_{t+n} - f_t = \lambda + (\theta - 1)(f_t - s_t) + v_{t+n}, \tag{22.37}$$

where v_{t+n} is the error term. Given rational expectations and risk-neutrality, (22.34) implies that $\lambda = 0$ and $\theta = 1$ and the error term exhibits up to an $n-1$ order moving average error. In fact, a vast amount of empirical work has reported estimates of θ that are not only significantly different from unity but also significantly negative (see, e.g., Fama, 1984; Hodrick, 1987; Backus *et al.*, 1993). The negative value of θ implies that the more the foreign currency is at a premium in the forward market, the less the home currency is predicted to depreciate. In that case the spot exchange rate next period moves, on average, in the opposite direction to that currently predicted by the forward premium. This implication has become the forward bias puzzle in the literature. Of course, one explanation could be the absence of rational or informed expectations and numerous evidence on the properties of survey evidence on expectation formation support this view (Frankel and Froot, 1987). However, the systematic nature of the pattern in empirical estimates of θ over both the interwar and post-war period rather suggests *a priori* that expectation formation cannot play a major role in the explanation even if one attaches reasonable weight to the quality of survey data.

Numerous reasons have been set out to explain the puzzle and we now consider some of these. Fama (1984) considers the implications of a time-varying risk-premium for estimates of (22.36) and (22.37). Assuming rational expectations, we have as a property that:

$$s_{t+n} - s_t = Es_{t+n} - s_t + \epsilon_{t+n}. \tag{22.38}$$

Also, from rearrangement of (22.33):

$$f_t - s_t = E_t s_{t+n} - s_t + rp_t, \tag{22.39}$$

and from (22.34):

$$s_{t+n} - f_t = -rp_t + \epsilon_{t+n}. \tag{22.40}$$

Now the OLS estimate of θ in (22.36) must satisfy asymptotically:

$$\begin{aligned} plim(\widehat{\theta}) = \theta &= \frac{Cov(Es_{t+n} - s_t + \epsilon_{t+n}, E_t s_{t+n} - s_t + rp_t)}{Var(f_t - s_t)} \\ &= \frac{Var(E_t s_{t+n} - s_t) + Cov(rp_t, Es_{t+n} - s_t)}{Var(f_t - s_t)}; \end{aligned} \tag{22.41}$$

also, from (22.37):

$$plim(\widehat{\theta} - 1) = \theta - 1 = \frac{Cov(-rp_t + \epsilon_{t+n}, E_t s_{t+n} - s_t + rp_t)}{Var(f_t - s_t)}$$
$$= \frac{-Var(rp_t) - Cov(rp_t, Es_{t+n} - s_t)}{Var(f_t - s_t)}. \tag{22.42}$$

We note from (22.41) that a negative estimate of θ implies that $Cov(rp_t, Es_{t+n} - s_t) < 0$. This is the important point made by Fama (1984), that negativity of estimates of θ require a negative covariation between the risk premium and the expected rate of depreciation. In addition, this covariation has greater absolute magnitude than $Var(E_t s_{t+n} - s_t)$. From (22.42), a negative estimated coefficient implies that $Var(rp_t)$ has greater absolute magnitude than $Cov(rp_t, Es_{t+n} - s_t)$.

A time-varying risk premium is well motivated. For example, in a consumption capital asset pricing model (CAPM) framework, assuming logarithmic utility and that all variables are jointly lognormally distributed, we can derive that:

$$f_t - E_t s_{t+1} = 0.5 Var_t(s_{t+1}/s_t) - cov_t([s_{t+1}/s_t].p_{t+1}/p_t)$$
$$- \delta cov_t([s_{t+1}/s_t].\log(c_{t+1}/c_t)), \tag{22.43}$$

where δ is the coefficient of relative risk-aversion.[41] In general, optimizing models built on microtheoretic underpinnings will imply that the risk-premium depends on the variance of the exchange rate. As with other asset prices, there is considerable evidence of time-varying volatility in spot exchange rates at high frequencies. Various authors have employed extensions of the work of Engle (1982) and estimated multivariate GARCH models and included the own conditional variance in the mean equation (see, e.g., Baillie and Bollerslev, 1990; Bekaert and Hodrick, 1993). For instance, the basic idea (without the multivariate generalization) is to estimate:

$$s_{t+1} - s_t = \alpha_0 + \alpha_1(f_t - s_t) + \alpha_2 h_{t+1} + \epsilon_{t+1}, \tag{22.44}$$

$$h_{t+1} = \delta_0 + \delta_1 h_t + \delta_2 \epsilon_t^2 + \delta_3 \left| f_t - s_t \right|, \tag{22.45}$$

where variables are defined as above and h_t is the conditional variance of the error term. The absolute difference $|f_t - s_t|$ is included in the variance equation based on empirical observation by Hodrick (1989).

GARCH effects disappear with aggregation (Drost and Nijman, 1993) and so are not usually statistically significant in low-frequency data such as monthly or quarterly. Also consumption and price data are not available at weekly or daily levels. Consequently, some of the terms in the risk-premium have to be assumed constant in empirical work. Nevertheless, it would appear that a time-varying risk-premium does not rationalize the forward premium anomaly.[42] However, it is interesting in this context to note the results reported by Flood and Rose (1996). They found that estimates of θ were positive in credible periods in the EMS target zone when risk-premia might, *a priori*, be expected to be smaller in magnitude.[43]

Another important possibility is inference problems arising from the different statistical properties of changes in the the spot rate and forward premium. Baillie and Bollerslev (2000) consider a sample of monthly observations on the DM/$ spot and one-month forward rates from January 1974 to December 1991, realizing a total of 215 observations. They report that the monthly sample standard deviation of percentage changes in the spot rate is 2.75 and the corresponding figure for the monthly forward premium as 0.217. These figures are typical. Changes in the spot rate usually exhibit a standard deviation at least 100 times bigger than the forward premium. In addition, the forward premia are generally very persistent whilst changes in the spot rate are not. In fact, Baillie and Bollerslev (1994), Byers and Peel (1996), and Maynard and Phillips (2001) have argued that the temporal dependencies in the forward premium can be parsimoniously described by a fractionally integrated, or I(d), process.

Mathematically, the autoregressive fractional integrated moving average (ARFIMA) model for a time series process y_t can be written as:

$$\phi(L)(1-L)^d(y_t-\mu)=\theta(L)\epsilon_t, \tag{22.46}$$

where $\phi(z)=0$ and $\theta(z)=0$ have all roots lying in the unit circle and $\{\epsilon_t\}$ is a martingale difference sequence. The differencing operator, $(1-L)^d$, is defined as follows:

$$(1-L)^d=\sum_{j=o}^{\infty}\frac{\Gamma(j-d)L^j}{\Gamma(-d)\Gamma(j+1)},$$

where Γ is the gamma or generalized factorial function. A fractionally integrated process is one that exhibits long memory, with persistent local trends, but which nonetheless eventually "reverts to the mean." The degree of persistence is measured by the real-valued parameter d, lying on the unit interval.[44] Smallwood (2005) has an interesting discussion of the properties of the various estimators of the fractional parameter d in the context of PPP. One important property of fractional processes is the self-similarity property. This implies that the estimate of d should remain invariant over different temporal aggregates of the process. Ohanissian *et al.* (2007) have developed a statistical test based on this property. Their simulations show that the test has good size and power properties against some alternatives such as Markov-switching. The potential use of this test in exchange rate econometrics seems great. We also consider that the power of this test against alternatives such as ESTAR would be of interest.

From a purely statistical perspective the different properties of changes in the spot rate and the forward premium suggest that the orders of integration of the dependent and explanatory variables are not the same. One method of dealing with the long-memory characteristics of the forward premium, as suggested by Baillie and Bollerslev, is to regress the spot return on the fractionally differenced forward premium (see Maynard and Phillips, 2001; Abadir and Talmain, 2006):

$$s_{t+1}-s_t=\lambda+\theta(1-L)^d(f_t-s_t)+\epsilon_{t+1}. \tag{22.47}$$

Such a regression appears to imply rejection of efficiency. Granger and Joyeux (1980) illustrate how long memory can arise via aggregation. Alternatively, Granger and Hyung (2004) and Diebold and Inoue (2001) show that structural breaks or regime switching can generate spurious long-memory behavior in an observed time series. Granger and Teräsvirta (1999) provide an abstract example of a nonlinear model that can generate data with the misleading linear property of long memory. They suggest that other nonlinear models with this property are worth searching for. Byers and Peel (2003) show that data generated from an ESTAR can exhibit the long-memory property whether in raw or temporally aggregated form. That this might be the case was an early conjecture of Acosta and Granger (1995). In this respect, recent applied work which has tried to explain the anomaly by nonlinearities induced by transactions costs and other frictions seems promising (see, e.g., Coakley and Fuertes, 2001; Leon *et al.*, 2003; Sarno *et al.*, 2006).[45]

We know from analysis of the empirical work on PPP discussed in section 22.2 that fractional processes can appear to parsimoniously explain PPP deviations but are not as theoretically well motivated as the nonlinear models that also appear to parsimoniously explain the data. Leon *et al.* (2003) and Sarno *et al.* (2006) provide a nice rationale for nonlinearity based on arguments by Lyons (2001) as to the limits to speculation (see Shleifer and Vishny, 1997). The idea is that financial institutions will only engage in uncovered arbitrage – a currency trading strategy – if the strategy yields a Sharpe ratio at least equal to an alternative investment strategy, such as a buy-and-hold equity strategy. The Sharpe ratio is defined as $(E[R(s)] - R(f))/\sigma_s$, where $E[R(s)]$ is the expected return on the strategy, $R(f)$ is the risk-free interest rate, and σ_s is the standard deviation of the returns to the strategy. In the foreign exchange market the excess return equals $E[R(s)] - R(f) = E[s_{t+1} - s_t - (f_t - s_t)]$ and the denominator is determined by the exchange rate variances. In the case of multiple-exchange rate strategies, the covariances among the exchange rates considered in the currency strategy would also be included in the denominator.

The Sharpe ratio can be interpreted as the expected excess return from speculation per unit of risk. Sarno *et al.* (2006) point out that the Sharpe ratio for a buy-and-hold equity strategy has averaged about 0.4 on an annual basis for the US over the last 50 years or so. Only when θ departs from unity does the numerator of the Sharpe ratio becomes positive. In fact, perhaps surprisingly, only when $\theta \leq -1$ or $\theta \geq 3$ is the Sharpe ratio for currency strategies about the same magnitude as the average from a buy-and-hold equity strategy, i.e., 0.4 (see Lyons, 2001, p.210). Consequently, there is a band of inaction such that, if $-1 < \theta < 3$, financial institutions would have no incentive to take up a currency strategy. Deviations from uncovered interest parity are too small to attract speculative funds so that the spot exchange rate and forward exchange rate need not move together.

As with PPP, these types of considerations suggest either a threshold or an ESTAR type of adjustment mechanism. The latter is justifiable by an appeal to heterogeneous agents, who face different levels of position limits and the like. Consider the following ESTAR adjustment mechanism estimated by Sarno *et al.* (2006):[46]

$$s_{t+1} - s_t = \lambda_1 + \theta_1(f_t - s_t) + [\lambda_2 + \theta_2(f_t - s_t)] \times \Psi\left(s_t - f_{t-1}; \gamma\right) + \epsilon_{t+1}, \tag{22.48}$$

where $\Psi\left(s_t - f_{t-1}; \gamma\right) = 1 - \exp\left(-\gamma(s_t - f_{t-1})^2\right)$. Equivalently:

$$s_{t+1} - f_t = \lambda_1 + (\theta_1 - 1)(f_t - s_t) + [\lambda_2 + \theta_2(f_t - s_t)]\Psi\left((s_t - f_{t-1}); \gamma\right) + \epsilon_{t+1}. \tag{22.49}$$

When $s_t - f_{t-1}$ is small we obtain from (22.48):

$$s_{t+1} - s_t = \lambda_1 + \theta_1(f_t - s_t), \tag{22.50}$$

and when $s_t - f_{t-1}$ is large:

$$s_{t+1} - s_t = \lambda_1 + \lambda_2 + (\theta_1 + \theta_2)(f_t - s_t). \tag{22.51}$$

Sarno *et al.* (2006) report that the restriction $\theta_1 + \theta_2 = 1$ cannot be rejected for the currencies they examine and also that $\theta_1 < 0$. Simulated data from this model generate negative estimates of θ in the standard regressions (22.36) and (22.37). In fact, if the constraint that $\theta_1 + \theta_2 = 1$ is imposed, the model collapses to the form employing expected excess returns as:

$$s_{t+1} - f_t = -\theta_2(f_t - s_t)\exp\left(-\gamma\left[E_t(s_{t+1} - f_t)\right]^2\right) + \epsilon_{t+1}, \tag{22.52}$$

when $\lambda_1 + \lambda_2 = 0$, where $E_t(s_{t+1} - f_t)$ is the expected excess return formed on information available in period t. In this form the model allows expectations to be formed rationally, as in the arbitrage consistent STAR (ARBSTAR) model proposed by Peel and Venetis (2005), which remedies some economic difficulties when TAR, ESTAR, or LSTAR models are employed to model arbitrage.[47]

The estimates of Sarno *et al.* (2006)[48] suggest that the relationship between the excess return and the forward premium is nonlinear. However, it is not clear that the efficiency proposition is tested, or indeed that there is a well defined null, except under the assumption of risk neutrality. Time-varying risk premia will imply the lack of a unit relationship in the outer regimes. It would be of interest to estimate the Sarno *et al.* (2006) model when risk premia are *a priori* small – e.g., in credible periods in the Exchange Rate Mechanism (ERM), as in the analysis of Flood and Rose (1996) mentioned above.

An extension of the nonlinear STAR model has recently been employed to model forward premia and PPP deviations (see Smallwood, 2005; Baillie and Kapetanios, 2005, 2006).[49] The idea is that the fractional difference of a series is an ESTAR or LSTAR model, and the model is called FI-STAR. In particular, the FI-STAR model for a time series y_t is defined as:

$$(1-L)^d y_t = \left(\alpha_{1,0} + \sum_{j=1}^{p} \alpha_{1,j}(1-L)^d y_{t-j}\right) + \left(\alpha_{2,0} + \sum_{j=1}^{p} \alpha_{2,j}(1-L)^d y_{t-j}\right) G(y_{t-k}; \gamma, c) + \varepsilon_t, \tag{22.53}$$

where $G(\cdot)$ is the transition function of an LSTAR or ESTAR model and k is the delay parameter. Under the null hypothesis, $\gamma = 0$, the time series process is distributed as a long-memory ARFIMA(p,d,0). We outline Smallwood's test for joint fractional and ESTAR nonlinearity, which seems more appropriate in the context of exchange rate econometrics where issues of transactions bands and limits to arbitrage suggest ESTAR (or threshold) as the parametric form of nonlinearity.[50] The Smallwood test procedure is similar to that outlined in section 22.2.1 and consists of a first-order Taylor series expansion of model (22.53):

$$(1-L)^d y_t = \left(\alpha_{1,0} + \sum_{j=1}^{p} \alpha_{1,j}(1-L)^d y_{t-j}\right) + \left(\sum_{j=1}^{p} \alpha_{2,j}(1-L)^d y_{t-j} y_{t-k}\right) + \left(\sum_{j=1}^{p} \alpha_{3,j}(1-L)^d y_{t-j} y_{t-k}^2\right) + e_t. \tag{22.54}$$

Assuming the error term is Gaussian, the null hypothesis of a linear fractional process is given by $H_0 : \alpha_{2,j} = \alpha_{3,j} = 0$, $j = 1, \ldots, p$. Smallwood illustrates that the existence of the fractional differencing parameter complicates the construction of the LM-type test statistic based on (22.54). However, he shows that a χ^2 and F version can be calculated as follows. One first estimates an ARFIMA(p,d,0) model and obtains the estimate of d ($\widehat{d}$), and the set of residuals $\widehat{\varepsilon}_t$. The sum of squared errors, denoted SSR_R, is then constructed from the residuals $\widehat{\varepsilon}_t$. Second, a regression of $\widehat{\varepsilon}_t$ is run on $\sum_{j=1}^{t-1} \widehat{\varepsilon}_{t-j}/j$, 1, $(1-L)^{\widehat{d}} y_{t-1}, \ldots, (1-L)^{\widehat{d}} y_{t-p}$, $(1-L)^{\widehat{d}} y_{t-1} y_{t-k}, \ldots, (1-L)^{\widehat{d}} y_{t-p} y_{t-k}$, and $(1-L)^{\widehat{d}} y_{t-1} y_{t-k}^2, \ldots, (1-L)^{\widehat{d}} y_{t-p} y_{t-k}^2$. The unrestricted sum of squared residuals, SSR_{UR}, is formed from this regression. The χ^2 version of the LM test statistic is calculated as $\mathrm{LM}_{\chi^2} = T(SSR_R - SSR_{UR})/SSR_R$, and is distributed as a $\chi^2(2p)$. The F version of the LM test statistic is calculated as $\mathrm{LM}_F = \left[(SSR_R - SSR_{UR})(2p)^{-1}\right]\left[SSR_{UR}(T-3p-1)^{-1}\right]^{-1}$, and is distributed as an $F(2p, T-3p-1)$.

In practice, of course, the long-memory parameter is generally unknown. Different methods have been employed to obtain a consistent estimate in the first step of the test. Smallwood prefers the estimator of Beran (1995) based on the conditional likelihood function of the time series process. Baillie and Kapetanios (2006) employ the local Whittle semiparametric estimator.[51] We would also suggest that the test of Ohanissian *et al.* (2007) mentioned above would be worth exploring in this context. Its size properties given data generated from a FI-STAR model would be of interest and, similarly, its power properties for data generated from an ESTAR.[52]

22.4 Target zone models

There have been a large number of papers that have examined the behavior of exchange rates in target zones. The basic theory is due to Flood and Garber (1983), with the particular application to target zones by Krugman (1991). The model of

Krugman, cast in continuous time, is based on the log-linear monetary model with instantaneous purchasing power parity so that the reduced form for the logarithm of the exchange rate $s(t)$ is given by:

$$s(t) = f(t) + \alpha \frac{E[ds(t)]}{dt}, \tag{22.56}$$

where $f(t)$ is the logarithm of the fundamental and α represents the interest rate semi-elasticity of money demand. The fundamental is assumed equal to:

$$f(t) = m(t) + v(t), \tag{22.57}$$

where $m(t)$ represents the policy instrument and $v(t)$, which is assumed to follow a Brownian motion without drift, contains all the other determinants of the exchange rate which impact through the term $f(t)$. Krugman assumes a credible target zone exists so that $s^l \leq s \leq s^u$, where s^l and s^u are the lower and upper bounds respectively. The authorities are assumed to intervene by movements in m when the exchange rate reaches either boundary value s^l or s^u. The formal solution of the model given by Krugman (1991) or Taylor (1995) has the form:

$$s(t) = m(t) + v(t) + A\left[\exp\left(\theta(m+v)\right) - \exp\left(-\theta(m+v)\right)\right], \tag{22.58}$$

where $\theta = \sqrt{2/(\alpha\sigma^2)}$. A is uniquely determined by the "smooth-pasting" conditions (see, e.g., Taylor, 1995). The formal solution to the basic (symmetric) target zone model is an S-shaped function. The S shape illustrates the "honeymoon effect" and the "smooth-pasting conditions." If s is close to s^u then the probability that the exchange rate will fall is higher than that it will rise as the authorities intervene to stop the exchange rate breaching the upper band. Consequently, the exchange rate will be lower than if the exchange rate was freely floating. Similar considerations apply near the lower bound. This behavior implies that variation in the exchange rate will be smaller, for any variation in the fundamental, than under a freely floating regime. This is called the "honeymoon effect." The so-called "smooth-pasting" conditions ensure the absence of riskless speculative gains.

There have been numerous empirical tests of the target zone model with various refinements to the basic model.[53] We will consider the models of Iannizzotto and Taylor (1999), Taylor and Iannizzotto (2001) and Lundbergh and Teräsvirta (2006), which are empirical tests assuming that the zone is credible. Suitable data points are therefore chosen by them for the analysis given this assumption.

22.4.1 Method of simulated moments (MSM)

Iannizzotto and Taylor (1999) and Taylor and Iannizzotto (2001) employ the MSM. This method is based on work by Lee and Ingram (1991) and Duffie and Singleton (1993). The essential idea is to simulate data from the chosen target zone model for a range of parameter values and compare the statistical moments of the simulated data with the statistical moments of the real data. A loss function which penalizes the deviation between the actual and simulated moments is minimized over the

various parameter values. The simulated moments estimator is found by minimizing the following loss function given weak regularity conditions and a symmetric weighting matrix W_z:

$$L = \{H_z(k) - H_N[\gamma(\beta)]\}' W_z\{H_z(k) - H_N[\gamma(\beta)]\}, \tag{22.59}$$

where $H_z(k) = (1/Z)\sum_{z=1}^{Z} h(k_z)$, $H_n[\gamma(\beta)] = (1/N)\sum_{j=1}^{N} h[y_j(\beta)]$ are the sample moments of, respectively, the observed data for Z observations $(k_z, z = 1, 2, \ldots, Z)$; and the simulated data for N observations of the Krugman model conditional on a vector of parameters $\beta, (y_j(\beta), j = 1, 2, \ldots, N)$. Taylor and Iannizzotto note that Hansen (1982) shows that:

$$W_z^* = \left(1 + \frac{1}{n}\right)^{-1} \Omega^{-1},$$

is an optimal choice for the weighting matrix in that it yields the smallest asymptotic covariance matrix for the estimator. $\Omega = \sum_{i=-\infty}^{\infty} R_x(i)$, where $R_x(i)$ is the ith autocovariance matrix of the population moments of the observed process, and $n = N/Z$ is the ratio of the length of the simulated series to the length of the observed series. Given W_z^*, the MSM estimator converges in distribution to the normal:

$$\sqrt{Z}(\widehat{\beta}_{zN} - \beta_0) \xrightarrow{D} N\left(0, \left[B'\left(1 + \frac{1}{n}\right)^{-1} \Omega^{-1} B\right]^{-1}\right) \text{ as } Z, N \to \infty,$$

where $B \equiv E[\partial h(y_j(\beta))/\partial\beta]$. The moment restrictions are tested by Taylor and Iannizzotto by exploiting a result of Hansen (1982) that the minimized value of the loss function converges asymptotically to a χ^2 distribution given the null hypothesis of no errors in specification:

$$Z\{H_z(k) - H_N[\gamma(\widehat{\beta}_{zN})]\}' W_z^*\{H_z(k) - H_N[\gamma(\widehat{\beta}_{zN})]\} \xrightarrow{D} \chi^2(\varpi - k),$$

where ϖ is the number of moment conditions and k the number of parameters being estimated. Taylor and Iannizzotto's papers improve on previous literature in a number of respects. First, they employ daily data, making appropriate allowance for holidays and weekends, so that the frequency is more consistent with the underlying theoretical model. Second, they use data only from periods when the target zone was *a priori* credible – again trying to map the data to the underlying theoretical assumptions of the model. They report statistically significant parameters of plausible magnitudes and the inability to reject the model using specification tests. However, the degree of nonlinearity implied by their parameter estimates is very small, so that the estimated honeymoon effect is small. Another interesting finding, though perhaps not too surprising given their results on the magnitude of the honeymoon effect, is that standard unit root tests have low power against data generated from a credible target zone. They found, in fact, that the chances of non-rejection of the unit root hypothesis may exceed 90% even when the exchange rate conforms to a fully credible Krugman target zone.[54]

22.4.2 Smooth transition autoregressive target zone

Lundbergh and Teräsvirta (2006) propose a flexible parametric target zone model that nests the model of Krugman but also allows estimation of an implicit target zone if it exists. A feature of their model is that it allows joint modeling of both the conditional mean and the conditional variance. Their model builds on an earlier contribution of Bekaert and Gray (1998). They call their model the Smooth Transition Autoregressive Target Zone (STARTZ) model. The STARTZ model is a parameterization of the first and second moments of s_t, the deviation of the exchange rate from the central parity. The STARTZ model is given by the following equation:

$$s_t = \lambda_t + \epsilon_t, \tag{22.60}$$

with $\epsilon_t = \sqrt{z_t h_t}$, where $\{z_t\} \sim$ i.i.d.$(0,1)$ and h_t is the conditional variance of ϵ_t. The conditional mean λ_t is defined by:

$$\lambda_t = \varphi' x_t + (\mu s^l - \varphi' x_t) G^l(s_{t-1}; \gamma_a, \theta_a, \mu s^l) + (\mu s^u - \varphi' x_t) G^u(s_{t-1}; \gamma_a, \theta_a, \mu s^u),$$

where $x_t = (1, s_{t-1}, \ldots, s_{t-n})'$ and $\varphi = (\varphi_0, \varphi_{1,\ldots,} \varphi_n)'$ is the corresponding parameter vector. The two transition functions G^l and G^u have the form:

$$G^l(s_{t-1}; \gamma, \theta, c) = \left[1 + \exp\left(-\gamma(c - s_{t-1})\right)\right]^{-\theta},\ \gamma > 0, \theta > 0,$$
$$G^u(s_{t-1}; \gamma, \theta, c) = \left[1 + \exp\left(-\gamma(s_{t-1} - c)\right)\right]^{-\theta},\ \gamma > 0, \theta > 0,$$

where s_{t-1} is the transition variable, and γ, c and θ are the slope, location and asymmetry parameters, respectively. The lower and upper bounds of the zone are defined by s^l and s^u, so that $c = \mu s^l$ and $c = \mu s^u$ are location parameters.[55]

The target zone literature implies that the conditional variance of the exchange rate must be very small near the edges of credible, implicit or explicit, bands. Lundbergh and Teräsvirta (2006) parameterize this feature by assuming that the conditional variance has a parametric specification similar to the conditional mean and given by:

$$h_t = \eta' w_t + (\delta - \eta' w_t) G^l(s_{t-1}; \gamma_b, \theta_b, \mu s^l) + (\delta - \eta' w_t) G^u(s_{t-1}; \gamma_b, \theta_b, \mu s^u),$$

where $\eta = (\alpha_0, \alpha_1, \ldots, \alpha_q, \beta_1, \ldots, \beta_p)'$, $w_t = (1, \varepsilon^2_{t-1}, \ldots, \varepsilon^2_{t-q}, h_{t-1}, \ldots, h_{t-p})'$. It is assumed that $\delta > 0$ which, together with the restrictions $\alpha_0 > 0, \alpha_i \geq 0$, $i = 1, \ldots, q$, $\beta_j \geq 0$, $j = 1, \ldots, p$, is sufficient to ensure the conditional variance is positive. Because $\epsilon_t = s_t - \lambda_t$, such that φ is assumed not to depend on η, the conditional variance is a nonlinear function of the elements of w_t.[56]

Lundbergh and Teräsvirta obtain their parameter estimates by maximizing the log-likelihood under the assumption that $\{z_t\}$ is a sequence of independent standard normal errors. Under this assumption the (quasi) log-likelihood function equals:

$$l_t = const - 0.5 \ln h_t - 0.5 \frac{\epsilon_t^2}{h_t}.$$

They set out a battery of diagnostic tests for the model, some of which we discussed in section 22.2. The empirical results reported from employing daily data for the Swedish and Norwegian krone suggest the STARTZ model provides a parsimonious representation of the behavior of the Swedish krone between 1985 and 1991, and for the Norwegian krone between 1989 and 1990. The estimates accord with the theoretical models. We suggest that it would be useful to apply the STARTZ model to the daily datasets examined by Taylor and Iannizzotto. It would also be interesting to find out the properties of standard unit root or fractional tests from a simulated STARTZ model, where one expects that such tests will exhibit low power.

22.5 Speculative bubbles

22.5.1 Theory

Consider the discrete time stochastic differential equation that occurs in asset market exchange rate models (see Engel and West, 2005):

$$s_t = (1-b)a_1' x_t + b a_2' x_t + b E_t s_{t+1}, \quad b \in (0,1). \tag{22.61}$$

The above equation states that the exchange rate depends upon the current level of economic fundamentals x_t plus the discounted expected spot rate next period, where b is the discount factor. In the absence of rational bubbles, the forward solution to the above equation is:

$$s_t = (1-b)E_t\left(\sum_{j=0}^{\infty} b^j a_1 x_{t+j}\right) + bE_t\left(\sum_{j=0}^{\infty} b^j a_2 x_{t+j}\right). \tag{22.62}$$

The logarithm of the exchange rate can be written as the discounted sum of current and expected future fundamentals, such as interest rates, prices, money supplies and income. This is a general form of several exchange rate determination models based on macroeconomic fundamentals that can provide several insights concerning the empirical findings of studies on exchange rate forecasting discussed in section 22.6. By assuming Cagan-style money demand functions for the home and foreign countries with common parameters, we obtain:

$$s_t = m_t - m_t^* + y_t - \gamma(w_t - w_t^*) + \lambda(i_t - i_t^*), \tag{22.63}$$

where m_t is the log of the money supply, w_t is the log of real income, i_t is the short-term interest rate, γ and λ denote the income elasticity and interest rate semi-elasticity of money demand, and y_t is the real exchange rate. An asterisk denotes foreign quantities. The deviations from UIP, $rp_t = i_t - i_t^* - E_t\left(\Delta s_{t+1}\right)$, can be thought of as unobserved fundamentals. Substituting into (22.63) yields:

$$s_t = m_t - m_t^* + y_t - \gamma(w_t - w_t^*) + \lambda rp_t + \lambda E_t\left(\Delta s_{t+1}\right). \tag{22.64}$$

By iterating forward we obtain:

$$s_t = \frac{1}{1+\lambda} E_t \left(\sum_{j=0}^{\infty} \left(\frac{\lambda}{1+\lambda} \right)^j (m_{t+j} - m^*_{t+j} + y_{t+j} - \gamma(w_{t+j} - w^*_{t+j})) \right) + \frac{\lambda}{1+\lambda} E_t \left(\sum_{j=0}^{\infty} \left(\frac{\lambda}{1+\lambda} \right)^j rp_{t+j} \right). \tag{22.65}$$

In this case, $b = \lambda/(1+\lambda)$ and $a_2' x_t = rp_t$. If we assume, further, that PPP and UIP hold, then the exchange rate model simplifies to:

$$s_t = \frac{1}{1+\lambda} E_t \left(\sum_{j=0}^{\infty} \left(\frac{\lambda}{1+\lambda} \right)^j f_{t+j} \right), \tag{22.66}$$

where $f_t = a_1' x_t = \left(m_t - m^*_t\right) - \left(w_t - w^*_t\right)$.[57] However, it is well known that the above equation is a single solution from a potentially infinite set. Letting $s_{f,t}$ denote the fundamental solution, the rational expectations solutions to (22.64) are given by:

$$s_t = s_{f,t} + B_t, \tag{22.67}$$

where:

$$E_t B_{t+1} = \frac{(1+b)}{b} B_t. \tag{22.68}$$

The term B_t is the speculative bubble, which has to follow the form given by (22.68).[58] We can also write the solution for the bubble as (Salge, 1997):

$$B_t = \frac{M_t}{\lambda^t}. \tag{22.69}$$

From (22.69) and (22.68):

$$E_t B_{t+1} = \frac{E_t M_{t+1}}{\lambda^{t+1}} = \frac{1}{\lambda} \frac{M_t}{\lambda^t}, \tag{22.70}$$

so that:

$$E_t M_{t+1} = M_t, \tag{22.71}$$

implying that M_t is a martingale process. A more general form of a stochastic martingale process is given by:

$$M_t = \rho_t M_{t-1} + u_t, \tag{22.72}$$

where $E_t \rho_{t+1} = 1$, $E_{t-j} u_t = 0$, $j = 1, \ldots, n$, $E_t \rho_t M_t = 0$, and $E_t u_t M_t = 0$. In general, a bubble can depend on its lagged values, called a Markovian bubble, on an extraneous process "M," which follows a martingale process, or on fundamentals, called an intrinsic bubble (Froot and Obstfeld, 1991).[59]

Bubbles, if they exist, can of course pop and a variety of forms of rational bubbles that exhibit this property and are consistent with (22.68) have been proposed (see,

e.g., Blanchard and Watson, 1982; Evans, 1991). The bubble proposed by Evans takes the form:

$$B_{t+1} = \begin{cases} \lambda^{-1} B_t \epsilon_{t+1} & \text{if } B_t \leq k, \\ \left[\delta + \pi^{-1}\lambda^{-1}\phi_{t+1}\left(B_t - \lambda\delta\right)\right]\epsilon_{t+1} & \text{if } B_t > k, \end{cases} \tag{22.73}$$

where $E_t\epsilon_{t+1} = 1$, and ϕ_{t+1} takes the value one or zero with probabilities π or $1-\pi$. Taking expectations of the second equation in (22.73) we have that:

$$E_t B_{t+1} = \pi\left[\delta + \pi^{-1}\lambda^{-1}1\left(B_t - \lambda\delta\right)\right] + (1-\pi)\,\delta = \frac{B_t}{\lambda}. \tag{22.74}$$

In this case, when the Evans Markovian bubble exceeds the value of k then it grows at a faster rate till it pops to a value of δ. In expectation the bubble is explosive, which implies that s_t in (22.67) is explosive regardless of the integration properties of the fundamental. There appears to be no reason why an intrinsic bubble that pops could also not be specified – though as yet no research has investigated such bubbles.

22.5.2 Testing and evidence

Though the majority of applications are based on stock price data, Evans (1986) and Meese (1986) are two applications to exchange rates.[60] The empirical tests to date on exchange rates are inconclusive as to the existence of bubbles. However, in an important new development in testing for bubbles, Phillips *et al.* (2006) set out a unit root testing procedure that has good power characteristics in finite samples and enables dating the origination and the collapse of bubbles.[61] Their study is based on the presumption that bubbles can be identified by way of manifestation of explosive characteristics in the data. This can be achieved by estimating the regression equation:

$$s_t = \mu + \phi s_{t-1} + \sum_{j=1}^{J} \xi_j \Delta s_{t-j} + \varepsilon_{s,t}, \quad \varepsilon_{s,t} \sim NID(0, \sigma_s^2), \tag{22.75}$$

and testing the null hypothesis of a unit root, $H_0 : \phi = 1$ against the alternative $H_1 : \phi > 1$. Phillips *et al.* (2006) propose two tests, a right-side ADF test and a sup test, based on the recursive estimation of (22.75). Recursive estimation is implemented by fitting (22.75) for a fraction of the sample, say r_0, and sequentially increasing this fraction by including successive observations. Under the null the corresponding test statistics, denoted by ADF_r and $\sup_{r\in[r_0,1]} ADF_r$, are:

$$ADF_r \Rightarrow \frac{\int_0^r W dW}{\int_0^r W^2}, \tag{22.76}$$

$$\sup_{r\in[r_0,1]} ADF_r \Rightarrow \sup_{r\in[r_0,1]} \frac{\int_0^r W dW}{\int_0^r W^2}, \tag{22.77}$$

where W denotes Brownian motion and $r \in [r_0, 1]$. If the null hypothesis is rejected then confidence intervals for the parameter ϕ can be constructed on the basis of the work of Phillips and Magdalinos (2007) regarding the asymptotic distribution theory for mildly explosive processes.

Application of these methods to exchange rates and their fundamental determinants as well as forward premia would seem to be of interest. It might also be interesting to examine the power of their tests against certain nonlinear processes, given that the forward premium should embody any rational bubble and that it has been modeled by such processes as discussed in section 22.3.

Another important property of Markovian bubbles was proved initially by Lux and Sornette (2002). The standard empirical finding is that the distribution of asset returns belongs to the class of so-called fat-tailed distributions with hyperbolic decline of probability mass in the tails. They derived the implications of rational bubbles of the Blanchard–Watson type for the unconditional distribution of prices, price changes and returns. They proved that the Blanchard–Watson (1982) bubble exhibited a tail index of less than unity (see, e.g., Koedijk *et al.*, 1990; Loretan and Phillips, 1994; Huisman *et al.*, 2001; Wagner and Marsh, 2005).[62] Yoon (2005) proved the same result for the Evans (1991) bubble and this property was transferred to asset returns. In fact, the empirical results for exchange rates typically generate tail estimates of around 2–6, suggesting the absence of bubbles. However, the results of Phillips *et al.* (2006) are relevant here. For instance, the standard ADF test suggested the absence of bubbles when applied to the full sample of Nasdaq price data that they considered – February 1973 to June 2005. However, their new test procedure detects the presence of a bubble in June 1995 continuing until July 2001.

This suggests that one could, in principle, employ the Phillips procedure to indicate the potential presence of bubbles and use the indicated bubble samples to obtain tail estimates. It would also seem of interest to examine the properties of the cointegrating residuals using the Phillips *et al.* (2006) tests as well as their tail properties, perhaps estimating the cointegrating vector by the Phillips *et al.* (1996) FM-LAD estimator, the properties of which seem ideal in this context.

22.6 Exchange rates, economic fundamentals and forecasting

In their landmark paper, Meese and Rogoff (1983a) employed rolling regressions in order to generate forecasts for the level of the spot rate based on a comprehensive range of exchange rate determination models: the flexible-price monetary model (Frenkel–Bilson), the sticky-price monetary model (Dornbusch–Frankel), and the sticky-price asset model (Hooper–Morton). At the time there was widespread optimism about the potential of monetary models to explain the fluctuations of floating exchange rates.

A general "prediction" equation that nests all models under examination is:

$$s_{t+k} = a_{0,k} + a_{1,k}(m_t - m_t^*) + a_{2,k}(w_t - w_t^*) + a_{3,k}(i_t - i_t^*) + a_{4,k}(\pi_t^e - \pi_t^{e*}) + a_{5,k}tb_t + a_{6,k}tb_t^* + u_t, \quad (22.78)$$

where s_{t+k} denotes the log exchange rate (domestic price of foreign currency), m_t is the log of the money supply, w_t is the log of real income, i_t is the short-term interest rate, π_t^e denotes expected inflation, tb_t is the cumulated trade balance, u_t is a possibly serially correlated error term, and the a_ks are parameters corresponding to the kth forecast horizon, with $k = 1, 3, 6, 12$ months. An asterisk denotes foreign quantities. Meese and Rogoff (1983a) estimated the above regression by OLS, as well as GLS and instrumental variables (IVs) (Fair, 1970) so as to deal with the presence of serial correlation in the residuals and simultaneous equation bias due to the endogeneity of the variables. Surprisingly, on the basis of root mean squared error (RMSE), none of these models outperformed the naive RW model for horizons up to a year, even though realized values of the forcing variables were used.

The poor forecasting performance of the considered models can be attributed to a number of factors. First, the fact that the variables are highly persistent may lead to biased estimates of the coefficients (Rossi, 2005). If the error term is non-stationary (i.e., the exchange rate is not cointegrated with fundamentals), the coefficients will be inconsistent and forecasting will be meaningless. Second, equation dynamics (MacDonald and Taylor, 1994) are omitted from the regression equation and the case of a nonlinear DGP is not considered (see Taylor and Peel, 2000; Meese and Rose, 1990). Further, parameter instability may characterize empirical exchange rate models (Wolff, 1987; Rossi, 2006) and simultaneous equation bias may not have been properly accounted for. As far as the latter explanation is concerned, Meese and Rogoff (1983b) impose coefficient restrictions based on the theoretical and empirical literature on money demand and the rate at which shocks to the real exchange rate appear to damp out. This enables the examination of longer forecasting periods. Their findings indicate that, for horizons greater than a year, there are cases where the RMSE of the RW is larger than that of structural models, suggesting the presence of simultaneous equation bias and that the performance of structural models may improve at longer horizons (Meese and Rogoff, 1983b; Rogoff, 1999). These findings support the estimation of long-horizon regressions and the application of advanced inference procedures (see, e.g., Mark, 1995; Chinn and Meese, 1995).

22.6.1 Long-horizon regressions

Consider the monetary model (22.66) and let the fundamental term, f_t, follow a driftless RW. Then equation (22.66) reduces to $s_t = f_t$. The relationship between the exchange rate and the monetary fundamentals motivates Mark (1995) to examine whether current deviations of the exchange rate from its fundamental value, $z_t \equiv f_t - s_t$, contain predictive power for future movements in the exchange rate, as well as the horizon at which the predictive power of the deviations becomes apparent. Obviously, this contrasts with the view that exchange rates are best characterized

by a no-change model:

$$s_{t+k} - s_t = \varepsilon_{t+k}, \quad k = 1, 4, 8, 12, 16 \text{ quarters}, \tag{22.79}$$

and motivates the use of long-horizon regressions:

$$s_{t+k} - s_t = a_k + \beta_k z_t + \varepsilon_{t+k}, \quad k = 1, 4, 8, 12, 16 \text{ quarters}. \tag{22.80}$$

The exchange rate is expected to rise (fall) when it is below (above) its fundamental value. Thus the slope coefficient β_k should be positive and statistically significant. Formally, the null hypothesis to be tested is $H_0 : \beta_k = 0$ against the alternative $H_1 : \beta_k > 0$, or the joint hypothesis $H_0 : \beta_k = 0 \, \forall k$ versus $H_1 : \beta_k > 0$ for some k. The evaluation of the out-of-sample performance of the model involves generating recursive or rolling forecasts based on equations (22.66) and (22.79) and estimating a forecast evaluation statistic such as Theil's U-statistic, or the DM-statistic of Diebold and Mariano (1995).

In evaluating the statistical significance of the results Mark confronted a number of econometric problems. First, a highly persistent explanatory variable implies biased OLS estimates of the slope coefficients in finite samples (see Neely and Sarno, 2002, and the references therein). Second, the fact that the k-period change in s_t is used as the regressand induces serial correlation in the disturbances of order $(k - 1)$, for $k > 1$. In order to correct for serial correlation Mark used the Newey–West covariance matrix estimator based on either a fixed truncation lag of 20 or a truncation lag specified by Andrews' (1991) procedure. Finally, although the DM-statistic follows the standard normal distribution for non-nested models, long-horizon regressions nest the RW model and, therefore, the distribution of the DM-statistic is not known in general (McCracken, 1999). To this end, Mark proposed a bootstrap procedure:

1. Estimate the following vector autoregression (VAR), where the null of no predictability has been imposed:

$$\Delta s_t = a_0 + u_{s,t}, \tag{22.81}$$

$$z_t = \mu + \sum_{j=1}^{p} b_j z_{t-j} + u_{z,t}. \tag{22.82}$$

2. Use the estimates of the fitted model and draw from the bivariate normal distribution with mean 0 and covariance matrix equal to the covariance matrix of the estimated residuals, in order to recursively generate pseudo observations for Δs_t and Δz_t. Alternatively, if the error term is not normal, resample from the observed residuals.
3. In turn, estimate the long-horizon regression so as to obtain the slope coefficient, the t-statistics and R^2 for the simulated series and generate forecasts based on the monetary and the driftless RW model and compute Theil's U-statistic and the DM-statistic.

4. Repeat steps 2 and 3 2,000 times so as to obtain bootstrap distributions and the corresponding *p*-values.

Mark (1995) examines quarterly US dollar exchange rates for the Canadian dollar, Deutsche Mark, Japanese yen and the Swiss franc and the corresponding fundamentals from 1973:2 to 1991:4. The last 40 quarters are used for the out-of-sample forecasting exercise. His findings indicate that the hypothesis of no in-sample predictability, $H_0 : \beta_k = 0 \ \forall k$, can be rejected at the 5% significance level for Switzerland and Germany. The slope coefficients, the R^2s and the test statistics tend to increase with the forecast horizon for all countries. Furthermore, in several cases the monetary model forecasts are superior to the RW model, especially for long horizons. Mark (1995) concludes that, given the small size of the dataset, these results support the view that exchange rates are predictable.

22.6.1.1 Turning on the microscope

A number of subsequent studies questioned the validity of Mark's methodology and the resultant conclusions (see Neely and Sarno, 2002). An important assumption in Mark's study was that the process of the deviations of the exchange rate from its fundamental value is stationary. By the Granger representation theorem the exchange rate and the fundamentals must posses a vector error correction model (VECM) representation with cointegrating vector $(1, -1)$. The VECM model is expressed:

$$\Delta s_t = \mu_s + \lambda_s z_{t-1} + \sum_{i=1}^{p-1} \phi_i^s \Delta s_{t-i} + \sum_{i=1}^{p-1} \psi_i^s \Delta f_{t-i} + u_{s,t}, \tag{22.83}$$

$$\Delta f_t = \mu_f + \lambda_f z_{t-1} + \sum_{i=1}^{p-1} \phi_i^f \Delta s_{t-i} + \sum_{i=1}^{p-1} \psi_i^f \Delta f_{t-i} + u_{f,t}, \tag{22.84}$$

where λ_s and λ_f determine the speed of adjustment, μ_s and μ_f are intercepts, ϕ_i and ψ_i are parameters, and the disturbance terms $u_{s,t}$ and $u_{f,t}$ are i.i.d. Stationarity requires one of the speed of adjustment terms to be different from zero and $\lambda_f - \lambda_s < 0$.

Berkowitz and Giorgianni (2001) use the VECM representation and derive the following expression for the slope coefficient in the long-horizon regression (22.80):

$$\beta_k = \beta_1 \frac{1 - \theta^k}{1 - \theta}, \tag{22.85}$$

where $\theta = 1 + \lambda_f - \lambda_s < 0$ and $\beta_1 = \lambda_s$. The above equation provides several insights concerning long-horizon regressions under the assumption of a linear DGP. The rejection of the null hypothesis that the slope coefficients in the long-horizon regressions are zero implies that the exchange rate is weakly exogenous. In this case, although the fundamentals do not contain predictive power, the existence of a long-run relationship between fundamentals and the exchange rate is not ruled out. It follows that, in the context of a linear model, the fundamentals cannot

contain predictive power at long horizons without the presence of short-run predictability, given that $\beta_1 = 0$ implies $\beta_k = 0 \forall k$. Thus, either Mark's results are spurious, or the DGP is misspecified.[63]

Spurious inference may arise due to the fact that Mark's procedure is based on the assumption that the deviation process is stationary. Conditioning on cointegration when cointegration fails may result in false inferences. The LS estimates of the long-horizon regression will be inconsistent without having any economic interpretation and conventional statistical tests will not be valid, especially for long-horizons (see Berben and van Dijk, 1998). Let s_t follow an RW: it follows that, for large k, the dependent variable $s_{t+k} - s_t$ will also approximate an RW. Given that $z_t \sim I(1)$, the long-horizon regression involves regressing an $I(1)$ variable on another $I(1)$ variable. This gives rise to a near-spurious regression problem (Granger and Newbold, 1974).[64] To this end, Berkowitz and Giorgianni (2001) apply the Horvath–Watson test (Horvath and Watson, 1995) without being able to reject the null of no cointegration for all countries except Switzerland. It is noted, however, that if the deviation process is, in fact, nonlinear then linear cointegration techniques may suffer from low power (Paya and Peel, 2007a).

Kilian (1999) emphasizes that the stability of the bootstrap DGP is not ensured in the procedure proposed by Mark. To this end, he suggests feasible generalized least squares (FGLS) estimation subject to a stability constraint. Furthermore, he notes that Mark's approach is inconsistent and may result in spurious inference due to the fact that a drift is included in the bootstrap exchange rate series but forecasts are based on the no-change model. Thus, the superior forecast performance of the long-horizon regression may be due to either the contribution of the fundamentals or just the inclusion of the drift term. The VECM bootstrap proposed consists of the following steps:

1. Define the VECM model as the DGP:

$$\Delta s_t = \mu_s + \lambda_s z_{t-1} + \sum_{i=1}^{p-1} \phi_i^s \Delta s_{t-i} + \sum_{i=1}^{p-1} \psi_i^s \Delta f_{t-i} + u_{s,t},$$

$$\Delta f_t = \mu_f + \lambda_f z_{t-1} + \sum_{i=1}^{p-1} \phi_i^f \Delta s_{t-i} + \sum_{i=1}^{p-1} \psi_i^f \Delta f_{t-i} + u_{f,t}.$$

2. Impose the null that all the coefficients in the first equation except for the intercept are zero and specify the lag order by using an information criterion such as the AIC. Estimate the model by FGLS subject to the stability constraint.
3. Use the coefficient estimates and draw with replacement from the observed recentered residuals to recursively generate pseudo-observations for Δs_t and Δf_t.
4. Estimate the long-horizon regressions for the pseudo-series and construct the test statistics under examination.
5. Repeat steps 3 and 4 2,000 times so as to obtain bootstrap distributions of the test statistics and the corresponding p-values.

Kilian extends the sample period from 1991:4 to 1997:4 and applies both Mark's bootstrap methodology and the VECM bootstrap. The former methodology indicates that for the extended data set the *p*-values of the various statistics are stable or increasing and there is overall predictability only for Switzerland.[65] Kilian also shows that the effect of small sample bias, together with the fact that Mark's bootstrap is inconsistent, has a substantial impact on inference. When allowing for a drift in the forecasts of the RW, both bootstrap methodologies detect overall predictability for Switzerland and Canada.

22.6.1.2 Forecast evaluation measures

In the late 1990s, the scientific consensus was that the Meese and Rogoff (1983a, 1983b) results still stood (Rogoff, 1999). However, the findings of Clark and McCracken (2001, 2003, 2005) raise concerns regarding the power of commonly used *t*-type tests. This motivates McCracken and Sapp (2005) to investigate the out-of-sample performance of exchange rate determination models using new test statistics regarding the comparison of nested models.[66]

Let $y_{t+k} = s_{t+k} - s_t$ denote the variable to be predicted and $x_{2,t} = (x'_{1,t}, x'_{22,t})'$ be a vector of predictors. The number of in-sample and out-of-sample observations is R and P, respectively, so that $T = R + P$. Forecasts are generated by estimating two linear models of the form $x_{1,t}\beta_1$ and $x'_{22,t}\beta_2$ recursively by OLS. The forecast errors are $\hat{u}_{1,t+k} = y_{t+k} - x'_{1,t}\hat{\beta}_{1,t}$ and $\hat{u}_{2,t+k} = y_{t+k} - x'_{22,t}\hat{\beta}_{2,t}$. Under the null hypothesis the first model is nested within the second and the two forecast errors are identical. In the present context, the first model is the RW with a drift and the second the long-horizon regression model, which implies that $x_{1,t} = 1$ and $x_{22,t} = z_t$.

The first two test statistics examined are used to test for forecast accuracy. The former is a *t*-type test and the latter is its *F*-type counterpart. The null hypothesis is that the two mean squared errors (MSEs) are equal against the alternative that the MSE for the second model is smaller. Let $\widehat{d}_{t+k} = \widehat{u}^2_{1,t+k} - \widehat{u}^2_{2,t+k}$, $\bar{d} = (P - k + 1)^{-1} \sum_{t=R}^{T-k} \widehat{d}_{t+k} = \text{MSE}_1 - \text{MSE}_2$, $\widehat{\Gamma}_{dd}(j) = (P - k + 1)^{-1} \sum_{t=R+j}^{T-k} \widehat{d}_{t+k}\widehat{d}_{t+k-j}$ for $j \geqslant 0$ and $\widehat{\Gamma}_{dd}(j) = \widehat{\Gamma}_{dd}(-j)$, and let $\widehat{S}_{dd} = \sum_{j=-\bar{j}}^{\bar{j}} K(j/M)\widehat{\Gamma}_{dd}(j)$ be the long-run covariance of d_{t+k} estimated using a kernel-based estimator with function $K(\cdot)$, bandwith parameter M and maximum number of lags $\bar{j}$. The tests for forecast accuracy are:

$$\text{MSE} - t = (P - k + 1)^{1/2} \frac{\bar{d}}{\widehat{S}_{dd}^{1/2}}, \tag{22.86}$$

$$\text{MSE} - F = (P - k + 1)^{1/2} \frac{\bar{d}}{\text{MSE}_2}. \tag{22.87}$$

The next two tests concern forecast encompassing and are built upon the statistic used by Harvey *et al.* (1998) for non-nested models. In this case, the null hypothesis is that the forecast of the RW model encompasses that of the structural exchange rate model and, therefore, the covariance between the forecast

errors of the RW and the difference of the forecasts errors of the two models will be equal to or smaller than zero. Under the alternative, the deviations from fundamentals contain valuable information, implying that the covariance is positive. Let $\widehat{c}_{t+k} = \widehat{u}_{1,t+k}(\widehat{u}_{1,t+k} - \widehat{u}_{2,t+k})$. The forecast-encompassing test statistics are:

$$\text{ENC} - t = (P - k + 1)^{1/2} \frac{\bar{c}}{\hat{S}_{cc}^{1/2}}, \tag{22.88}$$

$$\text{ENC} - F = (P - k + 1)^{1/2} \frac{\bar{c}}{MSE_2}. \tag{22.89}$$

The limiting distributions of the test statistics considered so far are non-standard and depend upon nuisance parameters. Thus, critical values for the test statistics should be generated by bootstrap procedures, such as the VECM bootstrap of Kilian (1999).

The final statistic, derived by Chao *et al.* (2001), is also used to test for forecast encompassing and follows a χ^2 distribution. Let $\widehat{h}_{t+k} = \widehat{u}_{1,t+k}x_{1,t}$, $\widehat{b}_{t+k} = \widehat{u}_{1,t+k} + x_{22,t}$, $\bar{b} = (P - k + 1)^{-1} \sum_{t=R}^{T-k} \widehat{b}_{t+k}$, $\widehat{F} = -(P - k + 1)^{-1} \sum_{t=R}^{T-k} x_{22,t}x'_{1,t}$, and $\widehat{B} = [(P - k + 1)^{-1} \sum_{t=R}^{T-k} x_{1,t}x'_{1,t}]^{-1}$. Furthermore, let $\hat{\Gamma}_{bb}(j) = (P - k + 1)^{-1} \sum_{t=R+j}^{T-k} \hat{b}_{t+k}\hat{b}'_{t+k-j}$, $\hat{\Gamma}_{hh}(j) = (P - k + 1)^{-1} \sum_{t=R+j}^{T-k} \hat{h}_{t+k}\hat{h}'_{t+k-j}$, $\hat{\Gamma}_{bh}(j) = (P - k + 1)^{-1} \sum_{t=R+j}^{T-k} \hat{b}_{t+k}\hat{h}'_{t+k-j}$, for $j \geqslant 0$, with $\hat{\Gamma}_{bb}(j) = \hat{\Gamma}_{bb}(-j)$, $\hat{\Gamma}_{hh}(j) = \hat{\Gamma}_{hh}(-j)$, $\hat{\Gamma}_{bh}(j) = \hat{\Gamma}_{bh}(-j)$. Finally, let $\hat{S}_{bb} = \sum_{j=-\bar{j}}^{\bar{j}} K(j/M)\hat{\Gamma}_{bb}(j)$, $\hat{S}_{hh} = \sum_{j=-\bar{j}}^{\bar{j}} K(j/M)\hat{\Gamma}_{hh}(j)$, $\hat{S}_{bh} = \sum_{j=-\bar{j}}^{\bar{j}} K(j/M)\hat{\Gamma}_{bh}(j)$. The test statistic is written as:

$$\text{CCS} = (P - k + 1)\bar{b}'\Omega\bar{b}, \tag{22.90}$$

where $\Omega = \hat{S}_b b + \hat{\lambda}_{bh}(\hat{F}\hat{B}\hat{S}'_{bh} + \hat{S}'_{bh}\hat{B}'\hat{F}') + \hat{\lambda}_{bb}\hat{F}\hat{B}\hat{S}'_{hh}\hat{B}'\hat{F}'$, $\hat{\pi} = (P - k + 1)R^{-1}$, $\hat{\lambda}_{bh} = 1 - \hat{\pi}^{-1}ln(1 + \hat{\pi})$, $\hat{\lambda}_{bh} = 2[1 - \hat{\pi}^{-1}ln(1 + \hat{\pi})]$. The null hypothesis of no predictability based on macroeconomic fundamentals requires the covariance between $u_{1,t+k}$ and $x_{22,t}$ to be zero. If fundamentals contain predictive power then the covariance should deviate from zero.

McCracken and Sapp (2005) employ the long-horizon regression (22.80), but follow Meese and Rogoff (1983a, 1983b) and determine the fundamental value of the exchange rate according to various structural models. This approach results in a vast number of tests, which raises concerns about the reliability of inference.[67] In order to mitigate the multiple testing problem, McCracken and Sapp (2005) follow recent developments in the statistical genetics literature and calculate *q*-values along with the *p*-values.[68] Using both *p*-values and *q*-values, they find evidence of predictability for many cases. The encouraging results can be attributed to the fact that the new *F*-type tests are more powerful than the *t*-type tests. Despite the fact that RMSEs are similar to those reported by Kilian (1999), the *F*-type tests are able to detect the superiority of the structural models over the RW with a drift. As far as the monetary model is concerned, *F*-type tests of equal forecast accuracy indicate

more short horizon predictability for Germany and more long-horizon predictability for Canada and Switzerland. Moreover, tests of forecast encompassing appear to be superior in detecting predictability of exchange rates compared to tests of forecast accuracy.

22.6.2 Nonlinear models

Taylor and Kilian (2003) investigate the forecasting performance of long-horizon regressions in the presence of ESTAR dynamics in the real exchange rate. They employ the long-horizon regression of Mark (1995) and draw inferences from bootstrap distributions of the test statistics generated under the null hypothesis that the nominal exchange rate s_t follows an RW and the real exchange rate z_t is an ESTAR process:[69]

$$s_t = \mu_s + u_{s,t}, \tag{22.91}$$

$$z_t = \mu_z + \left[\phi_1(z_{t-1} - \mu_z) + (1 - \phi_1)(z_{t-2} - \mu_z)\right] \times \exp\left(-\gamma \sum_{d=1}^{5} (z_{t-d} - \mu_z)^2\right) + u_{z,t}. \tag{22.92}$$

Taylor and Kilian (2003) use quarterly data for seven OECD countries for the period 1973:1 to 1998:4. Long-horizon regressions appear to be significantly more accurate than the naive RW model in several cases, especially when the Newey–West standard errors are used with the truncation lag specified by Andrews' procedure. However, the out-of-sample results are not as encouraging.[70] The *DM*-statistics indicate that the long-horizon regression model is capable of beating the RW model only for the UK and Switzerland at the three-year horizon. The authors conclude that incorporating nonlinearities increases the predictability of models based on macroeconomic fundamentals. However, it is difficult to detect the improvement in the forecast accuracy due to the small time span and the rarity of large deviations from the fundamentals.

Another group of recent studies focuses on the Markov-switching (MS) model, which allows exchange rate dynamics to alternate between regimes.[71] Clarida *et al.* (2003) argue that the forward rate has predictive content regarding the spot rate. The authors build upon the results of Clarida and Taylor (1997) and apply an MS-VECM model, which allows for shifts in the intercept and the error variance. Their findings indicate that the MS-VECM outperforms both the linear VECM and the naive RW model, especially at long horizons.

Sarno *et al.* (2004b) employ a long span of data for the US dollar exchange rate and show that fundamentals are useful in explaining the behavior of numerous exchange rates under different monetary regimes by estimating MS-VECM models. Frömmel *et al.* (2005), motivated by the market microstructure literature (Lyons, 2001) and questionnaire surveys (e.g., Cheung and Chinn, 2001) showing that market participants regard the importance of fundamentals as time-varying, establish that there are significant regime changes in real interest differential (RID) variants of the monetary model (Frankel, 1979) for three major US dollar exchange rates.[72]

The MS model employed can be written as (see Hamilton, 1994):

$$r_t = \alpha(S_t) + \beta(S_t)\text{fund}_t + \varepsilon_t, \quad S_t = 1, \ldots, M, \tag{22.93}$$

where r_t is the 12-month percentage change of the exchange rate and fund_t denotes the vector of RID fundamentals, which covers relative changes in money supply, industrial production, money market interest rates and the government bond yield. The vectors of coefficients, α and β, are governed by the unobservable state variable, S_t. In MS models the regime-generating process is an ergodic Markov chain with a finite number of states, M, defined by the transition probabilities $p_{ij} = Pr(S_{t+1} = j | S_t = i)$ with $\sum_{j=1}^{M} p_{ij} = 1 \; \forall i, j \in 1, \ldots, M$. Frömmel *et al.* (2005) set the number of states equal to two and assume that the error term, ε_t, is a white-noise process with constant variance. The estimation of the model is implemented by using an expectation maximization (EM) algorithm (Kim and Nelson, 1999).

Wald tests indicate that the null hypothesis of constant parameters can be rejected for all exchange rates. For each exchange rate the coefficients are in line with the RID model for one of the regimes. Furthermore, the MS-RID model produces a lower RMSE than the RW model. In contrast to the in-sample results, the out-of-sample performance of the MS-RID model is not as encouraging. Frömmel *et al.* (2005) use a rolling sample of ten years and calculate the conditional expectations of the percentage change of the exchange rate. Although the MS-RID model is superior to the standard RID model, it cannot beat the naive RW on the basis of the *DM*-statistic. This finding is not surprising, since non-linear models in general, and MS models in particular, may produce superior in-sample fits compared to linear models but not necessarily superior forecasts (see Dacco and Satchell, 1999).

22.6.3 Real-time forecasting and market expectations

It is common practice in studies of exchange rate forecasting to employ the most recent datasets on macroeconomic fundamentals. However, these datasets are subject to extensive revisions and are not available to real-time forecasters. Provided that market participants' expectations depend on currently available data on fundamentals, real-time data may lead to a better approximation of market expectations than revised data (Neely and Sarno, 2002). According to the present value model (22.61), exchange rates are influenced by market expectations of future fundamentals and, therefore, real time data may improve upon the predictability of exchange rates.

Faust *et al.* (2003) investigate the impact of using real time data for the currencies examined by Mark (1995). Their findings indicate that long-horizon predictability is present only in less than a two-year window around the vintage used by Mark. In order to isolate the effect of data revisions from the sample period, the authors fix the estimation and the forecast periods to be the same as Mark's and use all vintages of data from 1992 onward. Overall, the evidence of predictability weakens. As far as real-time forecasting is concerned, the out-of-sample performance of the monetary model is poor. The RMSEs are generally greater than those of the RW model and increase with the horizon. However, real-time forecasts produce significantly lower

Theil U-statistics than forecasts based on the revised data, indicating the superiority of real-time data.[73]

Engel and West (2005) provide a thorough analysis of the role of market expectations and the value of the discount factor. According to the rational expectations present value model (22.61), the importance of expected future fundamentals relative to current fundamentals increases with the discount factor, b. For large b and non-stationary fundamentals, the movement in the exchange rate at time t will be almost uncorrelated with information known at time $(t-1)$, since the exchange rate will be largely driven by the expected future path of the fundamentals. By the Engel and West (2005) theorem, if $a_1' x_t \sim I(1)$ and $a_2 = 0$ or $a_2' x_t \sim I(1)$ then, as $b \to 1$, the exchange rate exhibits near random walk behavior.[74] The theorem highlights the fact that movements in the exchange rate reflect changes in expectations. If expectations contain valuable information about future fundamentals then changes in the exchange rate should be useful in forecasting fundamentals. This provides an alternative approach concerning the evaluation of the performance of the various models under examination.

A different perspective for the implications of the Engel and West theorem is provided by Evans and Lyons (2005) in the context of market microstructure. Lyons show that micro-based models can establish a link between expectational surprises and specific types of non-public information. The key idea is that the trades of private agents reveal new information to the market makers about future fundamentals. In this framework prices are determined by the market makers' expectations, E_t^m, about the future values of fundamentals. The market makers construct their information sets and revise their forecasts on the basis of the order flow, $x_{o,t}$, that is signed transaction flow. Suppose that innovations in order flow are correlated with the innovations in fundamentals growth:

$$\Delta x_{o,t} = \lambda \Delta x_{o,t-1} + \eta_t, \tag{22.94}$$

$$\Delta f_t = \phi \Delta f_{t-1} + u_t + \delta \eta_t, \tag{22.95}$$

and that market makers observe order flow innovations and, hence, the current state of the economy, with a time delay $f_t - E_t^m f_t = \delta \eta_t$. Evans and Lyons (2005) show that, under these assumptions, the present value model (22.61) implies that changes in the exchange rate depend on lagged order flow:

$$\Delta s_{t+1} = \frac{1-b}{b}(s_t - E_t^m f_t) + \frac{1}{1-b\phi} u_{t+1} + \frac{[1+\phi(1-b)]\,\delta}{1-b\phi}(x_{o,t} - \lambda x_{o,t-1}). \tag{22.96}$$

It follows from the above equation that $b \to 1$ does not rule out forecastability. In order to test whether order flow contains predictive power for the movements in the exchange rate, they employ the following regression equations:

$$s_{t+1} - s_t = \alpha_0 + \alpha x_{o,t}^{agg} + \varepsilon_{t+1}, \tag{22.97}$$

where $x_{o,t}^{agg}$ denotes aggregate order flow, and:

$$s_{t+1} - s_t = \alpha_0 + \sum_{j=1}^{6} \alpha_j x_{o,t}^{j} + \varepsilon_{t+1}, \tag{22.98}$$

where $x^{j}_{o,t}$ denotes order flow from end-user segment j. Six end-user segments are considered: trades implemented in the US and non-US markets for non-financial firms, investors and leveraged trades. The forecasting performance of the micro-based model is compared to that of an RW and a structural model using data for the largest spot market, the US dollar/euro, for the period from 1993 to 1999. In general, the findings indicate that, for horizons between 10 and 20 days, the micro-based models are able to beat the RW benchmark and the structural model, irrespective of the type of order flow used.

Large values of the discount factor and highly persistent fundamentals provide an explanation for the failure of structural models in out-of-sample forecasting. However, forecastability of the changes in the exchange rate is still possible in the presence of stationary terms. Consider the present value model (22.61) and let $f_t = a_1' x_t$ and $a_2' x_t = rp_t$. If the deviations from the UIP, rp_t, follow a stationary AR(1) process:

$$rp_t = \theta rp_{t-1} + e_t, \tag{22.99}$$

where $e_t \sim$ i.i.d. and $\sigma_e^2 = var(e_t)$, and f_t is an RW process, with innovation η_t and $\sigma_\eta^2 = var(\eta_t)$, then the forward solution for the exchange rate is:

$$s_t = f_t + \frac{b}{1 - b\theta} rp_t. \tag{22.100}$$

The k-period change in the exchange rate is:

$$\begin{aligned} s_{t+k} - s_t &= f_{t+k} - f_t + \frac{b}{1 - b\theta}(rp_{t+k} - rp_t) \\ &= \sum_{j=1}^{k} \eta_{t+k} + \frac{b}{1 - b\theta}(\theta^k - 1) rp_t + \frac{b}{1 - b\theta} \sum_{j=1}^{k} \theta^{k-j} e_{t+k} \\ &= \sum_{j=1}^{k} \eta_{t+k} + (1 - \theta^k) z_t + \frac{b}{1 - b\theta} \sum_{j=1}^{k} \theta^{k-j} e_{t+k}, \end{aligned} \tag{22.101}$$

where z_t are the deviations from the observed fundamentals, and the corresponding R_k^2 is:

$$\begin{aligned} R_k^2 &= \frac{(\theta^k - 1)^2 \text{var}(f_t)}{\text{var}(s_{t+k} - s_t)} \\ &= \frac{(1 - \theta^k)^2 \sigma_e^2}{(1 - \theta^k)^2 \sigma_e^2 + (1 - \theta^{2k})^2 \sigma_e^2 + k(1 - \theta^2)(1 - b\theta)^2 \sigma_\eta^2 / b^2}. \end{aligned} \tag{22.102}$$

Engel *et al.* (2007) set $b = 0.9$, $\theta = 0.95$ and $\sigma_\eta / \sigma_e = 3$ and calibrate the model. They find that predictability, in terms of R_k^2, exhibits a hump shaped pattern with respect to k. At short horizons there is not much evidence of predictability, e.g., $R_1^2 = 0.02$,

but, as the horizon increases, the value of R^2 becomes larger and reaches a maximum at a horizon of 44 quarters, where $R^2_{44} = 0.38$. The authors argue that, in this framework, panel estimation techniques may be useful in detecting predictability by picking up a common element to the risk-premium across exchange rates.

22.6.4 Panels

Empirical studies based on country-by-country estimations are confronted with the problem of low power and poor parameter estimates. The possibility of common elements in the DGPs motivates the use of pooled time series estimation in order to increase the power of predictability tests.[75] A number of recent studies using panel datasets provide evidence in favor of a long-run relationship of the deviations of the exchange rate from its fundamental value.[76]

Mark and Sul (2001) investigate if panel estimation techniques are useful in forecasting exchanges rates by exploiting interdependencies of exchange rates with the same numeraire, namely the US dollar, the Swiss franc and the Japanese yen. The dataset includes 19 OECD countries and spans the period from 1973:1 through 1997:1. Their study centers on the panel version of the equation employed in Mark (1995):

$$s_{i,t+1} - s_{i,t} = \beta z_{i,t} + e_{i,t+1}, \tag{22.103}$$

$$e_{i,t+1} = \gamma_i + \theta_{t+1} + u_{i,t+1}, \tag{22.104}$$

where γ_i is a country-specific effect, θ_{t+1} is a time-specific error and $u_{i,t+1}$ is an idiosyncratic error. Before examining the out-of-sample performance of the multi-country monetary model, Mark and Sul (2001) follow Berkowitz and Giorgianni (2001) and test for cointegration. However, due to the fact that the standard least squares dummy variable (LSDV) estimator suffers from second-order bias, causing the t-statistic to diverge asymptotically, the panel dynamic OLS estimator is adopted. The system of equations for the changes in the exchange rates is:

$$s_{i,t+1} - s_{i,t} = \gamma_i + \theta_t + \beta z_{i,t-1} + \sum_{j=-p_i}^{p_i} \delta_{ij} \Delta x_{i,t-j-1} + u_{i,t}. \tag{22.105}$$

Although the corresponding t-ratio is asymptotically normally distributed, Mark and Sul (2001) also use a bootstrap procedure to account for possible finite sample bias. The null DGP for the bootstrap is a restricted VAR:

$$\Delta s_{i,t} = \mu^i_s + \varepsilon^i_{s,t}, \tag{22.106}$$

$$\Delta z_{i,t} = \mu^i_z + \sum_{j=1}^{q_i} \phi^i_{1,j} \Delta s_{i,t-j} + \sum_{j=1}^{q_i} \phi^i_{2,j} \Delta z_{i,t-j} + \varepsilon^i_{z,t}. \tag{22.107}$$

The equations for $\Delta z_{i,t}$ are fitted by iterated seemingly unrelated regression (SUR).[77] For all three numeraire currencies, both the asymptotic and the

bootstrap p-values indicate that the null hypothesis of no cointegration is rejected at the 5% level. In turn, Mark and Sul (2001) test for short-horizon in-sample predictability in the presence of cointegration.[78] The results provide strong evidence in favor of predictability based on both monetary and PPP fundamentals. Finally, the authors examine whether macroeconomic fundamentals contain power in forecasting exchange rates at horizons $k = 1, 16$. They use Theil's U-statistic and construct bootstrap critical values under the assumption of cointegration. Overall, forecasts based on monetary fundamentals dominate forecasts based on the PPP fundamentals and the RW with a drift for the majority of countries when the US dollar or the Swiss franc is the numeraire currency, but not in the case of the Japanese yen.[79]

In this section we have shown how, more than 30 years after the breakdown of Bretton Woods, the difficulty of forecasting exchanges rates using economic fundamentals has become a stylized fact in international finance. Although the availability of longer datasets on modern floating rates and the application of recent sophisticated econometric techniques regarding panel data, nonlinear models, as well as forecast evaluation measures, are promising, researchers and practitioners are still faced with the problem of deriving models with robust behavior in terms of out-of-sample forecasting across exchange rates and time periods.

22.7 Conclusions

We have provided a selective overview of a few of the key relationships which will play critical roles in determining the behavior of the exchange rate and an evaluation of the efficacy of forecasting methods. The major change in their analysis over the last decade has been the application of more sophisticated time series techniques motivated by theoretical considerations such as the limits to arbitrage and the microstructure of the exchange market. Nonlinear models seem able to provide some explanation of the PPP puzzle and the forward bias problem. However, issues of how data sampled at a different frequency to the economic decision impacts on the nonlinear models needs further investigation. Also, the recent finding of joint long memory and nonlinearity in these relationships is a new puzzle. The possibility that the exchange market can exhibit bubbles is of long-standing interest. The new analysis of Phillips *et al.* (2006) would appear to be an exciting development and might provide new insights on this issue over the next few years.

The nonlinear methods appear to offer scope for improved forecasts than the previous linear models. However, researchers and practitioners are still faced with the problem of deriving models with robust behavior in terms of out-of-sample forecasting across exchange rates and time periods, even when the model employed for estimation or forecasting is appropriate for the policy regime in operation (or anticipated).

Notes

1. In fact, the first example of such arrangements was apparently Austria-Hungary between 1896 and 1914 (Flandreau and Komlos, 2003). Other important examples where the

anticipation of a change in policy regime has been an important focus of the analysis of exchange rates are: (i) the possible anticipation of the return to gold of sterling prior to April 1925 (e.g., Flood and Garber, 1983; Michael *et al.*, 1997), (ii) the anticipation of a fixed exchange rate between the East and West German Mark following German monetary union (Burda and Gerlach, 1993).

2. Similarly, chaotic behavior, which we do not have space to consider (see, e.g., De Grauwe *et al.*, 1993).
3. This would imply a half-life of around five years. Assuming $y_t \sim$ AR(1), the half-life (h) of a unit shock would be $0.5 = \beta^h$, or taking logs, $\ln 0.5 = h \ln \beta$, $h = \frac{\ln 0.5}{\ln \beta}$.
4. Linear univariate autoregressive time series models for the real exchange rate have not been restricted to integer orders of integration. Explosive as well as fractional processes have been used to model real exchange rates. Bleaney *et al.* (1999) fitted a stochastic unit root process to the real exchange rate of high inflation countries (Argentina, Brazil, Chile, and Israel). The real exchange rate process is as follows:

$$y_t = (1 + \delta_t) y_{t-1} + \nu_t,$$

where $\nu_t \sim$ i.i.d.$(0, \sigma_\nu^2)$ $\delta_t \sim$ i.i.d.$(0, \sigma_\delta^2)$. Leybourne *et al.* (1996) derive a test for the null hypothesis $H_0 : \sigma_\delta^2 = 0$ against $H_1 : \sigma_\delta^2 > 0$. It is worth mentioning that, even under the null, PPP is assumed non-stationary in this model. A different order of integration for PPP deviations is proposed by the fractional literature (see section 22.3.2: see, e.g., Diebold *et al.*, 1991; Pippenger and Goering, 1993; Taylor *et al.*, 2001). These papers also show that standard unit root tests may exhibit low power against the fractional alternative. However, neither the stochastic unit root nor fractional process have clear theoretical underpinnings.
5. Paya and Peel (2007a) also analyze the asymptotically efficient estimator for cointegration regression introduced by Saikkonen (1991). Cointegration is then tested using the Shin (1994) statistic, which is a residual-based test where the null hypothesis is that of cointegration or stationary residuals in the Saikkonen regression. Using simulated data, Paya and Peel (2007a) find that the Saikkonen estimator produces estimates of the cointegrating weights which are much closer on average to their true values, and with much smaller standard errors than the Johansen method.
6. The smooth adjustment process is suggested in the analysis of Dumas (1992), noted by Teräsvirta (1994) and demonstrated by Berka (2002).
7. The other common form of STAR is the logistic STAR (LSTAR), where the transition function $F(\cdot)$ is logistic:

$$F(z_{t-d}; \gamma, c) = [1 + \exp(-\gamma(z_{t-d} - c))]^{-1}.$$

The LSTAR transition function is asymmetric about $(y_{t-d} - c)$ and admits the limits:

$$F(\cdot; \gamma) \to 1 \text{ as } (z_{t-d} - c) \to +\infty,$$
$$F(\cdot; \gamma) \to 0 \text{ as } (z_{t-d} - c) \to -\infty.$$

LSTAR models have also been fitted to real exchange rates (see Sarantis, 1999; Copeland and Heravi, 2007). Even though the theoretical argument is not as strongly supported as with ESTAR, there are some attempts to rationalize the asymmetric adjustment in the real exchange rate (see Campa and Goldberg, 2002).
8. The effect of nonlinearities on traditional cointegration techniques have been examined. Paya and Peel (2007a) assume that the DGP is given by the ESTAR process. Using simulated data from such a model, in which proportionality, $(1, -1)$, is imposed, they examine the empirical results obtained when the Johansen method is employed to determine whether the spot exchange rate is cointegrated with domestic and foreign prices and whether proportionality can be rejected. Empirical results show that the Johansen method produces

poor estimates, on average, of the cointegrating vector, with a range of values that include those reported in the literature.

9. Conventional maximum likelihood theory is therefore not applicable. If one were to use a maximum likelihood estimator, the testing procedure would be analogous to the one described below but using the partial derivatives of the likelihood function evaluated under the null (see Granger and Teräsvirta, 1993, Ch. 6).
10. That is, $y_t = \beta' \widetilde{y}_t + \gamma \phi' \widetilde{y}_t (y_{t-d} - c)^2 + \gamma \phi' \widetilde{y}_t (y_{t-d} - c)^4$. Note that even powers of the Taylor approximation of the logistic function are all zero while odd powers of the Taylor approximation of the exponential are all zero. The logistic function has one inflection point while the exponential possesses two, which is the point of using a second-order Taylor expansion.
11. In particular, they propose to use the White heteroskedasticity consistent covariance matrix in the LM test. Their analysis is based on MacKinnon and White (1985). See also Wooldridge (1990).
12. See Lundbergh and Teräsvirta (1998) for the specification, estimation and evaluation of models with nonlinear behavior in the mean (STAR) and in the conditional variance (STGARCH), the STAR-STGARCH model.
13. See below for a description and references of this methodology.
14. However, its distribution is the same when the transition variable y^*_{t-1} is substituted by y^*_{t-d} or moving averages of y^*_{t-1} (see Venetis *et al.*, 2005). What changes is the form of the auxiliary regressions, which generalize to:

$$\Delta y^*_t = \delta y^*_{t-1} y^{*2}_{t-d} + error,$$

$$\Delta y^*_t = \sum_{j=1}^{p} a_j \Delta y^*_{t-j} + \delta y^*_{t-1} y^{*2}_{t-d} + error.$$

The corollary results in Venetis *et al.* are particularly important since it is possible to generalize KSS tests against wider alternatives that assume longer adjustment periods.

15. The linear unit root hypothesis against an ESTAR has also been tested using a different methodology to that of a Taylor approximation. Kiliç (2003) overcomes the identification problems for γ and c in his test by using a grid search over the space of values for the parameters γ and c to obtain the largest possible t-value for ϕ in the following regression:

$$\Delta y^*_t = \phi y^{*3}_{t-1} \left[1 - \exp(-\gamma (z_t - c)^2) \right] + error,$$

where z_t is the transition variable, which in our framework would be Δy^*_{t-1}. He tests the null hypothesis of $H_0 : \phi = 0$ (unit root case) against $H_1 : \phi < 0$. Kiliç (2003) claims that the advantages of his procedure over KSS is twofold. First, it computes the test statistic even when the threshold parameter needs to be estimated in addition to the transition parameter. Second, it claims to have higher power. Using quarterly data for 17 real exchange rates of developed countries against the dollar for the floating period, Kiliç finds strong evidence of nonlinear ESTAR behavior.

16. This approach is suggested by Vogelsang (1998).
17. PPP has also been tested using nonlinear cointegration. Kapetanios *et al.* (2003b) (KSSb) propose a testing procedure to detect the presence of a cointegrating relationship that follows a STAR process. Venetis *et al.* (2005) and Paya and Peel (2006a) find evidence of nonlinear cointegration between the real exchange rate and productivity proxies. Further support for nonlinear cointegration has been found with a cointegration method that uses a transformation of the variables. Breitung (2001) suggests a rank test procedure based on the difference between the sequences of ranks of the variables involved in the cointegrating relationship. Haug and Basher (2005) also apply the Breitung test for the dollar and DM based real exchange rates of the G10 countries and only found evidence of nonlinear long-run PPP in two of them, the pound/dollar and Belgian franc/DM.

18. The order of autoregression is chosen through inspection of the PACF function of y_t^*.
19. In the ESTAR model (22.15), if the error variance is not reported as standardized but has a standard error of *se*, it is necessary to multiply the estimated speed of adjustment parameter γ by (se^2) for comparison purposes.
20. Under the null hypothesis $H_0 : \gamma = 0$, y_t is generated as an RW with initial values $\{y_i\}_{i=-\max\{d,p\}}^{0} = 0$ and sample size set equal to the observed sample size. The underlying noise process u_t is $NID(0, s^2)$. The value of s is chosen to be equal to the standard error of each estimated model. Regression (22.15) is estimated using the respective d values and the t-ratios are stored for the estimates of γ. This is repeated 10,000 times and the critical values are obtained from the upper empirical quantiles since the empirical distributions are not symmetric and interest rests on the one-tail alternative $\gamma > 0$. See Paya and Peel (2006b) for a discussion of possible bias in the estimated γ for small samples.
21. We know from the transition function $F(\cdot)$ in ESTAR models that adjustment is time-varying and depends on the size of the deviation. However, for comparison purposes, we need a value of speed in time periods. The generalized impulse response function (GIRF) introduced by Koop *et al.* (1996) successfully confronts the challenges that arise in defining impulse responses for nonlinear models and is defined as:

$$\widehat{GIRF}_h(h, \delta, \omega_{t-1}) = E(y_{t+h}|u_t = \delta, \omega_{t-1}) - E(y_{t+h}|u_t = 0, \omega_{t-1}),$$

where $h = 1, 2, \ldots$ denotes horizon, u_t is a random shock of size δ occurring at time t, ω_{t-1} is defined by all sets $\{y_{1+i}^*, \ldots, y_{d+i}^*\}_{i=0}^{T-d-1}$, and Ω_{t-1} is a random variable defining possible history sets. Since analytic expressions for the conditional expectations involved in the expression above are not available for $h > 1$, Gallant *et al.* (1993) and Koop *et al.* (1996) used stochastic simulation to approximate it (see Venetis *et al.*, 2007, for an analytical expression for the "naive" impulse response function of an ESTAR model). Taylor and Peel (2000) conduct GIRF analysis on the deviations of real exchange rates from monetary fundamentals and Taylor *et al.* (2001) use impulse response functions to gauge how long shocks survive in real exchange rate nonlinear models. The half-life of shocks is dramatically shorter than that obtained or implied by linear models.
22. Analytic results are available on the impact of temporal aggregation on a linear series (e.g., Rossana and Seater, 1995) but not for nonlinear series.
23. For instance, MacKinnon and White (1985) showed that in finite samples the White HCCME can be seriously biased.
24. In Paya and Peel (2006a) the real dollar–sterling exchange rate series spans several exchange rate regimes, and within this context, a parametric form may not adequately capture the conditional heteroskedasticity in the data (see Gonçalves and Kilian, 2003).
25. Wild resampling typically underestimates the variance of the parent distribution. This can be remedied by replacing the observed residuals with "leveraged" residuals $\frac{\widehat{u}_t}{1-h_t}$, where h_t is the leverage for the ith residual estimated from the parametric model (see Davidson and Hinkley, 1997).
26. An alternative wild bootstrap has the following distribution: $\varepsilon_i = 1$ with $p = 0.5$; and $\varepsilon_i = -1$ with $p = 0.5$ (see Davidson and Flachaire, 2001).
27. The wild bootstrap matches the moments of the observed error distribution around the estimated regression function at each design point $(\widehat{y}^b)$. Liu (1988) and Mammen (1993) show that the asymptotic distribution of the wild bootstrap statistics are the same as the statistics they try to mimic.
28. For the cases where the time-varying equilibrium is defined by deterministic components, such as dummies and time trends, see Paya and Peel (2003, 2004).
29. Kapetanios (1999) considers the properties of model selection using information criteria in the context of nonlinear threshold models: in particular, Akaike information criterion (AIC), Schwarz criterion (SC), Hannan–Quinn (HQ) criterion, the generalized information criterion (GIC) and the informational complexity criterion (ICOMP). In a Monte Carlo

exercise he shows that standard information criteria (AIC, SC, HQ) have an important role to play in model selection for nonlinear threshold models. Others (GIC, ICOMP) are less reliable.

30. This particular type of TAR model is called a self-exciting threshold autoregressive (SETAR) model.
31. Peel and Taylor (2002) adopted a similar strategy in a threshold model under the null of RW. See Duarte *et al.* (2005, Appendix B) for the case where the errors display autocorrelation.
32. Estimate the model using the actual data for a set of values of c in the range C and in each case calculate the likelihood ratio (LR) statistic $LR(c)$ for that value of c against the value of the likelihood obtained by unrestricted LS, i.e., $LR(c) = T(\hat{\sigma}^2_T(c) - \hat{\sigma}^2_T(\hat{c}))/\hat{\sigma}^2_T(\hat{c})$. Notice that for $c = \hat{c}$ we get $LR(c) = 0$. Then plot $LR(c)$ against c and draw a flat line that corresponds to the β-level critical value $c^*(\beta)$ given in Hansen (1997, table 1, p. 5). For $\beta = 5\%$, $c^*(\beta) = 7.35$. The confidence interval LR^c is given by $LR^c = \{c : LR(c) \leq c^*(\beta)\}$.
33. This is generalized for the case where the attractor might be different than 0, say a_0, and also for the case of a linear trend, $a_0 + a_1 t$.
34. The threshold value λ should be between the 15th (λ_1) and 85th percentile (λ_2) of y_t. $\lambda \in \Lambda = [\lambda_1, \lambda_2]$.
35. Further support for the TAR behavior of real exchange rates is found in De Jong *et al.* (2007). They consider an extension of the simple TAR model above: an asymmetric TAR model where the adjustment in the upper part of the "action band" might differ from the one in the lower part of the "action band." The asymmetric TAR can be written as:

$$\Delta y_t = \begin{cases} u_t & \text{if } c_1 \leq y_{t-1} \leq c_2, \\ \rho_1(y_{t-1} - c_1) + u_t & \text{if } y_{t-1} < c_1, \\ \rho_2(y_{t-1} - c_2) + u_t & \text{if } y_{t-1} > c_2, \end{cases} \tag{22.26}$$

where $\rho_1, \rho_2 \in (-2, 0)$. De Jong *et al.* (2007) propose a three-regime threshold unit root (TUR) test that is robust to errors that are not i.i.d. They propose an asymptotically pivotal test statistic that optimizes over the parameter that is unidentified under the null and allows for weakly dependent errors. De Jong *et al.* (2007) apply their statistic to monthly real exchange rates of six developed countries against the dollar. While ADF and PP could not reject the null of a unit root, their test statistic found evidence against unit root real exchange rates.

36. See Taylor (1995) and Sarno and Taylor (2002) for numerous references and further discussion.
37. Canjels *et al.* (2004) employ threshold autoregression to analyze the efficiency of international arbitrage under the gold standard from 1879 to 1913. A theoretical model is developed and estimated employing continuous daily data.
38. For example, Monoyios and Sarno (2002) employ an ESTAR model to describe the mispricing between spot and futures. Employing daily data, they report a lag structure of five days. The impulse response functions reported by them imply an arbitrage process taking weeks for small shocks and days for large shocks. However, other researchers using minute by minute data for the same market, and ESTAR or TAR adjustment mechanisms, report adjustment mechanisms taking several minutes (Dwyer *et al.*, 1996; Taylor *et al.*, 2000).
39. This estimator retains the properties of the FM-OLS estimator in that it can deal with non-stationary data and serial dependence in the equation errors. However, the FM-LAD estimator is based on a "fully modified" extension of the LAD regression estimator, which is a robust procedure well known in the treatment of non-normality of error terms when the regressors are stationary (Bassett and Koenker, 1978; Phillips, 1991). The FM-LAD estimator developed by Phillips has all the features of the LAD estimator but is applicable in models where the regressors are non-stationary, there is endogeneity in the regressors and serial dependence in the errors. In addition, the FM-LAD estimator is valid even when the data do not have finite variances.

40. When s_t and f_t are integrated variables, a regression of s_{t+n} on f_t will give the same coefficient as one of s_t on f_t, at least asymptotically. Maynard and Phillips (2001) show that in small samples the overlapping errors induced by employing s_{t+n} in the regressions can give rise to different estimates.
41. See Minford and Peel (2002) for a textbook derivation.
42. However, we note that the properties of regressions with $f_t - s_t$ as the dependent variable and the conditional variance as a regressor would be of interest in this context. They would determine whether the estimates of the conditional variance have predictive content for the forward premium.
43. An alternative economic explanation of the anomaly that might be relevant for particular periods is the one advanced by McCallum (1994). He suggests that the negative coefficient may be the result of simultaneity induced by the existence of a policy reaction function where the interest rate differential is set in order to stabilize current exchange rate movements. Another important possibility is set out by Evans and Lewis (1995) and Spagnola *et al.* (2005). They show that if the "long" swings in exchange rate regimes between depreciating and appreciating periods have *ex ante* predictability, then in small samples a peso problem occurs. They assume that the exchange rate regimes can be captured by a Markov-switching process (see, e.g., Hamilton, 1990). Again, whilst the peso problem is undoubtedly important to some policy periods, the systematic nature of the forward anomaly over different time periods and different numeraire currencies suggests there are other factors at work.
44. At the one extreme, $d = 0$ represents the short memory case. If $d > 0.5$, the process is not wide-sense stationary, having infinite variance. And at the other extreme, $d = 1$ corresponds to the ordinary integrated process, familiarly known as an RW, which is well known not to revert to the mean, but eventually to wander arbitrarily far from the starting point. The autocorrelations of a fractional process dissipate but at a slow hyperbolic rate rather than the geometric rate of a standard ARMA process (see Granger, 1980; Granger and Joyeux, 1980). (see Granger , 1980; Granger and Joyeux, 1980).
45. Peel and Davidson (1998) fit a nonlinear error correction mechanism to the spot-forward relationship based on the idea of nonlinearities in the unobserved risk-premium which might be captured by a bilinear process.
46. Baillie and Kiliç (2006) prefer the logistic function as the transition function. This implies asymmetric behavior of the deviations as to whether they are positive or negative. Given this, their results have the same qualitative implications as those of Sarno *et al.* (2006), even though the symmetric transition function appears to be better economically motivated.
47. The standard ESTAR model exhibits a maximum expected deviation from equilibrium. Note that if the dataset does not actually include a maximum or minimum then the value of γ estimated has to be such, i.e., smaller, to ensure that a max or min occurs outside of the range of estimated data. An economic rationale for the maxima or minima is unclear. This line of reasoning suggests a simple modification of the ESTAR model, which is to assume that the variable forcing the process towards its equilibrium value is not observed from past deviations but from the expected deviation at time t.
48. They employ survey data to measure anticipated excess returns.
49. See also Van Dijk *et al.* (2002) for an earlier application to unemployment rates, and Tsay and Härdle (2007), who set out a general class of Markov-switching ARFIMA processes.
50. Baillie and Kapetanios (2005) consider a test based on neural networks.
51. The FI-STAR model is clearly of interest. If it is the case that forward premia (or PPP) are parsimoniously described by such a process then it seems to pose a challenge for theoretical work.
52. We note that numerous studies have been conducted to determine the empirical relationship between real interest rates and the real exchange rate. From the uncovered parity conditions, ignoring any time-varying risk-premia for simplicity:

$$i_t - E_t p_{t+n} + p_t = i_t^* - E_t p_{t+n}^* + p_t^* + E_t y_{t+n} - y_t, \tag{22.55}$$

where i and i^* are the domestic and foreign nominal interest rates, p and p^* are logs of the domestic and foreign price level, and y is the log of the real exchange rate. We note immediately that empirical work that examines the relationship between real interest rates and excludes the real exchange rate will, in general, be misspecified unless the real exchange rate follows an RW as suggested by Roll (1979). However, this does not appear to be either theoretically or empirically justified (see Taylor and Sarno (2004); Minford and Peel (2007), and the references suggesting real exchange rates are nonlinear mean reverting processes above).

The empirical studies on the relationship between real interest rates and real exchange rates are problematic and inconsistent. For example, a number of studies have examined the relationship in a cointegration framework, though there are no theoretical grounds for expecting the real exchange rate to be cointegrated with the real interest rate differential, as noted by Baxter (1994).

The implications of nonlinear real exchange rate adjustment have also not been integrated into the empirical literature. As discussed above, temporal aggregation of the "monthly" process changes the form of the ESTAR process (Paya and Peel, 2006b). In particular, the number of autoregressive terms increases. One procedure, if the correct DGP is an ESTAR process, is to derive multi-period forecasts from it using Monte Carlo methods. These forecast changes should be employed as regressors in empirical work. Our exercise shows why, in empirical studies, the reported results and their implications are likely to change as the horizon of expectations and the temporal nature of the data changes. These implications appear worthy of investigation in further work.

53. Bertola and Svensson (1993) consider imperfect credibility, Miller and Weller (1991) consider price-stickiness. Bauer *et al.* (2007) develop a non-rational model based on chartists and fundamentalists.
54. Chung and Tauchen (2001), using the efficient method of moments proposed by Gallant and Tauchen (1996, 2000), allow for intermarginal intervention. They report evidence that this model parsimoniously describes the dynamics of the French franc/Deutsche Mark exchange rate from January 1987 until July 1993. We note that they employ weekly data, and further tests with daily data appear warranted.
55. Lundbergh and Teräsvirta (2006) point out that the asymmetry parameter is essential to ensure that movements of the exchange rate are restricted by the bounds. The parameter restrictions $\gamma > 0$, $\theta > 0$ are identifying restrictions, and $\mu < 1$ identifies an implicit bound. Non-symmetry around the lower or upper bound – explicit or implicit – can be allowed for by different values of γ, θ.
56. The STARTZ model can capture the dynamics of behavior implied by many theoretical target zone models. When the exchange rate is near the centre of the band, such that G^l and G^u are close to zero, then the exchange rate will depend on its own lags, $\varphi' x_t$. Given previous research we would anticipate that the exchange rate would appear to be a unit root process in this vicinity. As the exchange rate approaches the edges of the bands, so that G^l and G^u are close to unity, then the exchange rate process will be described by white noise like behavior around μs^l or μs^u. Also, as the deviation from the central parity increases, so that G^l and G^u approach unity, there is smooth transition from the standard GARCH model represented by $\eta' w_t$ towards a constant $\delta > 0$ that is expected to be close to zero. The assumption that δ is non-zero means there is a positive probability that the exchange rate could leave the band even though no realignment takes place. This feature implies that a credible zone can be one in which occasional breaches occur.
57. Following Mark (1995), the money demand income elasticity is set equal to one.
58. The mathematical form of the bubble is the same as that obtained in the stock market. If the exchange model exhibited sticky prices the process followed by the speculative bubble would be different although the features are qualitatively the same. For example, with a simple sticky-price adjustment of the form $p_t - p_{t-1} = \theta(s_t - p_{t-1})$, $\theta \in [0, 1]$, the bubble

takes the form:

$$B_t = \frac{b}{b+\theta} E_t B_{t+1} - \frac{(1-\theta)b}{b+\theta} E_{t-1} B_t + \frac{(1-\theta)b}{b+\theta} B_{t-1}.$$

For $\theta = 1$ we obtain the bubble solution as in (22.68) above. If $E_{t+1}B_t = \delta B_t$ then the analysis can proceed as above. The magnitude of $\delta > 1$ could be important as to whether the bubble is asymptotically stationary (see Yoon, 2005).

59. In the latter case, the form of the bubble depends on the time series process followed by the fundamentals. For the geometric process:

$$B_t = c s_{f,t}^{\beta} \ln s_{f,t} - \ln s_{f,t-1} = \mu + \omega_t,$$

where $\omega_t \sim N(0, \sigma_h^2)$ and μ is a drift term, β is the solution of $\beta\mu + 0.5\beta^2\sigma_h^2 + \ln\lambda = 0$ and c is an arbitrary constant. Minford and Peel (2002) provide a textbook treatment, while Bidarkota and Dupoyet (2007) extend the analysis.

60. Diba and Grossman (1988) tested for bubbles by applying unit root tests to the asset price, real stock prices and dividends. If the fundamental is an integrated process, say $I(1)$, then from (22.67) the bubble will imply rejection of cointegration. The important insight of Evans was to show via simulation that standard unit root and cointegration tests have little power to detect his periodically collapsing bubble. Yoon (2005) demonstrates that Evans bubbles tail indices are less than one, a property we comment on below. Gurkaynak (2005) has a useful survey of many of the empirical tests for bubbles.
61. Phillips *et al.* (2006) demonstrate that Evans bubbles with a π as low as 0.25 may be detectable.
62. Note that, for comparison, the tail index for the student t-distribution is its degrees of freedom.
63. The latter justification is in line with recent empirical evidence which suggests that the relationship between the exchange rate and the fundamental value is characterized by significant nonlinearities (Taylor and Peel, 2000; Taylor *et al.*, 2001).
64. However, spurious regression problems may rise even at short horizons. Ferson *et al.* (2003) decompose asset returns into expected returns and an unpredictable noise component. In this setting, although the dependent variable is not a persistent process, the possibility of persistent expected returns and explanatory variables may lead to spurious results.
65. Hence, Mark's conjecture that the mixed evidence on long-horizon predictability is due to the small sample size is not supported by the data.
66. Abhyankar *et al.* (2005) adopt a different approach which utilizes the realized end-of-period wealth so as to evaluate forecasts based on monetary fundamentals. Their findings suggest that there is evidence of economic value to exchange rate predictability, especially at long horizons.
67. Four hundred tests are implemented since four models, four bilateral exchange rates, five forecast horizons and five test statistics are considered.
68. A q-value is defined as the minimum possible false discovery rate for which the null hypothesis is rejected (Storey, 2003). The false discovery rate is the ratio of the number of tests for which we reject the null, F, over the total number of tests, S, given that the null is true, $E(F/S)$. A detailed description of the computation of q-values and their properties is provided in McCracken and Sapp (2005) and the references therein.
69. The particular ESTAR specification remains the same under the null and the alternative, and is determined in the preliminary analysis on the basis of the goodness-of-fit, the significance of the coefficients and residual diagnostics (Eitrheim and Teräsvirta, 1996). The bootstrap procedure is similar to the VECM bootstrap of Kilian (1999) and was described in section 22.6.1.1.
70. Taylor and Kilian (2003) conduct Monte Carlo experiments to investigate the power and size properties of the tests. Their findings indicate that in-sample tests have substantially higher power than out-of-sample tests.

71. A regime switching behavior of the exchange rate can be attributed to factors such as the heterogeneity of opinions among agents, the presence of transaction costs, the interaction of chartists and fundamentalists, the peso problem, different monetary and fiscal policies between countries, as well as the implications of the dirty floating exchange rate regime (see Engel and Hamilton, 1990; De Grauwe and Vansteenkiste, 2001; Lee and Chen, 2006).
72. The use of MS is also motivated by parameter instability in empirical exchange rate models (see Rossi, 2006), which may be attributed to "swings" in expectations about future values of the exchange rate (Frankel, 1996), as well as by rational expectations models of exchange rate determination in which the weight attached to fundamentals by practitioners changes over time (Bacchetta and van Wincoop, 2004).
73. In a related study, Sarno and Valente (2005) examine the evolution of the relationship between fundamentals and the exchange rate by employing the recursive procedure of Pesaran and Timmermann (1995) to real-time data. The authors use a broad set of fundamentals for five major US dollar exchange rates over the post-Bretton Woods era. In the preliminary analysis, a "virtual search" is conducted over all possible models and the optimal combination of fundamentals is determined period by period. In the cases where the best model outperforms the RW, a real-time forecasting exercise is implemented. The main implication of the experiment is that fundamentals contain predictive power for the movements of the exchange rate. However, the importance of each of the fundamental variables changes over time. Furthermore, conventional model selection criteria cannot identify the "correct" model to beat the RW in real time.
74. Engel and West (2005) note that estimates of the interest semi-elasticity of money demand λ typically range from 29 to 60, which implies that in the monetary model b is between 0.97 and 0.98.
75. However, Sarno and Taylor (1998) note that panel unit root tests tend to reject the null of a unit root even if a single series is stationary. Moreover, Rapach and Wohar (2004) emphasize the importance of the homogeneity assumption. If such an assumption is not empirically supported then pooling data across countries may result in false inference.
76. For example, Frankel and Rose (1996) and Lothian (1997), among others, show that real exchange rates mean revert in the long run by using pooled data; Groen (2000) and Groen and Kleibergen (2003) find evidence of cointegration between monetary fundamentals and exchange rates.
77. Bootstrap samples are generated according to the fitted VAR by sampling from the estimated residuals with replacement. Next, the slope coefficient is estimated by panel dynamic OLS and the corresponding t-ratio is computed. The above procedure is repeated 2,000 times so as to obtain bootstrap distributions and p-values.
78. The bootstrap procedure is the same as before, with the exception that the second equation of the previous null DGP becomes:

$$\Delta z_{i,t} = \mu_z^i + \gamma_i z_{i,t-1} + \sum_{j=1}^{q_i} \phi_{1,j}^i \Delta s_{i,t-j} + \sum_{j=1}^{q_i} \phi_{2,j}^i \Delta z_{i,t-j} + \varepsilon_{z,t}^i.$$

    Cointegration requires $-2 < \gamma_i < 0$.
79. Groen (2005) emphasizes the importance of expectations on the validity of the monetary model. He examines the European Union exchanges rates of Canada, the US and Japan for the period from 1975 to 2000. The cointegration framework adopted is an extension of the Johansen method for a panel of VECM models which allows heterogeneous short-run dynamics (see Groen and Kleibergen, 2003). Overall, exchange rates appear to be predictable at medium- to long-term horizons, i.e., one to four years. However, the results are sensitive to the cointegrating parameters restriction.

The Econometrics of Convergence

Steven N. Durlauf, Paul A. Johnson and Jonathan R.W. Temple

Abstract

The presence or absence of convergence between rich and poor countries represents one of the most important questions in the new growth economics. New growth theories have been explicitly designed to explain forms of divergence which do not appear in their neoclassical counterparts. Despite substantial empirical work on convergence, there is no consensus as to whether it is present in cross-country data. This chapter surveys the econometrics of convergence as well as the range of empirical claims that have appeared. Particular attention is given to the relationship between statistical versus economic notions of convergence. We argue that the disparities in claims across empirical studies can to some extent be understood as reflecting inadequate attention to the relationship between the statistical and economic notions.

23.1 Introduction

The question of whether nations converge or diverge has long been of interest to historians and social scientists. One classic passage of Edward Gibbon's *The Decline and Fall of the Roman Empire*[1] expresses the hope that all societies will exhibit progress in the long run:

> If, in the neighbourhood of the commercial and literary town of Glasgow, a race of cannibals has really existed, we may contemplate, in the period of Scottish

> history, the opposite extremes of savage and civilised life. Such reflections tend to enlarge the circle of our ideas; and to encourage the pleasing hope, that New Zealand may produce, in some future age, the Hume of the Southern Hemisphere. (book II, ch. XXV)

But another famous passage notes the permanent effects of particular events, arguing that, had the Franks not defeated the Arabs at the Battle of Poitiers in 732, "Perhaps the interpretation of the Koran would now be taught in the school of Oxford, and her pulpits might demonstrate to a circumcised people the sanctity and truth of the revelation of Mahomet" (book V, ch. LIII). Modern social science is neither as literary nor as broad in its sweep, yet Gibbon's remarks resonate with the broad questions involved in the study of convergence. Over long epochs, will initially different societies or economies evolve towards a common form, or will their initial conditions play a role in determining their long-run outcomes?

The nature of interest in convergence has varied over time, referring to different countries and different socioeconomic forms. From the vantage point of the Cold War, one debate concerned the extent of the differences between the West and the Soviet bloc. It was not uncommon to argue that capitalist and socialist economies would converge over time, as market institutions began to shape socialist economies, while capitalism might increasingly be accompanied by extensive government regulation and intervention, and a range of activist social welfare policies. More recently, a new convergence debate has focused on issues related to the persistence or transience of differences between rich and poor countries, with parallel interest in the income differences of regions, states, and districts. Convergence here is typically conceived in terms of narrowing differences in per capita income, rather than broader socioeconomic institutions. It is this literature that we will review in this chapter. The possibility of income convergence has been studied more intensively than any other hypothesis in growth economics, even if the effort to identify growth determinants, both proximate and fundamental, has become the main area of current empirical research.

Contemporary interest in the convergence hypothesis stems from at least three factors. The first is the enormously high levels of international inequality, and attendant levels of human suffering in poorer societies. This inequality means that the extent to which economies are converging or diverging, and at what rate, forms the background for almost any discussion of globalization and the work of international institutions and aid agencies. In popular commentary, it is often claimed that the gap between rich countries and poor countries is widening, and the study of convergence helps to evaluate such claims in a rigorous way.

Second, endogenous growth models, at least when based on increasing returns to scale, often imply long-run divergence of per capita incomes. Hence the investigation of convergence came to be seen – perhaps mistakenly, as we will discuss below – as the best way to discriminate between the new growth theories and their neoclassical predecessors. Finally, the greater availability of internationally comparable data for a broad cross-section of countries, primarily due to the work

of Summers and Heston (1988, 1991), has meant that it is now possible to study convergence for a wide range of countries.[2]

In this chapter, we first describe various statistical notions of convergence that have arisen as part of the modern economic growth literature. Our goal is not only to characterize the range of convergence notions that have been used in empirical work, but also to give some sense of their links to substantive economic claims.

23.2 β-convergence

The first statistical convergence concept used in the modern growth literature is based on the relationship between initial income and subsequent growth. Intuitively, this convergence notion is simple: two countries exhibit convergence if the one with lower initial income grows faster than the other and so tends to "catch up" with the higher-income country. This is the concept used in Abramovitz (1986), Baumol (1986) and Marris (1982), and which also plays a central role in Barro (1991), Barro and Sala-i-Martin (1992) and Mankiw, Romer and Weil (1992).[3] One posited driving force behind catching-up is that a position well below the technological frontier creates the potential for rapid advancement, through the installation of capital embodying the current frontier technology, for example. Another convergence mechanism, which is usually associated with the neoclassical growth model and which has played a greater role in the literature, emphasizes the role of diminishing returns. It predicts that countries which begin with a relatively low level of income will grow relatively rapidly, but this growth will slow down as the economy approaches its balanced growth path and the marginal product of capital declines towards its steady-state level.[4]

23.2.1 Convergence and the neoclassical growth model

Convergence as a property of the neoclassical growth model may be understood in terms of the behavior of output around the model's unique and stable steady-state. Let $Y_{i,t}$ denote output, $L_{i,t}$ the labor force, and $A_{i,t}$ the level of (labor-augmenting) efficiency in economy i at time t. From these, following the standard logic by which steady-states are constructed in the neoclassical growth model, define $y^E_{i,t} = Y_{i,t}/(A_{i,t}L_{i,t})$ as output per efficiency unit of labor input at any time t and $y^E_{i,\infty} = \lim_{t\to\infty} y^E_{i,t}$ as its associated stable steady-state value. Assuming that $y^E_{i,0} > 0$, a log-linear approximation around the stable steady-state implies the law of motion:

$$\log y^E_{i,t} = (1 - e^{-\lambda_i t}) \log y^E_{i,\infty} + e^{-\lambda_i t} \log y^E_{i,0}. \tag{23.1}$$

The parameter λ_i, which may be shown to be positive, depends on the other parameters of the model and characterizes the speed with which $y^E_{i,t}$ adjusts towards its steady-state value.[5]

Given this general law of motion for output per efficiency unit of labor, it is straightforward to describe the behavior of the observable output per unit of labor input, $y_{i,t} = Y_{i,t}/L_{i,t}$. Letting g_i be the (constant) rate of (labor-augmenting)

technological progress, so that $A_{i,t} = A_{i,0}e^{g_i t}$, equation (23.1) may be rewritten as:

$$\log y_{i,t} - g_i t - \log A_{i,0} = (1 - e^{-\lambda_i t}) \log y^E_{i,\infty} + e^{-\lambda_i t}(\log y_{i,0} - \log A_{i,0}) \qquad (23.2)$$

so that:

$$\log y_{i,t} = g_i t + (1 - e^{-\lambda_i t}) \log y^E_{i,\infty} + (1 - e^{-\lambda_i t}) \log A_{i,0} + e^{-\lambda_i t} \log y_{i,0}.^6 \qquad (23.3)$$

Letting $\gamma_i = t^{-1}\left(\log y_{i,t} - \log y_{i,0}\right)$ denote the growth rate of $y_{i,t}$ between 0 and t and subtracting $\log y_{i,0}$ from both sides of (23.3), division by t yields:

$$\gamma_i = g_i + \beta_i(\log y_{i,0} - \log y^E_{i,\infty} - \log A_{i,0}), \qquad (23.4)$$

where $\beta_i = -t^{-1}(1 - e^{-\lambda_i t})$.

Equation (23.4) decomposes the growth rate of $y_{i,t}$ into two parts. The first, g_i, is growth due to technological progress, and the second, $\beta_i(\log y_{i,0} - \log y^E_{i,\infty} - \log A_{i,0})$ is growth due to the closing of the initial gap between output per worker and the steady-state value – "catching up." Because $\beta_i \to 0$ as $t \to \infty$, the importance of this term, and hence the role of initial conditions in determining contemporaneous output, diminishes to zero. The long-run rate of growth of the economy is g_i, the rate of technological progress.

While equation (23.4) provides a characterization of the sources of economic growth, it is not yet in a form that can be estimated. One reason is that the parameters λ_i and g_i are country-specific. The empirical growth literature often assumes that these parameters are identical across countries, so that we have $\lambda_i = \lambda$ and $g_i = g$, $\forall i$. Under these assumptions, (23.4) simplifies to:

$$\gamma_i = g - \beta \log y^E_{i,\infty} - \beta \log A_{i,0} + \beta \log y_{i,0}. \qquad (23.5)$$

Equation (23.5) implies, *ceteris paribus*, a negative relationship between average rates of growth and initial levels of output per capita, over any time period, when estimated for a cross-section of countries. Those countries with low income are further below their balanced growth path and will grow relatively quickly: their low income implies that the capital-output ratio is lower, and the marginal product of capital higher, than in countries starting with a higher level of income. This mechanism leads to a period of relatively fast growth, so that the countries initially behind will catch up with other countries that have the same levels of steady-state output per effective worker and initial efficiency. Similarly, countries that begin above their balanced growth path, perhaps because some determinants of steady-state income have deteriorated over time, must grow relatively slowly. In these economies, the capital-output ratio is high and the marginal product of capital relatively low, leading to a period of growth at below the rate of technical progress. This movement towards a balanced growth path is the economic notion of convergence implied by the neoclassical model.

23.2.2 Cross-country regressions and β-convergence

In order to translate this economic notion of convergence into a statistical model, it is necessary to address the unobservable variables $y^E_{i,\infty}$ and $A_{i,0}$. One possibility is to assume that (i) all countries have a common steady-state so that $y^E_{i,\infty}$ is a constant, y^E_{∞}; and (ii) $\log A_{i,0} = \log A + \varepsilon_i$ where, ε_i is a country-specific shock.[7] Subsuming y^E_{∞}, $\log A$ and g into the constant term, unconditional β-convergence holds if $\beta < 0$ in the regression:

$$\gamma_i = \alpha + \beta y_{i,0} + \varepsilon_i. \tag{23.6}$$

When using a sample of countries, one rarely finds unconditional β-convergence, unless the sample is restricted to similar entities such as the Organization for Economic Cooperation and Development (OECD) member countries. There is rarely a strong correlation between initial income and subsequent growth in large, heterogeneous samples, such as those found in the Penn World Table.[8]

Relative to equation (23.6), heterogeneity in countries naturally suggests that $y^E_{i,\infty}$ is not, in fact, constant. In the augmented Solow model estimated by Mankiw *et al.* (1992), for example, $y^E_{i,\infty}$ is shown to depend on the rates of physical and human capital accumulation and the rate of population growth. More generally, letting Z_i be the set of variables that determine a country's steady-state income level, conditional β-convergence is said to hold if $\beta < 0$ in the regression:

$$\gamma_i = \alpha + \beta y_{i,0} + Z_i\Gamma + \varepsilon_i. \tag{23.7}$$

While many differences exist in the choice of controls, most studies include several determinants inspired by some version of the Solow growth model. Unlike unconditional β-convergence, evidence of conditional β-convergence has been found in many contexts. For the cross-country case, the finding is generally attributed to Barro (1991), Barro and Sala-i-Martin (1992) and Mankiw *et al.* (1992).

The Mankiw *et al.* (1992) analysis is of particular interest, as it is based on a regression suggested by the dynamics of the Solow growth model. Their findings have been widely interpreted as evidence in favor of diminishing returns to capital (the source of $\beta < 0$ in the Solow model) and as evidence against some endogenous growth models. The analysis especially calls into question models which emphasize increasing returns in capital accumulation (either human or physical) as a source of perpetual growth. However, some endogenous growth models are consistent with β-convergence, and therefore some caution is needed in drawing inferences about the nature of the growth process from the results of β-convergence tests.[9]

Given an estimate of β, an estimate of λ, the implied rate of convergence, can be obtained from $\beta = -t^{-1}(1 - e^{-\lambda t})$. In cross-section studies, this typically yields an estimated convergence rate of about 2% per year; in other words, over the course of a year, countries will close just 2% of the gap between their current position and the balanced growth path.[10] This result is found using datasets on a wide variety of economic entities and from time periods more than 100 years apart.[11] While

some have (perhaps with a degree of irony) accorded the 2% value a status akin to that of a universal constant in physics, others have been rather more skeptical of its generality. There is nothing in the logic of the neoclassical growth model to suggest that this parameter should be invariant across environments, and this in itself might lead to skepticism about the supposed universality of the 2% figure. On the other hand, there are reasons to believe that the time series structure of per capita output data could produce a "universal" convergence estimate because of inadequate attention to temporal dependence in the data. Quah (1996b), for example, suggests that the 2% finding may be a statistical artifact that arises for reasons unrelated to convergence *per se*. Specifically, he argues that, if each per capita output series in a cross-section regression contains a unit root, this can produce a β estimate such that a 2% convergence rate is produced, even if the series are independent. Quah's argument is important in motivating the importance of time series approaches to evaluating convergence, which are discussed later.

23.2.3 Critiques

The evidence of convergence obtained from cross-country growth regressions has been subjected to a number of criticisms. Here we focus on those that seem most important (see Durlauf, Johnson and Temple, 2005, for a more complete treatment).

The first criticism relates to the choice of control variables, and whether claims about convergence are robust to alternative choices. Any claims about conditional convergence, in particular, necessarily depend on a specific choice for the set of control variables Z_i. This is a serious concern, given the lack of consensus in growth economics about which growth determinants are empirically important. This lack of consensus is reflected in the "growth regression industry" that has arisen, as researchers have added a range of controls, of varying degrees of plausibility, to those of the basic Solow model.[12]

The most conceptually satisfying response to this problem has been the use of model averaging methods, as in Fernandez, Ley and Steel (2001) and Sala-i-Martin, Doppelhofer and Miller (2004). The model averaging approach constructs estimates (or posterior means, depending on whether one is evaluating convergence along frequentist or Bayesian lines) based upon a model space of candidate growth regressions. Information on convergence in each model is aggregated with weights corresponding to posterior model probabilities. These studies show that the cross-country finding of conditional β-convergence is robust to the choice of controls. Both studies conclude that the posterior probability that initial income is part of the linear growth model is high. The Sala-i-Martin *et al.* study reports a posterior expected value for the β regression parameter of -0.0085, implying an estimated convergence rate of 1% per year.

A second critique, which is perhaps better called a class of critiques, is that there are many good reasons to believe that the model errors in growth regressions are correlated with the associated regressors, leading to inconsistent estimates. One can understand a number of developments in the econometrics of β-convergence as efforts to address this problem.

A first source of correlation derives from country-specific heterogeneity. Cross-section growth regressions assume that the error terms ε_i are uncorrelated with the $\log y_{i,0}$ terms, but this is unlikely to hold if there is country-specific unobserved heterogeneity in output levels. If such effects were present, they would typically imply a link between ε_i and $y_{i,0}$. For this reason, a number of researchers have investigated convergence using panel data. This leads to models of the form:

$$g_{i,t} = c_i + y_{i,t-1}\beta + Z_{i,t}\gamma + \varepsilon_{i,t} \tag{23.8}$$

where growth is now measured between $t-1$ and t. This approach means that individual ("fixed") effects can be used to control for (time-invariant) unobserved heterogeneity. In practice, this has often been supplemented with the use of instrumental variables to address the endogeneity of variables like investment rates. Panel analyses have been conducted by Bond, Hoeffler and Temple (2001), Caselli, Esquivel and Lefort (1996), Islam (1995, 1998) and Lee, Pesaran and Smith (1997, 1998), among others. These studies generally find that conditional convergence takes place at higher rates than estimated in the cross-section studies. For example, Caselli *et al.* (1996) report annual convergence rate estimates of 10%.

As discussed in Durlauf and Quah (1999) and Durlauf *et al.* (2005), panel data approaches to convergence suffer from the problem that, once country-specific effects are allowed, it becomes harder to interpret the results in terms of specific economic explanations. One problem is that, once the growth model includes individual effects, then the question of convergence is changed, at least if the goal is to understand whether initial conditions matter; simply put, the country-specific effects may partly reflect the effects of varying initial conditions. When studies such as Lee *et al.* (1997, 1998) allow for rich forms of parameter heterogeneity across countries, β-convergence becomes the equivalent of the proposition that there is some mean reversion in a country's output process. The rate of mean reversion could be informative about the extent of diminishing returns, but not about whether certain types of contemporaneous inequalities are increasing or decreasing. This does not lessen the interest of these studies as statistical analyses, but means their economic import can be unclear.

A second source of correlation between the error term and explanatory variables is that some variables are endogenously determined. Variables such as investment rates and initial income[13] are themselves equilibrium outcomes, in the same way as growth rates. This has led some authors to propose instrumental variables approaches to estimating β. Barro and Lee (1994) analyze growth data in the periods 1965–75 and 1975–85 using five-year lagged explanatory variables as instruments, but find that this makes little difference to the coefficient estimates. Although motivated by the possibility of measurement error, Romer (1990) finds that estimating a growth regression using instrumental variables (IVs) eliminates the negative and significant coefficient on initial income typically found when the equation is estimated by ordinary least squares (OLS). As noted above, Caselli *et al.* (1996) find estimates of β of the order of 10% – much larger than the typical 2% of cross-section studies – using a generalized method of moments

(GMM) estimator to analyze a panel variant of the standard cross-country growth regression. The variation in the outcomes of these responses to endogeneity suggests that the effects of endogeneity on β-convergence tests remain an open question.

A distinct third source of correlation between errors and regressors is measurement error. This is a particular concern in growth contexts since, despite the best efforts of those compiling the data, it is inevitable that output per capita will be mismeasured, particularly in developing economies. Measurement errors in initial levels of per capita income will tend to bias estimates of β in favor of the β-convergence hypothesis, through the effects of the standard attenuation bias. One way to see this is to consider convergence in terms of the association (or correlation) between final output and initial conditions. When convergence is rapid, final output will be only weakly associated with initial conditions; when convergence is slow, the two will be strongly associated. The standard attenuation bias implies that when initial output is measured with temporary error, this weakens the partial correlation between initial and final output, and so biases the regression finding towards a rate of convergence that is too fast. Exactly the same logic carries over when the dependent variable is the growth rate, since a model relating growth to initial log income can alternatively be reparameterized as a model that relates the log of final output to the log of initial output.[14]

However, as Temple (1998) notes, in more general settings the actual direction of the bias will depend on the stochastic properties of the measurement error itself, as well as the possibility of measurement errors in several of the Z_i control variables. He investigates the effects of allowing for measurement error in the models estimated by Mankiw *et al.* (1992), using the measurement error diagnostics developed by Klepper and Leamer (1984) and Klepper (1988), together with classical method of moments adjustments. The possibility of small errors in the measurement of initial income implies a lower bound on the estimated rate of convergence that, while positive, is too close to zero to give conditional convergence the status of a stylized fact.

Mindful of the possible effects of measurement error, Romer (1990) estimates a growth equation by both OLS and IV using the number of radios per 1,000 inhabitants and (the log of) per capita newsprint consumption as instruments for initial income and the literacy rate. In the OLS case, he finds a negative and significant coefficient on initial income, but in the IV case the coefficient is insignificant, perhaps suggesting that the significance in the OLS case is attributable to measurement error. Using lagged income as instruments for initial income, Barro (1991) and Barro and Sala-i-Martin (2004) find little change in the estimated convergence rates compared to OLS, and conclude that measurement error is not an important factor behind their findings supporting β-convergence.

Another important criticism of β-convergence regressions concerns the power of the test against non-convergent alternatives, such as models with endogenous growth or poverty traps. As shown above, $\beta < 0$ is an implication of the neoclassical growth model, but $\beta < 0$ is also potentially consistent with economically interesting alternatives. To see this, assume that there is no technical change or

population growth, that each country has a common set of control variables Z_i, and that convergence does not occur because of the presence of a threshold externality, as in Azariadis and Drazen (1990). In the Azariadis–Drazen model, such an externality can produce multiple steady-states, with the long-run outcome for an economy depending on whether its initial capital stock is above or below a threshold. Those starting below the threshold will converge to one steady-state, while those starting above will converge to another.

Relative to the economic idea of convergence as manifested in the neoclassical model, the Azariadis–Drazen model does not exhibit convergence, and different initial conditions lead to different steady-states. Yet the data generated by the Azariadis–Drazen model will not necessarily lead to the finding that $\beta \geq 0$, as shown in Bernard and Durlauf (1996). To see why, consider the growth process:

$$\gamma_i = k + \beta(\log y_{i,0} - \log y^*_{l(i)}) + \varepsilon_i, \tag{23.9}$$

where country i has steady-state $l(i)$ with associated output per capita $y^*_{l(i)}$, a value common across all countries with that steady-state. Suppose that the (now misspecified) cross-country growth regression (23.6) is employed to test for convergence. The regression coefficient will, in the probability limit, equal:

$$\beta_m = \beta\left(1 - \frac{\text{cov}(\log y^*_{l(i)}, \log y_{i,0})}{\text{var}(\log y_{i,0})}\right). \tag{23.10}$$

The sign of β_m cannot be determined *a priori*, as it depends on $\text{cov}(\log y^*_{l(i)}, \log y_{i,0})$, which is determined by the relationship between initial incomes and steady-states. It is clearly possible for β_m to be negative, implying statistical convergence, defined as $\beta < 0$, despite the absence of economic convergence.

This problem is more than a theoretical possibility, as shown in Durlauf and Johnson (1995). They estimate a model with multiple growth regimes motivated by the Azariadis and Drazen (1990) framework and find that it fits cross-country data better than does the linear Solow model. The issue is also highlighted in work by Liu and Stengos (1999) and Durlauf, Kourtellos and Minkin (2001), who find that β appears to depend nonlinearly on initial conditions and may be equal to zero for some countries. These and related findings will be discussed in the next section on nonlinearities and multiple regimes.

Similar results may be derived in linear environments in which the distinction between neoclassical and endogenous growth theories depends on returns to scale in the aggregate production function as embodied in a particular parameter value. Kocherlakota and Yi (1995) analyze a representative agent model in which $y_t = A_t k_{t-1}^{\alpha}$, so that $\log y_t = \log A_t + \alpha \log k_{t-1}$. For this production function, the difference between the neoclassical and endogenous growth models concerns the value of the parameter α. The case of $\alpha \geq 1$ represents a version of endogenous growth: the model yields perpetual growth regardless of whether there is a deterministic drift in technology.

Specifically, the Kocherlakota–Yi analysis provides conditions under which:

$$E(\log y_t - \log y_{t-1} \,|\log A_1, \log k_1) \text{ is decreasing in } \log A_1, \tag{23.11}$$

even if $\alpha \geq 1$. This means that a finding of β-convergence may occur when endogenous growth is the relevant case. The key assumption for this case is that $\log A_t = g + \rho \log A_{t-1} + \varepsilon_t$ with $0 < \rho < 1 - \delta$, where δ is the discount rate. In this case, the presence of an endogenous growth component is swamped by transitional dynamics, as the effects of shocks die out. These findings parallel the result in Bernard and Durlauf (1996) but using a different mechanism.

Kocherlakota and Yi (1995) also give conditions under which:

$$E(\log y_t - \log y_{t-1} \,|\log A_1, \log k_1) \text{ is increasing in } \log A_1, \tag{23.12}$$

even if $\alpha < 1$. This means that a positive β can occur in a cross-country growth regression, even when returns to capital are diminishing. The key to the result is a unit root in the level of technology; formally, they assume $\log A_t = g + \log A_{t-1} + \varepsilon_t$. Intuitively, intertemporal optimization, at least for their choice of utility function, means that higher initial income leads to higher investment, and this can yield a positive correlation between growth and initial income.

These findings show the difficulties that can arise when convergence findings are used to discriminate between growth models. The above analyses may be understood as arguing that tests for β-convergence fail to distinguish between behavior along a transition path to a steady-state and behavior in the steady-state, in the way needed to allow reliable discrimination between neoclassical growth models and newer alternatives.

23.3 Nonlinearities and multiple growth regimes

Clearly, tests for β-convergence may have low power against the alternative hypothesis of multiple steady-states. With this in mind, some studies have explicitly searched for statistical evidence of multiple steady-states. Durlauf and Johnson (1995) use classification and regression tree (CART) methods to search for nonlinearities in the growth process implied by the existence of multiple steady-states.[15] This procedure identifies sub-groups of countries that obey a common linear growth model based on the Solow variables, and enables a test of the null hypothesis of a common growth regime against the alternative hypothesis of multiple regimes. In their study, allowing for multiple regimes means that economies with similar initial conditions (such as literacy rates) are allowed to converge or behave in similar ways, without imposing any requirement that steady-states are unique. Using the Mankiw *et al.* (1992) data, Durlauf and Johnson (1995) reject the single regime model required for global convergence. Instead, they conclude that there is a role for initial conditions in explaining variation in cross-country growth behavior, even after controlling for the structural heterogeneity implied by the

augmented Solow model estimated by Mankiw *et al.* (1992).[16] These findings are extended in Tan (2008), who employs GUIDE (generalized, unbiased interaction detection and estimation) and finds strong evidence that measures of institutional quality and ethnic fractionalization define sub-groups of countries which obey common growth models.[17]

Other research has produced additional evidence consistent with multiple regimes using alternative statistical methods. Some of these study the behavior of the entire cross-country distribution of per capita income, as we discuss below. Here we highlight the work of three other researchers. Desdoigts (1999) uses projection pursuit methods and finds several interesting clusters, which can be described as the OECD member countries, Africa, Southeast Asia, and Latin America.[18] He argues that the first of these is identified by variables that proxy for the effects of initial conditions on subsequent growth behavior. Kourtellos (2003) uses projection pursuit to construct models of the growth process and finds evidence of two steady-states. Canova (2004) utilizes a procedure with Bayesian origins that both estimates the number of groups and assigns countries to groups. The researcher orders the countries by various criteria (for example, output per capita in the pre-sample period) and the estimation procedure chooses cluster boundaries and memberships to maximize the predictive ability of the overall model. He finds that ordering the data by initial income divides the regions of Europe into four clusters, with statistically and economically significant differences in long-run income levels and little across-cluster mobility, consistent with the existence of multiple steady-states. He also finds two clusters among the OECD countries with initial per capita income again being the preferred ordering variable. There is little mobility between the clusters, and the implied long-run difference in the average incomes is "economically large."

As discussed in Durlauf and Johnson (1995) and Durlauf *et al.* (2005), studies of nonlinearity also suffer from identification problems with respect to questions of convergence. One problem is that a given dataset cannot fully uncover the nature of growth nonlinearities without strong additional assumptions. As a result, it becomes difficult to extrapolate those relationships between predetermined variables and growth to infer steady-state behavior. Durlauf and Johnson (1995) give an example of a data pattern that is compatible with both a single steady-state and multiple steady-states. A second problem concerns the interpretation of the conditioning variables in these exercises. Suppose one finds, as in Durlauf and Johnson, that high- and low-literacy economies are associated with different aggregate production functions. One interpretation of this finding is that the literacy rate proxies for unobserved fixed factors, for example, culture, implying that these two sets of economies will never obey a common production function, and so will never exhibit convergence. Alternatively, the aggregate production function could structurally depend on the literacy rate, so that as literacy increases, the aggregate production functions of economies with low current literacy will converge to those of the high literacy ones. Data analyses of the type that have appeared to date cannot easily distinguish between these possibilities.

23.4 σ-convergence

An alternative statistical convergence concept focuses on the cross-section dispersion of log per capita output across countries, and whether it is increasing or shrinking. This has a natural connection to debates on whether inequality across countries is widening or diminishing. Discussion of this form of convergence often emphasizes the cross-section variance of log incomes, but the variance is not a sufficient statistic for the overall dispersion, and so can mask interesting forms of cross-section inequality. Although most empirical studies use the log variance, other measures of inequality can easily be used, such as the Gini coefficient or the Atkinson (1970) class of measures. These will sometimes be preferable to the log variance on axiomatic grounds.

A reduction in the dispersion of log income is interpreted as convergence because, as with β-convergence, it suggests that contemporary income differences are transitory. Letting $\sigma^2_{\log y,t}$ denote the variance across i of $\log y_{i,t}$, σ-convergence occurs between t and $t+T$ if:

$$\sigma^2_{\log y,t} - \sigma^2_{\log y,t+T} > 0. \tag{23.13}$$

Barro and Sala-i-Martin (2004, Ch. 11) report declines in the variance of the logarithm of income for the US states between 1880 and 2000, for the Japanese prefectures between 1930 and 1990, and for regions within five European countries between 1950 and 1990. In contrast, the variance of log income per capita in the world as a whole increased between 1960 and 2000.

These results are consistent with the outcomes of unconditional β-convergence tests, but there is no necessary relationship between β- and σ-convergence. It is easy to see how σ-divergence can occur even when, by an economic measure, convergence is present. For example, if all countries start from the same position but shocks are present, then divergence will occur, regardless of the speed of mean reversion. A more subtle point is that, if output changes for all countries obey $y_{i,t} - y_{i,t-1} = \beta y_{i,t-1} + \varepsilon_{i,t}$, then $\beta < 0$ is compatible with a constant cross-sectional variance, which in this example will equal the variance of $y_{i,t}$. The alternative, but mistaken, idea that mean reversion in a time series must imply a falling variance is known as Galton's fallacy. The mistake here is to ignore the role of ongoing shocks in sustaining the variance. The relevance of these types of arguments to understanding the relationship between convergence concepts in the growth literature was identified by Friedman (1992) and Quah (1993a).

Several authors have recently proposed tests for σ-convergence that employ regression specifications. Following Friedman (1992), Cannon and Duck (2000) argue that a possible test for σ-convergence could use regressions of the form:

$$\gamma_i = T^{-1}(\log y_{i,t+T} - \log y_{i,t}) = \alpha + \pi \log y_{i,t+T} + \varepsilon_i. \tag{23.14}$$

As the probability limit of the OLS estimator of π is $T^{-1}\left(1 - \sigma_{\log y_{i,t},\log y_{i,t+T}} / \sigma^2_{\log y_{i,t+T}}\right)$, a negative estimate of π implies $\sigma_{\log y_{i,t},\log y_{i,t+T}} > \sigma^2_{\log y_{i,t+T}}$. This

inequality in turn implies $\sigma^2_{\log y,t} > \sigma^2_{\log y,t+T}$, as otherwise $(\sigma_{\log y_{i,t},\log y_{i,t+T}})^2 < \sigma^2_{\log y_{i,t+T}}\sigma^2_{\log y_{i,t}}$, the condition for positive definiteness of the variance-covariance matrix of $\log y_{i,t}$ and $\log y_{i,t+T}$, would be violated. Hence a test that rejects the null hypothesis $\pi = 0$ in favor of the alternative $\pi < 0$ is evidence of σ-convergence. Their application of the test finds convergence among the US states and the European regions but not among the countries of the world.

Egger and Pfaffermayr (2007) suggest a test of conditional σ-convergence that, in the growth context, would involve a test of the hypothesis that $\pi_T = 1-\sigma^2_{u_T}/\sigma^2_{\log y_{i,t}}$ against the alternative that $\pi_T < 1 - \sigma^2_{u_T}/\sigma^2_{\log y_{i,t}}$, where π_T is the coefficient on $\log y_{i,t}$ in the cross-section regression $\log y_{i,t+T} = \pi_T \log y_{i,t} + Z_i\Gamma + u_{iT}$, where, as above, Z_i is a vector of country-i specific, time-invariant control variables. This test generalizes the unconditional σ-convergence test of Carree and Klomp (1997), which those authors use to provide evidence of σ-convergence within the OECD countries. Egger and Pfaffermayr (2007) apply their test to a large dataset on the size of European manufacturing firms; its power for the samples typically used in growth applications is not yet clear.

Bliss (1999a, 1999b) points out that the interpretation of tests of σ-convergence can be problematic in the presence of non-stationarities; an evolving distribution for the data makes it difficult to think about the distributions of test statistics under the null hypothesis. Further difficulties arise when unit roots are present.

23.5 Convergence and the cross-country distribution of per capita income

Both β- and σ-convergence are directly motivated by the law of motion of the neoclassical growth model. A distinct approach to convergence was pioneered by Quah (1993a, 1993b, 1996a, 1996b, 1996c, 1997). He focuses on "distribution dynamics": the evolution of the entire cross-country distribution of income per capita. We will question whether analyses of this kind can speak directly to the convergence hypothesis, but the approach has helped to establish some stylized facts that could be important in assessing the empirical salience of different growth theories.

One strand of this literature takes snapshots of the distribution of income per capita at points in time. For example, Bianchi (1997) tests for multimodality in kernel density estimates of the cross-country distribution of per capita income. He finds evidence of bimodality in densities estimated using Penn World Table data on gross domestic product (GDP) per capita for 1970, 1980 and 1989.[19] He also notes a tendency for the two modes to become more distant from each other over time, supporting the view that the cross-country distribution of per capita income has become increasingly polarized. He finds very little mobility within the distribution; most of the countries nearer to either the upper or lower mode in 1970 are still there in 1989. Henderson, Parmeter and Russell (2007) confirm Bianchi's findings using a longer span of data and more advanced statistical tests.

Others have estimated the density of the cross-country distribution using mixture models, based on weighted sums of component distributions.[20] Multiple components, like multiple modes, can be indicative of multiple steady-states in the dynamic process describing the evolution of per capita income. Paap and van Dijk (1998) fix the number of components at two *a priori*, based on the bimodality of histograms of their data, and then use goodness-of-fit tests to select the shapes of the component distributions. They study mobility between the components by assigning each country to a component in each year according to the maximal conditional probabilities of component "membership," computed using their parameter estimates. They find only limited mobility across components: most of the countries initially assigned to the poorer component remain so throughout the sample period. Pittau, Zelli and Johnson (2008) estimate mixture models of the distribution of GDP per worker at five-year intervals from 1960 to 2000.[21] They use goodness-of-fit and likelihood ratio (LR) tests to conclude that a three-component mixture is the preferred model. As in Paap and van Dijk (1998), they find little mobility between components, and so interpret their results as evidence of the presence of multiple steady-states, contrary to the convergence hypothesis. The results of Davis, Owen and Videras (2007), who fit a mixture model that allows for conditioning on a typical set of proximate growth determinants, suggest that these results are robust to cross-country variation in those variables.

Bloom, Canning and Sevilla (2003) also derive a mixture model for $\log y_{i,t}$. They argue that, if long-run outcomes are determined by fundamental forces alone, the relationship between income levels and exogenous variables ought to be unique. If there are multiple steady-states, so that initial conditions play a role in long-run outcomes, the relationship will not be unique. Instead, under suitable regularity conditions, it will be described by a two component mixture model if there are two steady-states and if large shocks and resultant movements between steady-states are sufficiently infrequent.[22] Using 1985 income data from 152 countries with the absolute value of the latitude of the (approximate) center of each country as the fundamental exogenous variable, they are able to reject the null hypothesis of a single regime model in favor of the alternative of a model with two regimes. The regimes correspond to a high-level ("manufacturing and services") steady-state, in which income does not depend on latitude, and a low-level ("agricultural") steady-state in which income does depend on latitude, perhaps through its influence on climate and agricultural productivity. Further, the probability of being in the high-level steady-state is found to rise with latitude.

Other analyses of the distributions of income and growth have focused on the differences in these distributions across time and across sub-sets of countries. Anderson (2004) uses stochastic dominance methods to compare distributions at different points in time and to construct measures of polarization, arguably the antithesis of convergence. Using nonparametric estimates of the cross-country distribution of per capita income, he finds increased polarization – shifts in probability density mass that increase disparities between relatively rich and relatively poor economies – between 1970 and 1995. Pittau, Zelli and Johnson (2008) reach a

similar conclusion using the Duclos, Esteban and Ray (2004) polarization index. Maasoumi, Racine and Stengos (2007) find that the distributions of growth rates for OECD and non-OECD member countries are persistently different between 1965 and 1995, with the OECD distribution's variance reducing over time whereas the non-OECD distribution appears to be becoming less concentrated.

The methods discussed above permit comparison of distributions at different points in time, but are not explicitly dynamic. In most of these contributions, the process describing the evolution of the cross-country distribution of per capita income over time is not specified or described. Quah (1993a, 1993b, 1996a, 1996b, 1996c, 1997) introduced methods into the growth literature for studying the evolution of distribution dynamics, in order to illuminate issues of mobility, stratification, and polarization that are typically obscured by the standard regression approaches used for testing the convergence hypothesis. In addition, a description of the process governing the evolution of the cross-country income distribution enables analysis of the long-run tendencies implied by that process, through computation of long-run or ergodic distributions.[23]

One way of studying distribution dynamics is to assume that the process describing the evolution of the distribution is described by a time-invariant and first-order Markov chain.[24] Using cross-country per capita income data from the early 1960s through to the mid 1980s, Quah (1993b) takes this approach. He finds that the elements on the main diagonal of the estimated transition matrix are often close to unity, indicating a high degree of persistence, or lack of mobility, within the distribution. Moreover, the implied ergodic mass function is bimodal or "twin-peaked." Together, these findings of persistence and bimodality could be seen as consistent with the presence of multiple basins of attraction or "convergence clubs."

Evidence of bimodality in the long-run cross-country distribution of per capita incomes is also found by Kremer, Onatski and Stock (2001), who update Quah's analysis using more recent data. However, their point estimates imply that most countries will ultimately move to the high-income state, and they are unable to reject the hypothesis that there is a single right-hand peak in the long-run distribution. Quah (2001) observes that the imprecision of their estimates of the ergodic distributions is sufficiently large that it is not possible to reject a wide range of null hypotheses about their shape, including, as it is the point estimate, that of bimodality.

Feyrer (2003) observes that the development traps implied by the "twin peaks" finding could stem from traps in the accumulation of physical or human capital or in total factor productivity (TFP). He uses a combination of Quah's methods and those of development accounting to examine this question, based on data from 1970 to 1989. In particular, he examines whether the possible bimodality in the distribution of GDP per capita can be traced to bimodality in the distributions of aggregate TFP (measured as a residual), the capital-output ratio, or the average level of human capital, measured in the usual way as a Mincerian function of years of schooling. If traps in the accumulation of physical capital are, for example, an important proximate cause of the bimodality in the distribution of output per capita, the distribution of the capital-output ratio should also be bimodal. Feyrer's

estimates imply that the ergodic distributions of both GDP per capita and the productivity residual are bimodal, while those of the accumulable factors of production are not.[25] Consistent with the emphasis of Klenow and Rodriguez-Clare (1997) and Hall and Jones (1999) on productivity differences, he concludes that the proximate cause of the "twin peaks" in the distribution of GDP per capita is bimodality in the distribution of productivity, and accordingly advocates more research on models that emphasize traps in TFP.

Fitting a Markov chain to a continuous variable like GDP per capita requires a discretization of the state space. This is problematic, as it can easily alter the probabilistic properties of the data (Quah, 1996c, 1997, 2001; Bulli, 2001). Reichlin (1999) showed that the inferred dynamic behavior and the long-run implications of that behavior can depend on the discretization scheme that is used. To address this problem, Quah (1996c, 1997) proposed a continuous state space version of the approach that avoids the problems caused by discretization. If the cross-country income distribution at time t has a density function, $f_t(x)$, and if the process describing the evolution of the distribution is time-invariant and first-order Markov, the density at time $t+\tau$, $\tau > 0$, will be given by $f_{t+\tau}(x) = \int_0^\infty g_\tau(x|z) f_t(z) dz$, where $g_\tau(x|z)$ is the τ-period-ahead density of x conditional on z. The function $g_\tau(x|z)$ is the continuous analog of the transition matrix. The implied ergodic (long-run) density function, $f_\infty(x)$, if it exists, solves $f_\infty(x) = \int_0^\infty g_\tau(x|z) f_\infty(z) dz$. Quah (1996c, 1997) uses kernel density methods to estimate various $g_\tau(x|z)$ using cross-country data on output per capita, and finds a general concentration of the mass near points where $x = z$, that is, along the "main diagonal," as well as a tendency for peaks in the plot near the ends of the main diagonal and a trough in the middle. These features imply a lack of mobility within the cross-country distribution of income per capita and a tendency for mass to accumulate in the tails of the long-run distribution.[26] The estimated ergodic densities in Bulli (2001), Johnson (2005) and Fiaschi and Romanelli (2008) are also bimodal and hence support this conclusion. While Quah (2001) observes that there is not yet a theory of inference for these methods, Fiaschi and Romanelli (2008) propose a bootstrap procedure for computation of confidence intervals for the ergodic density, and their results suggest that the bimodality is statistically significant.

These methods have been important in establishing stylized facts concerning the cross-country distribution of per capita output, but there have been relatively few attempts to explore the implications for the empirical relevance of alternative growth theories. Quah (1996c) finds that conditioning on measures of physical and human capital accumulation similar to those used by Mankiw *et al.* (1992), and a dummy variable for the African continent, has little effect on the estimated dynamics of the distribution. This suggests that the heterogeneity revealed by the distributional approaches is, at least in part, due to the existence of convergence clubs rather than heterogeneity in steady-state determinants.[27] Azariadis and Stachurski (2003) derive the form of the $g_\tau(x|z)$ function implied by a stochastic version of the model in Azariadis and Drazen (1990). They estimate the model's parameters and compute forward projections of the sequence of cross-country

income distributions as well as the ergodic distribution implied by the model. Consistent with Quah (1996c, 1997), they find bimodality to be a pervasive feature of the sequence of distributions for about 100 years, even though the ergodic distribution is unimodal. Hence, even if bimodality eventually disappears, it may persist for a long time, as Quah notes in his response to Kremer *et al.* (2001).

There are some possible limitations to the use of distributional dynamics in reaching conclusions about substantive economic questions, especially when convergence is the main focus of interest. It is true that multiple modes in a distribution are consistent with the hypothesis of non-convergence, as they can be a consequence of multiple steady states. But they can also arise in the Solow model if, for example, there are multiple modes in the distribution of investment rates or population growth rates. Hence multimodality is not sufficient for concluding in favor of the existence of convergence clubs. Moreover, the existence of meaningful clubs also requires some degree of immobility within the distribution, so that countries in the vicinity of a mode will tend to remain there for extended periods.

A further point is that, while multimodality and immobility provide evidence of a lack of global convergence in the form of convergence clubs – groups of countries that converge locally but not globally – convergence clubs may be relevant even if the unconditional distribution of GDP per capita is unimodal. We can summarize some of these points by observing that the distribution dynamics literature typically investigates the shape and evolution of the whole cross-country distribution of per capita income at particular points in time, whereas economic debates about convergence are partly about the shape of the long-run or ergodic distribution *for a given country.*

23.5.1 Structural analysis

A final approach to convergence is to take a theoretical model with multiple steady-states and calibrate it to cross-country data. Graham and Temple (2006) carry out this kind of exercise for a two-sector general equilibrium model. The combination of increasing returns to scale in one sector (manufacturing and services) and intersectoral capital and labor mobility gives rise to multiple steady-states. They calibrate the model to data for 127 countries, and find that about a quarter are in a low-output equilibrium. The income differences across the equilibria are sizeable, and imply that multiplicity is capable of explaining up to a quarter of the cross-country dispersion in the logarithm of GDP per worker. Given the importance of structural models in business cycle analysis, it is remarkable how little work of this type has appeared in the convergence literature.

23.6 Time series approaches to convergence

Time series approaches to convergence are based on direct evaluation of the persistence or transience of income per capita differences between economic units, for example between pairs of countries or regions. This approach permits precise statistical definitions of hypotheses about convergence, but has the disadvantage of not being explicitly linked to particular growth theories.

Bernard and Durlauf (1995) define convergence for a set of countries I as occurring if:

$$\lim_{T\to\infty} \text{Proj}(\log y_{i,t+T} - \log y_{j,t+T} \,|\, \Im_t) = 0 \quad \forall i, j \in I, \tag{23.15}$$

where Proj$(a|b)$ denotes the projection of a on b and $\Im_t$ denotes some information set, which will generally include functions of time as well as current and lagged values of $\log y_{i,t}$ and $\log y_{j,t}$. Such a $\Im_t$ would imply a type of unconditional convergence, whereas inclusion of control variables such as investment rates would admit conditional convergence, but this has not been explored in the literature.

Most implementations of this definition have generally focused on the detection of deterministic or stochastic trends in $\log y_{i,t} - \log y_{j,t}$, as the presence of either implies a violation of (23.15). Consequently, time series tests of convergence have typically been implemented by testing for the presence of a unit root in the $\log y_{i,t} - \log y_{j,t}$ process.

Using an approach based on unit root tests, Bernard and Durlauf (1995) find little evidence of convergence in a group of 15 advanced industrialized economies between 1900 and 1989 based on data from Maddison (1982, 1989). Hobijn and Franses (2000) similarly find little evidence of convergence across a group of 112 Penn World Table countries over the period 1960–89.[28] Their work is based on a clustering algorithm to identify groups of converging countries. They find many small clusters, which they view as having distinct steady-states; but their multiplicity, and the absence of controls for structural characteristics, means that these clusters could simply reflect differences in those characteristics, rather than differences in long-run outcomes due to differences in initial conditions. The breadth of the sample used also suggests that the Bernard and Durlauf (1996) argument, about the need for consideration of the substantive economic assumptions that underlie time series methods for studying convergence, is applicable in this case.

One criticism of these tests focuses on the validity of unit root tests in the presence of structural breaks. Perron (1989) has argued that the failure to allow for structural breaks can lead to spurious evidence in support of the presence of a unit root (or, more precisely, can diminish the ability to reject the null of a unit root). Greasley and Oxley (1997) impose breaks exogenously and find convergence for Denmark and Sweden, in contrast to Bernard and Durlauf (1995), who did not allow for breaks. Li and Papell (1999) allow for endogenous trend breaks and find that this reduces, relative to Bernard and Durlauf (1995), the number of country pairs that fail to exhibit convergence.

Carlino and Mills (1993) study US regions and reject convergence except with specifications that allow for a trend break in 1946. However, a trend break violates (23.15), as it implies that some component of $\log y_{i,t} - \log y_{j,t}$ is predictable in the long run. Thus claims that allowing for data breaks produces evidence in favor of convergence invites the question of what is meant by convergence. Note that the sort of violation of (23.15) implied by a trend break is different from the type implied by a unit root, as a break associated with the level of output means that the output difference between two countries is always bounded. The issue of

trend breaks raises the general question of whether convergence dynamics obey a nonlinear process. Chong *et al*. (2008) employ a smooth transition autoregressive process to model output and conclude that OECD member countries are converging to the US level of output per capita. Their analysis is again difficult to interpret in economic terms, as their functional form assumptions do not correspond to any particular economic model and therefore invite questions about the appropriate choice of nonlinear structure.

A second criticism of time series tests has been made by Michelacci and Zaffaroni (2004). They argue that evidence of unit roots in per capita output may be spurious because of a lack of attention to the possibility that dependence in these individual series exhibits long memory, that is, dependence decays at a hyperbolic rather than a geometric rate. If it is the case that the individual series are stationary in levels, the differences between them cannot contain unit roots, so that convergence is occurring. They further argue that long memory can explain the 2% convergence rate found in cross-section regressions. This is an intriguing argument, although Durlauf *et al*. (2005) question the strength of the empirical evidence for long memory as well as its theoretical plausibility. Michelacci and Zaffaroni also do not directly study the behavior of per capita output differences, so it is unclear how to match their analysis with other studies.

The time series and σ approaches to convergence are merged in Evans (1996). He studies the time series properties of σ_t^2, the cross-section variance of $\log y_{i,t}$. He shows that, when there is no cointegration among the series $\log y_{i,t}$, σ_t^2 may be represented as a unit root process with a quadratic time trend, and this suggests a time series test of convergence based on unit root tests applied to a time series for σ_t^2. He uses this test to conclude that there is convergence to a common trend among 13 industrial countries over the period 1870–1989 and among a group of 51 countries over the period 1950–92, although the evidence in the latter case is less conclusive.

Evans (1997) provides a time series approach to estimating rates of convergence. For the contiguous US states over the period 1929–91, he finds that about one-third of the point estimates are negative and about two-thirds of the confidence intervals contain zero. For a sample of 48 countries over the period 1950–90, about half of the point estimates are negative and all but two of the confidence intervals contain zero.

23.6.1 Transitions versus steady-state dynamics

There are important differences between the time series approach to convergence and the β and distribution shape approaches. As argued in Bernard and Durlauf (1996), time series tests assume that the underlying stochastic processes are time invariant, so that countries have transited to an invariant output process. In contrast, cross-section approaches, such as β-convergence and σ-convergence, are motivated by the assumption that countries are in transition to a steady-state, so that the data for a given country at time t are drawn from a different stochastic process than the data at some future time.[29] Bernard and Durlauf further indicate

how convergence under a cross-section test can, in fact, imply a failure of convergence under a time series test, because of these different assumptions. To be clear, it is possible for data from a stationary process to exhibit β-convergence, for example, but it is not clear what the economic interpretation is.

Harvey and Carvalho (2002) and Carvalho and Harvey (2005a, 2005b) propose a number of time series analyses of convergence which distinguish between evaluating whether countries have converged, and whether countries are converging. The idea of this framework is to interpret convergence as involving adjustments of output in a given country to gaps between its past output and that of other countries. It allows one to evaluate the presence of common deterministic trends, as well as tendencies for economies to adjust based on differences with the rest of the world. Relative to the other unit root tests, this approach allows for level differences between economies and so distinguishes between convergence to a common level and convergence to common growth paths. Harvey and Carvalho (2002) use this approach to conclude that there is convergence between the US and Japanese growth paths; Carvalho and Harvey (2005a, 2005b) find both convergence and divergence between Euro zone countries and various pairs of US regions respectively. An additional finding of these papers is that unit root tests of convergence are highly sensitive to the inclusion of time trends and constant terms.

Phillips and Sul (2006) extend the distinction between economies that have converged and economies that are converging, by explicitly addressing the question of invariance of the time series process for output. Their analysis focuses on models of the form:

$$y_{i,t} = b_{i,t}\beta_t + \kappa_{i,t}, \tag{23.16}$$

where β_t is a common trend (deterministic and/or stochastic) and $\kappa_{i,t}$ is a cyclical term. The key advance in this formulation is that $b_{i,t}$, the weights on the common trend, are allowed to vary both with respect to the country and with respect to time. This approach allows one to estimate a transition curve for individual economies which, by tracing out $b_{i,t}\beta_t$, allows for explicit evaluation of how the long-run components of national output co-evolve. Their analysis finds evidence of convergence for the OECD member countries and for US states, but not for a broader sample of countries drawn from the Penn World Table.

23.7 The economics of convergence

The various approaches to convergence that we have discussed are all purely statistical, so it remains to consider convergence as an economic concept, in order to assess what can be learned from econometric studies. In this section we provide some definitions of convergence that, while statistical in nature, can be used to move between the economic notion of convergence and the statistical notions that have been employed to assess it.

Broadly speaking, we take the substantive economic content of the convergence hypothesis to be the claim that initial conditions have no effect on long-run

economic outcomes. As argued in Durlauf *et al.* (2005), the empirical task is then to determine the role of initial conditions in explaining cross-country differences in per capita output. This task is complicated by the role of structural heterogeneity in also explaining those differences; so the empirical literature must disentangle the effects of initial conditions and structural heterogeneity. There are three possibilities: (i) unconditional convergence (to a common long-run level) occurs if differences in per capita incomes are temporary; (ii) conditional convergence occurs if permanent differences reflect only cross-country structural heterogeneity; and (iii) club convergence occurs if initial conditions determine, to some extent at least, long-run outcomes, with countries with similar initial conditions exhibiting similar long-run outcomes.[30]

To formalize these ideas, we associate with economy i initial conditions $\rho_{i,0}$ and say that these initial conditions do not matter in the long run if:

$$\lim_{t\to\infty} \mu(\log y_{i,t}|\rho_{i,0}) \text{ does not depend on } \rho_{i,0}, \tag{23.17}$$

where $\mu(\cdot)$ is a probability measure.[31] Letting $\|\|$ denote a metric for computing the distance between probability measures, we say that countries i and j converge if:

$$\lim_{t\to\infty} \|\mu(\log y_{i,t}|\rho_{i,0}) - \mu(\log y_{j,t}|\rho_{j,0})\| = 0, \tag{23.18}$$

which implies convergence in average income levels in the sense that:

$$\lim_{t\to\infty} E(\log y_{i,t} - \log y_{j,t}|\rho_{i,0}, \rho_{j,0}) = 0. \tag{23.19}$$

This definition can be modified to require that the limiting expected difference between $\log y_{i,t}$ and $\log y_{j,t}$ is bounded if the equality of steady-state growth rates is of interest. This definition is the one that underlies all of the time series approaches to convergence: the differences between Harvey and Carvalho (2002) and Phillips and Sul (2006) and the earlier time series tests of Bernard and Durlauf (1995) and others reflect differences in how this long-run forecast similarity is calculated. This is also consistent with the economic notion of convergence that appears in the neoclassical growth model. Our criticism of some of the cross-section and panel approaches to convergence partially derives from their failure to evaluate this condition fully.

Bernard and Durlauf (1996) suggest a definition of partial convergence that requires contemporaneous income differences be expected to diminish, that is:

$$E(\log y_{i,t} - \log y_{j,t}|\rho_{i,0}, \rho_{j,0}) < \log y_{i,0} - \log y_{j,0}, \tag{23.20}$$

for $\log y_{i,0} > \log y_{j,0}$. Hall, Robertson and Wickens (1997) suggest a definition that requires the variance of output differences to diminish to zero, that is:

$$\lim_{t\to\infty} E((\log y_{i,t} - \log y_{j,t})^2|\rho_{i,0}, \rho_{j,0}) = 0, \tag{23.21}$$

and hence convergence requires output for a pair of countries to behave similarly in the long run. This is a strong requirement since it does not permit $\log y_{i,t} - \log y_{j,t}$ to be stochastic in the long run, as would be the case if the two countries have different short-run shock processes. Hall *et al.* point out the lacuna in the definition (23.19) in the case of long-run deviations whose current direction is not predictable. If, for example, $\log y_{i,t} - \log y_{j,t}$ obeys a random walk with current value zero, then definition (23.19) would hold despite the fact that future output deviations between countries i and j could be large. This problem is avoided by the modified definition:

$$\forall r \geq 0, \qquad \lim_{t \to \infty} E(\log y_{i,t} - \log y_{j,t} | \rho_{i,r}, \rho_{j,r}) = 0. \tag{23.22}$$

This modification has no bearing on the relationship between long-run unforecastability of differences and either theory or the various convergence tests we have described.

The β-convergence concept represents the idea of the long-run irrelevance of initial output per capita by decomposing the growth rate of $y_{i,t}$ into two parts, technological progress and "catching up." In the Solow model a positive rate of conditional convergence, λ, implies that final output is ultimately independent of initial conditions, so that the initial gap between output and its steady-state value ceases to play a role in long-run growth. As we have discussed, a testable implication of a positive λ is a negative β.

In contrast, the literature that focuses on nonlinearities in the growth process seeks to identify sub-groups of countries that obey a common growth model distinct from that obeyed by the countries in other groups. Such behavior is consistent with initial conditions that are relevant even in the long run, as it is consistent with a global growth model with multiple steady-states in which economies with similar initial conditions tend to converge to one another. The convergence approaches that study the behavior of the entire cross-country distribution of output per capita look for evidence of the long-run importance of initial conditions in the form of accumulation points in the distribution, as evinced by intervals with large quantities of probability mass, between which there is little mobility. This behavior is consistent with a dynamic growth process that exhibits multiple basins of attraction and so produces convergence clubs.

The convergence definitions given in (23.19) and (23.20) above make no distinction between the long-run effects of initial conditions and those of structural heterogeneity, and so fail to distinguish conditional convergence from the existence of convergence clubs. This is a serious deficiency for those seeking to use the outcomes of convergence tests to adjudicate between competing theories of economic growth. Long-run effects of cross-country differences in preferences are, for example, consistent with both the neoclassical and endogenous or "new" classes of growth theories. However, neoclassical theories are inconsistent with long-run effects of cross-country differences in initial human and physical capital stocks, whereas this would not be the case for all endogenous growth models. In other words, the finding of a long-run role for initial conditions constitutes evidence in

favor of non-neoclassical models, but care must be taken to control for the long-run effects of differences in preferences and other structural characteristics.

More formally, successful empirical work on the convergence issue requires the distinction between initial conditions $\rho_{i,0}$ and structural characteristics $\theta_{i,0}$. Steady-state effects of the former imply the existence of convergence clubs, but steady-state effects of the latter do not. In order to make this distinction we modify (23.18) and say that countries i and j exhibit convergence if:

$$\lim_{t\to\infty} \|\mu(\log y_{i,t}|\rho_{i,0}, \theta_{i,0}) - \mu(\log y_{j,t}|\rho_{j,0}, \theta_{j,0})\| = 0 \text{ if } \theta_{i,0} = \theta_{j,0}. \tag{23.23}$$

The corresponding modification to the notion of convergence in expected value is:

$$\lim_{t\to\infty} E(\log y_{i,t} - \log y_{j,t}|\rho_{i,0}, \theta_{i,0}, \rho_{j,0}, \theta_{j,0}) = 0 \text{ if } \theta_{i,0} = \theta_{j,0}, \tag{23.24}$$

and the other convergence concepts discussed above can be similarly modified. While conceptually clear, the distinction between initial conditions and structural heterogeneity is potentially difficult in practice. Typically, researchers have treated initial human and physical capital stocks as instances of initial conditions, and other variables as representing structural heterogeneity – for example, those that often appear as controls in cross-country growth regressions, a practice that is problematic if these variables are, in fact, endogenously determined by initial conditions.

Disentangling the respective roles of structural heterogeneity and initial conditions in determining growth performance remains one of the most important challenges for the convergence literature. Economic theory does not always provide a guide to the relevant control variables, let alone the appropriate distinction between variables that capture structural heterogeneity and those that should be classed as initial conditions. It is also important to emphasize that none of the statistical definitions of convergence discussed above is necessarily of any intrinsic interest *per se*; each is useful only to the extent that it can illuminate some economically interesting notions of convergence such as that in (23.24). The failure to distinguish between convergence as an economic concept and convergence as a statistical concept has led to much confusion in the growth literature.

23.8 Conclusions

The empirical convergence literature contains many interesting findings and has helped to identify a number of important generalizations about cross-country growth behavior. At the same time, it has yet to reach any sort of consensus on the deep economic questions for which the statistical analyses were designed. It is not difficult to highlight some of the relevant problems. The fundamentally nonlinear nature of endogenous growth theories renders the conventional cross-section and panel convergence tests inadequate as ways to discriminate between the main classes of theories. Evidence of convergence clubs may simply be evidence of deep nonlinearities in the transitional dynamics towards a unique

steady-state. Time series evidence against divergence does not distinguish between conditional and unconditional convergence. Further, cross-section, panel, and time series approaches to convergence not only yield different results, but are predicated on different views of the nature of transitory versus steady-state behavior of economies, differences that themselves remain hard to test.

None of this is to say that the study of convergence is not a meaningful or productive subject for research. Clearly, considerable progress has been made, and Phillips and Sul (2006) represents a key first step in integrating the transitory and steady-state perspectives. Much remains to be done, and research on convergence should continue to develop in interesting ways. Our belief is that progress is most likely if the economic content of specific versions of convergence is placed at the center of the analysis, so that statistical sophistication is not an end in itself.

Further, we think that more attention should be made to time horizons. Much of the convergence literature has treated the question as a zero–one outcome, whereas it is probably more sensible to ask questions about partial convergence over shorter horizons. While attention to convergence rates addresses this question, it generally has not focused on understanding differences in timing across regions or how timing is affected by various initial conditions. These questions are especially important in assessing anti-poverty policies such as those advocated by the United Nations in the Millennium Development Goals, and they perhaps matter for introducing some much needed modesty into the growth literature.

Finally, we see value in shifting discussions of convergence away from national per capita incomes. Cross-country differences in mortality and morbidity are an obvious context where convergence is of intrinsic interest. In addition, we see some scope for considering convergence for units outside the nation state. This seems clear when one considers the effects of institutions and culture on economic activity. We go so far as to conjecture that important aspects of long-run persistence in national incomes mirror long-term divergence in phenomena that are not nation-specific, which is, of course, an idea that goes back to Max Weber. Thomas Macaulay wrote,[32] comparing the Catholic Church to the British Empire: "she may still exist in undiminished vigor when some traveler from New Zealand shall, in the midst of a vast solitude, take his stand on a broken arch of London Bridge to sketch the ruins of St. Paul's," which well illustrates how all claims of convergence versus divergence or permanence versus transience depend on the choice of context.

Notes

1. Quotations are taken from the Penguin edition.
2. See Durlauf (1996) and the subsequent papers in the July 1996 *Economic Journal*; Durlauf and Quah (1999), Islam (2003), Barro and Sala-i-Martin (2004), and Durlauf, Johnson and Temple (2005) for, *inter alia*, surveys of the convergence literature.
3. Abramovitz (1986) also uses σ-convergence, which we will discuss below.
4. Mankiw (1995, p. 301), for example, argues that for "understanding international experience, the best assumption may be that all countries have access to the same pool of knowledge, but differ by the degree to which they take advantage of this knowledge by investing in physical and human capital." Dowrick and Rogers (2002) argue

that both diminishing returns and technology transfer are important contributors to the convergence process. See also Bernard and Jones (1996) and Barro and Sala-i-Martin (1997).

5. That $\lim_{t\to\infty} y^E_{i,t} = y^E_{i,\infty}$ follows from $\lambda_i > 0$. This long-run independence of $y^E_{i,t}$ from $y^E_{i,0}$ implies that initial conditions do not matter in the long run – an interpretation of convergence that we discuss below.
6. In parallel to equation (23.1), $\lim_{t\to\infty}(y_{i,t} - y^E_{i,\infty}A_{i,0}e^{g_i t}) = 0$, so that again the initial value of output per worker does not affect its long-run value.
7. This assumption is made, for example, by Mankiw *et al.* (1992), who argue that $A_{i,0}$ reflects not just technology, which they assume to be constant across countries, but country-specific influences on growth, such as resource endowments, climate and institutions. They assume these differences vary randomly across countries, independently of the determinants of the steady-state level of output per worker.
8. Barro and Sala-i-Martin (2004, Chs. 11, 12) implement β-convergence tests for a variety of datasets. As pointed out by DeLong (1988), the use of homogeneous groups runs the risk of *ex post* sample selection, especially if the homogeneity relates to final outcomes. In particular, he views the Baumol (1986) finding of unconditional β-convergence over 1870–1979 among a set of countries that were affluent in 1979, as tending to overstate the true degree of convergence. DeLong extends the sample to include countries with similar starting positions in 1870, but which have been less successful since, and this weakens the evidence for convergence.
9. In both Jones and Manuelli (1990) and Kelly (1992), steady-state growth occurs without exogenous technical change, but initially poor economies grow more quickly as β-convergence requires.
10. As Barro and Sala-i-Martin (1992) note, while there is some variation in estimated convergence rates, estimates generally range between 1% and 3%. They attribute this variation to unobserved heterogeneity in steady-state values; but to the extent that it is correlated with variables included in the regressions, this heterogeneity implies the parameter estimates are inconsistent. Panel studies such as Islam (1995), Caselli *et al.* (1996) and Lee, Pesaran and Smith (1998) have found more rapid rates of convergence.
11. For example, Barro and Sala-i-Martin (1991) present results for US states and regions as well as European regions; Barro and Sala-i-Martin (1992) for US states, a group of 98 countries and the OECD; Mankiw *et al.* (1992) for several large groups of countries; Sala-i-Martin (1996a, 1996b) for US states, Japanese prefectures, European regions, and Canadian provinces; Cashin (1995) for Australian states and New Zealand; Cashin and Sahay (1996) for Indian regions; Persson (1997) for Swedish counties; and Shioji (2001) for Japanese prefectures and other geographic units.
12. As Durlauf *et al.* (2005) document, the number of suggested control variables is now almost as large as the number of countries in the world.
13. Den Haan (1995) is an especially sophisticated discussion.
14. See Abramovitz (1986), Baumol (1986), DeLong (1988), Romer (1990) and Temple (1998).
15. An appendix to Durlauf and Johnson (1995) discusses the application of regression tree methods to the issue of locating multiple regimes in growth models. Breiman *et al.* (1984) contains a detailed general treatment of regression tree methods. While these methods suffer from the lack of a well-developed asymptotic theory for testing the number of regimes present in a dataset, they are consistent in the sense that, under relatively weak conditions, the correct model will be revealed as the sample size grows to infinity, if there are a finite number of regimes.
16. Papageorgiou and Masanjala (2004) observe that Durlauf and Johnson's findings could be due to misspecification of the aggregate production function. They estimate a version of the Solow model based on a constant elasticity of substitution (CES) production function rather than the Cobb–Douglas, following findings in Duffy and Papageorgiou (2000), and ask whether or not Durlauf and Johnson's multiple regimes remain under the CES

specification. Using Hansen's (2000) approach to sample splitting and threshold estimation, they find statistically significant evidence of four distinct growth regimes, broadly consistent with those found by Durlauf and Johnson (1995). Johnson and Takeyama (2001) also use the regression tree approach and find evidence of thresholds in US state economic growth behavior defined by variables likely to be proxies for the capital/labor ratio, agglomeration effects and communication effects.

17. For more on GUIDE methods, see Loh (2002).
18. Appendix A of Desdoigts (1999) provides a useful primer on projection pursuit which is developed in Friedman and Tukey (1974) and Friedman (1987).
19. Kernel density estimation is a nonparametric method of estimating density functions that has the attraction of flexibility as it does not impose *a priori* a functional form for the density. See Silverman (1986).
20. The finite mixture model is a semi-parametric alternative to the nonparametric kernel approach to density estimation. See McLachlan and Peel (2000).
21. Tsionas (2000) applies mixture models to US state data while Pittau (2005) and Pittau and Zelli (2006) apply them to EU regional data.
22. This requirement is consistent with the documented lack of mobility within the cross-country distribution of per capita income.
23. Again, multimodality in the ergodic distribution is neither necessary nor sufficient to imply the existence of convergence clubs – not sufficient because it reveals nothing about mobility and not necessary because the existence of multiple stochastic steady-states does not imply multiple modes in the long-run distribution.
24. Applications of Markov chain methods to the study of mobility issues in the social sciences predate the modern empirical growth literature. See, for example, Prais (1955). The time-invariance and first-order Markovian assumptions are testable, with Quah (1993b) presenting an informal test of the latter, while Fingleton (1997) and Bickenbach and Bode (2003) present more formal tests in the cases of EU regions and US states respectively.
25. Johnson (2005) re-examines Feyrer's (2003) results using the continuous state space methods discussed below and finds that, rather than TFP playing an exclusive role in the apparent bimodality in the long-run distribution of GDP per capita, the ergodic distribution of the capital-output ratio is also bimodal.
26. Quah's methods have been widely applied. For example, Andres and Lamo (1995) apply these methods to the OECD; Lamo (2000) to the regions of Spain; Johnson (2000) to US states; Bandyopadhyay (2004) to the Indian states; Andrade *et al.* (2004) to Brazilian municipalities; Ezcurra *et al.* (2005) to EU regions; Fotopoulos (2006) to Greek regions, and Pittau and Zelli (2006) to EU regions. In some cases, the small cross-section dimension of the samples must limit the reliability of the findings. These methods have also been extended to broader notions of distributional dynamics. Fiaschi and Lavezzi (2004) develop an analysis of the joint distribution of income levels and growth rates; their findings are compatible with the existence of multiple equilibria in the sense that countries may become trapped in the lower part of the income distribution.
27. Other efforts to find determinants of intertemporal mobility have produced mixed results. For the OECD countries, Andres and Lamo (1995) condition on the steady-state implied by the Solow model and find little change in the tendency to polarization unless country specific effects are permitted. Lamo (2000) finds only a small increase in mobility for Spanish regions after conditioning on interregional migration flows, while Bandyopadhyay (2004) shows that differences in infrastructure spending and education contribute to polarization between the rich and poor states of India.
28. These findings are echoed in Pesaran (2007), who uses both the Maddison and Penn World Table datasets and employs a convergence definition that explicitly focuses on the probability of large deviations between $\log y_{i,t}$ and $\log y_{j,t}$.

29. Panel studies circumvent this issue by heavy reliance on the adequacy of the log-linear approximation. The assumption is that countries in the sample are sufficiently close to their steady-states that their dynamics can be described by a stationary process. This is potentially problematic for studies that employ a broad cross-section of countries, at least some of which may begin far from their steady-state.
30. This taxonomy is due to Galor (1996), who discusses the relationship between it and the theoretical growth literature. His paper, and those of Azariadis (1996) and Azariadis and Stachurski (2005), give many examples of models in which initial conditions matter for long-run outcomes.
31. The discussion here is in terms of $\log y_{i,t}$, the log level of output per capita in country i at time t; but these definitions could be applied to other variables such as real wages or life expectancy. We use $\log y_{i,t}$ rather than $y_{i,t}$ due to the general interest in the literature in relative rather than absolute inequality.

The Methods of Growth Econometrics

Steven N. Durlauf, Paul A. Johnson and Jonathan R.W. Temple

Abstract

This chapter provides an overview of current practices in the econometric analysis of economic growth. We describe some of the main methodologies that have been developed to study growth as well as some of the major empirical findings with which they are associated. Further, we explore the relationship between econometric analyses and growth theories. While we argue that there are a number of respects in which growth econometrics is not adequately integrated with growth theory, we believe that substantial methodological progress has been made.

24.1 Introduction

In this chapter we will review some of the methods that have been used in the emerging field of growth econometrics. We define this field as the use of statistical models to explain variation in growth rates and productivity levels across countries or regions. This has long been an active field of research, especially since the mid 1980s, but the position of this field within economics remains somewhat uneasy. There are thoughtful and well-informed observers who regard this form of evidence as essentially inadmissible.

It is important to understand why this is so, and it is true that the field faces many problems, not least the constraints imposed by the available data. We will review these problems in detail, but argue that there are some grounds for optimism. At least in adopting methods appropriate to these datasets and economic questions, genuine progress has been made, and we will highlight areas where further progress seems especially likely. Moreover, the prospects for useful findings seem likely to improve over time, as more and better data become available, and more is learnt about the appropriate methods for analyzing such data.

The abiding interest of the study of aggregate productivity, whether in levels or growth rates, perhaps speaks for itself. Seeking to understand the wealth of nations is one of the oldest and most important research agendas in the entire discipline. At the same time, it is also one of the areas in which genuine progress seems hardest to achieve. The contributions of individual papers can often appear slender. Even when the study of growth is viewed in terms of a collective, incremental endeavor, the various papers cannot easily be distilled into a consensus that would meet the standards of evidence routinely applied in other fields of economics.

Faced with such criticisms, one traditional defence of empirical growth research is phrased in terms of expected payoffs. Each time an empirical growth paper is written, the probability of gaining genuine understanding may be low, but when and where it does emerge, the payoff to that understanding could be vast. Moreover, some contributions can be seen as stepping stones in the development of credible evidence. That gradual process, working towards better methods and more reliable findings, may take years, but could ultimately have a high payoff. From this perspective, even if much of this evidence lacks credibility, the literature is gradually evolving towards methods and findings that should be taken more seriously.

These arguments are plausible, but rely on an important tacit assumption. They all depend on the ability of researchers and policy makers to discriminate between the status of different pieces of evidence – the good, the bad and the ugly – and this process of discrimination carries many difficulties of its own. The accuracy, or otherwise, of such judgments plays a key role in the overall development and intellectual health of any empirical literature. This reinforces the case for building an understanding of the relevant methods, their strengths and limitations, and the ways in which the existing literature is often flawed or inconclusive.

Caution will be needed throughout. Rodriguez and Rodrik (2001) begin their skeptical critique of the evidence on trade policy and growth with an apt quote from Mark Twain: "It isn't what we don't know that kills us. It's what we know

that ain't so." This point applies with some force to almost the entirety of the empirical growth literature. It is well known that some claims have not survived later scrutiny, with Levine and Renelt (1992) an especially famous demonstration of the lack of robustness of some early results. To take a more recent example, few papers in economics have been as directly influential on policy debates as the study of foreign aid and growth by Burnside and Dollar (2000). Yet its claims have been vigorously contested in a series of subsequent papers, and a careful reading of those papers might suggest that the key hypotheses cannot be reliably tested given the limitations of the available data.

Such concerns have not prevented the proposals for growth determinants from increasing with every passing year. Indeed, the number of proposed determinants is now similar to the number of countries for which data are available. It is hard to believe that all these variables are central, yet the range of possibilities, the small number of countries that can be studied, and the arbitrary choices that are often involved in estimating a specific model, all conspire to make learning about economic growth unusually difficult.

These and other difficulties have prompted the field to evolve continuously, and to adopt a wide range of methods. We argue that the statistical tools that have been applied to growth questions are sufficiently rich that they collectively define a distinct field, growth econometrics. This chapter provides an overview of the current state of this field, updating and revising our earlier survey in Durlauf, Johnson and Temple (2005). The chapter will survey the body of econometric and statistical methods that have been brought to bear on growth questions, and provide some assessments of the value of these tools. In keeping with the rest of this book, the focus will predominantly be on the application of econometric methods and techniques and their interpretation, rather than attempting to summarize substantive findings. For an earlier survey with a greater focus on substantive findings, see Temple (1999), and for an earlier evaluation of the econometrics of growth, see Durlauf and Quah (1999).

The techniques that have been used in growth econometrics largely reflect the specialized questions that naturally arise in this context. Consider the identification of empirically salient determinants of growth when the range of potential factors is large relative to the number of observations. The associated model uncertainty is one of the most fundamental problems facing growth researchers. Individual researchers, seeking to communicate the extent of support for particular growth determinants, typically emphasize a single model (or small set of models) and then carry out inference as if that model had generated the data. But there are usually other models that have equally strong claims on our attention, and hence the standard errors will often understate the true degree of uncertainty about the parameters. Moreover, the decision to report one model rather than another is often somewhat arbitrary. The need for a more systematic and objective approach, one that properly accounts for model uncertainty, naturally leads to Bayesian or pseudo-Bayesian approaches to data analysis.

Bayesian approaches seem especially natural for growth econometrics, given the paucity of the available data. This represents a major constraint on the scope for

identifying causal effects. It may seem trivial to say that the main obstacle to understanding growth is the small number of countries in the world, but the problem goes beyond a fundamental lack of variation or information. It also limits the extent to which researchers can address obvious problems, such as measurement error and parameter heterogeneity. Sometimes the problem appears in especially stark form: imagine trying to infer the consequences of democracy for long-run development in poorer countries. The twentieth century provided relatively few examples of stable, multi-party democracies among the poorer nations of the world, and so statistical evidence can make only a limited contribution to this debate, unless one is willing to make exchangeability assumptions about nations that would seem not to be credible.[1] As we discuss later in the chapter, the recent literature has explicitly sought to address this kind of problem by considering the effects of transitions to democracy using within-country variation. This leads to some interesting findings, but the short span of the available data currently precludes the long-term assessment that will often be of most interest.

If there were a larger group of countries to work with, many of the difficulties that face growth researchers could be addressed in ways that are now standard in the microeconometrics literature. For example, Harberger (1987), Solow (1994) and many others have expressed considerable skepticism about any exercise that assumes a common linear model for a heterogeneous set of countries. In principle, these concerns might be addressed by estimating more general models, using interaction terms, nonlinearities or semiparametric methods, so that the marginal effect of a given explanatory variable can differ across countries or over time. The problem is that these solutions will require large samples if the conclusions are to be robust. Similarly, some methods for addressing other problems, such as measurement error, are only useful in samples larger than those available to growth researchers. This helps to explain the need for a flexible approach, and why growth econometrics has evolved in such a pragmatic and eclectic fashion, drawing on a range of statistical methods to a greater extent than is the norm in applied econometrics.

Given the small number of countries in the world, the scope for reliable evidence is likely to rest on the use of time series variation within countries, especially as new data become available. Many empirical growth papers are now based on the estimation of dynamic panel data models with fixed effects, sometimes in conjunction with a time-varying "treatment" variable, such as the advent of democracy or trade reform. The later sections of this chapter will discuss some of the relevant technical issues, and the connection between some of these studies and the microeconometric literature on treatment effects and program evaluation. This connection not only helps to clarify the strengths and limitations of this form of evidence, but also some of the weaknesses of the empirical growth literature generally.

Despite the many difficulties that arise in empirical growth research, we believe genuine progress has been made. Researchers have uncovered stylized facts that growth theories should endeavour to explain, and developed methods to investigate the links between these stylized facts and substantive economic arguments.

They have also helped to establish the clear limits that exist in employing statistical methods to address growth questions. One implication of these limits is that narrative and historical approaches have a lasting role to play in empirical growth analysis, as we will repeatedly emphasize.

The remainder of the chapter is organized as follows. Section 24.2 briefly sketches some of the relevant stylized facts. Section 24.3 describes the relationship between theoretical growth models and econometric frameworks for growth, with a focus on cross-country growth regressions and then an alternative approach, the "levels regression." Section 24.4 describes methods for identifying growth determinants, and a range of questions concerning model specification and evaluation are addressed. Section 24.5 discusses econometric issues that arise according to whether one is using cross-section, time series or panel data. Section 24.6 provides an extended discussion of endogeneity and the associated use of instrumental variable methods. Section 24.7 covers some remaining econometric issues, including the role of outliers and measurement error. Section 24.8 concludes by highlighting some possible directions for future research.

24.2 Stylized facts

The survey by Durlauf *et al.* (2005) and the textbook by Acemoglu (2008) include overviews of stylized facts, concentrating on the period between 1960 and 2000. Some of the relevant facts can be summarized as follows:

1. Over the 40-year period as a whole, most countries have grown richer, but vast income disparities remain. For all but the richest group, growth rates have differed to an unprecedented extent, regardless of the initial level of development.
2. Although past growth is a surprisingly weak predictor of future growth, it is slowly becoming more accurate over time, and so distinct winners and losers are beginning to emerge. The strongest performers are located in East and Southeast Asia, which have sustained growth rates at unprecedented levels. The weakest performers are predominantly located in sub-Saharan Africa, where some countries have barely grown at all, or even become poorer. The record in South and Central America is also distinctly mixed. In these regions, output volatility is high, and dramatic output collapses are not uncommon.
3. For many countries, growth rates were lower in 1980–2000 than in 1960–80, and this growth slowdown is observed throughout most of the income distribution. Moreover, the dispersion of growth rates has increased. A more optimistic reading would also emphasize the growth take-off that has taken place in China and India, home to two-fifths of the world's population and, historically at least, a greater proportion of the world's poor.

Recent observers, such as Collier (2007), have particularly emphasized the emergence of a distinct set of countries, home to perhaps a billion people, where stagnation or slow growth is the norm. These countries appear locked out of

the transitions to modern economic growth that have been seen elsewhere. The idea that countries have divided across two distinct paths is weakly supported by evidence in Durlauf *et al.* (2005) that correlations of growth rates across decades are tending to increase over time. Perhaps more directly and persuasively, it is supported by the finding that the proportion of countries that have stagnated over a 20-year period has gradually increased since the 1960s. It remains to be seen whether the strong world growth and commodity boom of the early 2000s, which has clearly benefited some of the countries in sub-Saharan Africa, will help to overturn this finding.

Even this brief overview of the stylized facts reveals that there is much of interest to be investigated and understood. The field of growth econometrics has emerged through efforts to interpret and understand these facts, partly in the light of predictions made by simple growth models. The complexity of the growth process and the limitations of the available data combine to suggest that scientific standards of proof are unattainable. Perhaps the best this literature can hope for is to constrain what can legitimately be claimed, but that in itself would be an achievement. As a direct consequence of growth econometrics, there are now various claims about the world – for example, that growth is independent of the extent of financial development – that are harder to sustain than would once have been the case.

Researchers such as Levine and Renelt (1991) and Wacziarg (2002) have argued that, seen in this more modest light, growth econometrics can provide a signpost to interesting patterns and partial correlations. Ultimately, this helps to rule out some versions of the world that might otherwise seem plausible, and shift the burden of proof in particular debates. Seen in terms of establishing stylized facts, empirical studies also help to shape the demands made of future theories, and can act as a discipline on quantitative investigations using calibrated models. These are important contributions. In discussing them further, we first describe the models that are usually applied in empirical growth research.

24.3 Cross-country growth regressions: from theory to empirics

The stylized facts of economic growth have led to two major themes in the development of the literature. The first theme is the study of convergence, and we review this work in our companion chapter. The second theme concerns the identification of growth determinants. This has been the more active area in recent research, and will be our central focus in this chapter. Section 24.3.1 provides a general theoretical framework for understanding growth dynamics. The framework is explicitly neoclassical and leads to a model which is the basis for most empirical growth research. Section 24.3.2 examines the relationship between this model and the specification of a growth regression. This also provides relevant background for section 24.3.3, which focuses on the "levels regression" that has become a popular alternative in the recent literature. We will argue that its advantages, relative to growth regressions, have sometimes been exaggerated. Finally, Section 24.3.4 discusses the interpretation of error terms in growth regressions.

24.3.1 Growth dynamics: basic ideas

Our exposition in this section and the next closely follows Durlauf *et al.* (2005). At the heart of the empirical growth literature is a cross-country regression, founded on the one-sector neoclassical growth model. That model implies that, to a first-order approximation, $y^E_{i,t}$, output per efficiency unit of labor, evolves according to:

$$\log y^E_{i,t} = \left(1 - e^{-\lambda_i t}\right) \log y^E_{i,\infty} + e^{-\lambda_i t} \log y^E_{i,0}, \tag{24.1}$$

where $y^E_{i,\infty}$ is the steady-state value of $y^E_{i,t}$ and $\lim_{t\to\infty} y^E_{i,t} = y^E_{i,\infty}$. As is standard, we define output per efficiency unit of labor input as $y^E_{i,t} = Y_{i,t}/(A_{i,t}L_{i,t})$, where $Y_{i,t}$, $L_{i,t}$, and $A_{i,t}$ denote, respectively, the level of output, the labor force, and the level of efficiency in economy i at time t. The labor force is assumed to follow $L_{i,t} = L_{i,0}e^{n_i t}$, where the population growth rate n_i is constant, while $A_{i,t} = A_{i,0}e^{g_i t}$, where g_i is the (constant) rate of labor-augmenting technical progress. The parameter λ_i measures the rate of convergence of $y^E_{i,t}$ to its steady-state value and will typically depend on other parameters in the model. Assuming that $y^E_{i,0} > 0$ and so eliminating the trivial equilibrium $y^E_{i,t} = 0\ \forall t$ when the convergence rate $\lambda_i > 0$, then the value of $y^E_{i,\infty}$ is independent of $y^E_{i,0}$. In this sense, initial conditions do not matter in the long run.

Equation (24.1) expresses growth dynamics in terms of the unobservable $y^E_{i,t}$. In order to describe dynamics in terms of the observable variable, output per labor unit $y_{i,t} = \frac{Y_{i,t}}{L_{i,t}}$, we can use $y_{i,t} = y^E_{i,t}A_{i,t} = y^E_{i,t}A_{i,0}e^{g_i t}$ to write (24.1) as:

$$\log y_{i,t} - g_i t - \log A_{i,0} = \left(1 - e^{-\lambda_i t}\right) \log y^E_{i,\infty} + e^{-\lambda_i t} \left(\log y_{i,0} - \log A_{i,0}\right), \tag{24.2}$$

so that:

$$\log y_{i,t} = g_i t + \left(1 - e^{-\lambda_i t}\right) \log y^E_{i,\infty} + \left(1 - e^{-\lambda_i t}\right) \log A_{i,0} + e^{-\lambda_i t} \log y_{i,0}. \tag{24.3}$$

Defining the growth rate of output per worker between 0 and t as $\gamma_i = t^{-1}\left(\log y_{i,t} - \log y_{i,0}\right)$ and subtracting $\log y_{i,0}$ from both sides of equation (24.3) allows it to be written as:

$$\gamma_i = g_i + \beta_i \left(\log y_{i,0} - \log y^E_{i,\infty} - \log A_{i,0}\right), \tag{24.4}$$

where $\beta_i = -t^{-1}(1 - e^{-\lambda_i t})$. This expression decomposes the growth rate in country i into two distinct components: the first, g_i, measures growth due to technical progress, while the second, $\beta_i \left(\log y_{i,0} - \log y^E_{i,\infty} - \log A_{i,0}\right)$, measures growth due to the gap between initial output per worker and the steady-state value. This second source of growth is one aspect of "catching up" and, as $t \to \infty$, its importance, which reflects the role of initial conditions, diminishes to zero.

Assuming that the rates of technical progress and convergence are constant across countries allows (24.4) to be rewritten as:

$$\gamma_i = g - \beta \log y^E_{i,\infty} - \beta \log A_{i,0} + \beta \log y_{i,0}, \tag{24.5}$$

with the key implication of a negative relationship between initial levels of output and subsequent growth in a cross-section of countries, over any time period. The mechanism is diminishing returns to capital: a country further below its balanced growth path will tend to grow more quickly, other things equal, because a given rate of investment has a larger effect on the growth rates of capital and output.

24.3.2 Cross-country growth regressions

The typical cross-country growth regression, the foundation of the empirical growth literature, is motivated by adding a random error term υ_i to (24.5), giving:

$$\gamma_i = g - \beta \log y^E_{i,\infty} - \beta \log A_{i,0} + \beta \log y_{i,0} + \upsilon_i. \tag{24.6}$$

Operationalization of (24.6) requires empirical analogues for $\log y^E_{i,\infty}$ and $\log A_{i,0}$. Mankiw, Romer and Weil (1992) do this by assuming that aggregate output is described by a three-factor Cobb–Douglas production function $Y_{i,t} = K^{\alpha}_{i,t} H^{\phi}_{i,t} \left(A_{i,t} L_{i,t}\right)^{1-\alpha-\phi}$, where $K_{i,t}$ denotes physical capital and $H_{i,t}$ denotes human capital, assumed to follow the accumulation equations $\dot{K}_{i,t} = s_{K,i} Y_{i,t} - \delta K_{i,t}$ and $\dot{H}_{i,t} = s_{H,i} Y_{i,t} - \delta H_{i,t}$, respectively, where δ denotes the depreciation rate and $s_{K,i}$ and $s_{H,i}$ are the respective (time-invariant) saving rates for physical and human capital and dots above variables denote time derivatives. These assumptions imply that the steady-state value of output per effective worker is:

$$y^E_{i,\infty} = \left(\frac{s^{\alpha}_{K,i} s^{\phi}_{H,i}}{\left(n_i + g + \delta\right)^{\alpha+\phi}} \right)^{\frac{1}{1-\alpha-\phi}}, \tag{24.7}$$

giving a cross-country growth regression of the form:

$$\begin{aligned} \gamma_i = {} & g + \beta \log y_{i,0} + \beta \frac{\alpha+\phi}{1-\alpha-\phi} \log\left(n_i + g + \delta\right) \\ & - \beta \frac{\alpha}{1-\alpha-\phi} \log s_{K,i} - \beta \frac{\phi}{1-\alpha-\phi} \log s_{H,i} - \beta \log A_{i,0} + \upsilon_i. \end{aligned} \tag{24.8}$$

Mankiw *et al.* argue that initial efficiency $A_{i,0}$ should be interpreted as reflecting not just technology, which they assume to be constant across countries, but also country-specific influences such as resource endowments, climate and institutions, assumed to vary randomly in the sense that $\log A_{i,0} = \log A + e_i$, where

e_i is a country-specific shock that is distributed independently of the explanatory variables.[2] Substitution into (24.8) and defining $\varepsilon_i = \upsilon_i - \beta e_i$ gives the regression:

$$\gamma_i = g - \beta \log A + \beta \log y_{i,0} + \beta \frac{\alpha + \phi}{1 - \alpha - \phi} \log (n_i + g + \delta) - \beta \frac{\alpha}{1 - \alpha - \phi} \log s_{K,i} - \beta \frac{\phi}{1 - \alpha - \phi} \log s_{H,i} + \varepsilon_i. \quad (24.9)$$

Note an appealing feature of this regression: although the role of initial income is predicated on diminishing returns to capital, the regression can be estimated without using capital stock data. The measurement of capital stocks, especially for developing countries, is fraught with problems, as discussed in Pritchett (2000b). The specification derived by Mankiw *et al.* (1992) neatly sidesteps some of these problems.

After assuming that $g + \delta = .05$ (based on data from the US and other economies), Mankiw *et al.* use data from 98 countries over the period 1960–85 to obtain estimates of $\hat{\beta} = -.299$ (implying an estimated λ of 0.0142), $\hat{\alpha} = .48$ and $\hat{\phi} = .23$. They are unable to reject the parameter restriction, implicit in (24.9), that the final three slope coefficients sum to zero.

There are many extensions to this "augmented" Solow model that can be characterized as adding control variables, Z_i, to the regression and understood as modeling heterogeneneity in the level of technology at a given instant. In effect, the $g_i - \beta \log A_{i,0}$ terms in (24.4) are replaced with $g - \beta \log A + \pi Z_i - \beta e_i$, giving the regression:

$$\gamma_i = g - \beta \log A + \beta \log y_{i,0} + \beta \frac{\alpha + \phi}{1 - \alpha - \phi} \log (n_i + g + \delta) - \beta \frac{\alpha}{1 - \alpha - \phi} \log s_{K,i} - \beta \frac{\phi}{1 - \alpha - \phi} \log s_{H,i} + \pi Z_i + \varepsilon_i. \quad (24.10)$$

Note that (24.10) does not identify whether the Z_i are correlated with steady-state growth g_i or the initial technology term $A_{i,0}$, so a believer in a common long-run growth rate will not be dissuaded by the finding that particular choices of Z_i help predict growth beyond the Solow regressors. The attribution of the predictive content of Z_i to technology levels versus steady-state growth must largely depend on a researcher's prior beliefs about the long-run process driving the diffusion of technology. It seems plausible, however, that the controls Z_i may sometimes be associated with differences in efficiency growth g_i, rather than simply explaining differences in initial technology levels. Even if all countries have the same rate of technical progress in the long run, that assumption is somewhat implausible over a sample period as short as 20 or 30 years.

The canonical growth regression can be understood as a version of (24.10) in which the embedded parameter restrictions are ignored. A generic representation of the regression is:

$$\gamma_i = \beta \log y_{i,0} + \psi X_i + \pi Z_i + \varepsilon_i, \quad (24.11)$$

where the vector X_i contains a constant, $\log(n_i + g + \delta)$, $\log s_{K,i}$ and $\log s_{H,i}$. The variables spanned by $\log y_{i,0}$ and X_i thus represent the growth determinants suggested by the Solow model, whereas the vector Z_i represents growth determinants that lie outside that model.[3] The distinction between the Solow variables and Z_i is important in understanding the empirical literature. The Solow variables appear in many of the specifications estimated in the literature, reflecting the use of the Solow model as an organizing framework for growth analysis, but choices concerning which Z_i variables to include often vary greatly across studies. This clearly introduces a degree of arbitrariness which will be discussed later in this chapter.

Equation (24.11) represents the baseline for much of growth econometrics and these regressions are sometimes known as "Barro regressions," following the influential early contribution of Barro (1991).[4] This workhorse of empirical growth research has been generalized in a number of dimensions. Some of these extensions reflect the application of (24.11) to time series and panel data settings. Others reflect the use of more general production functions, or allow for nonlinearities and parameter heterogeneity, and we will discuss all these variants below.

24.3.3 Levels regressions

An alternative approach became especially popular after the work of Hall and Jones (1997, 1999). Their work sought to model the cross-section variation in the level of development, rather than the growth rate over a specific time interval. In other words, the dependent variable is the level of gross domestic product (GDP) per capita or GDP per worker, and there is no role for initial GDP on the right-hand side of the regression. In principle, this "levels regression" approach could be attractive for a number of reasons. It seems better suited to theories which emphasize long-run, fundamental sources of differences in development levels, such as geographic characteristics or the historical path taken by institutions. It may also give a direct answer to a key question of interest: "What is the long-run effect of a particular variable on the level of GDP per capita or GDP per worker?"

There are two important limitations of this approach. The first can be seen by contrasting it with the framework for modeling economic growth described above. In that framework, modeling the level of GDP per capita, without allowing for a conditional convergence effect, is akin to assuming that we observe the country in its long-run steady-state. Mankiw *et al.* (1992) initially adopted this approach: having derived the implications of the Solow model for the steady-state level of income, they estimated models with the level of income as the dependent variable. But they also noted that this approach is only valid if countries are distributed randomly around their steady-state positions, and so they moved on to estimate conditional convergence regressions, which did not require that strong assumption. Put differently, the levels regression approach risks omitting a relevant variable, a point that Bhattacharyya (2007) has recently emphasized.

The second limitation is that many candidate explanatory variables are likely to be endogenous to the level of income. A researcher could readily run a regression which "explains" income levels in terms of luxury car ownership, or the number of televisions, but it would be hard to interpret this as a meaningful explanation

of differences in development levels. The same point holds for variables such as institutions or the extent of corruption, where the quality of institutions, and the nature of social norms, may well be partly a function of the level of development. The standard response in the literature has been to use instrumental variables, with Frankel and Romer (1999), Hall and Jones (1999) and Acemoglu, Johnson and Robinson (2001) as three particularly well-known and influential examples. This approach is potentially informative, and has greater claims to identify causal effects than much other work. But it is also open to a range of important criticisms that we will discuss in detail in section 24.6.

Some of these criticisms could be avoided by estimating models in which initial income appears on the right-hand side. In that case, the empirical model may still be used to identify the long-run impact of institutions on the level of development. Recall that in a conditional convergence regression, the explanatory variables are not necessarily explaining long-run growth, but instead determine the long-run steady-state position that countries are converging towards. Put differently, imagine that the hypothesis of interest is the effect of institutional quality on long-run income levels. If we take two countries with the same initial level of income, the country with better institutions should grow more quickly over a given time interval. This is because it must be further below its steady-state growth path; otherwise, its better institutions would not be consistent with initial income levels that are the same.

Hence, growth regressions are often best seen as models of the height of the balanced growth path – that is, as models of long-run level effects. This point is perhaps most easily understood by considering how the analysis in Mankiw *et al.* (1992) would be adapted to include geographical characteristics or measures of institutional quality. In either case, the extension is straightforward, and the growth regression framework can be retained. These points suggest that some of the arguments usually advanced in favour of levels regressions are potentially misguided, and that the conditional convergence regression still has much to recommend it. Based on arguments like these, Bhattacharyya (2004) is an example of a study which revisits the evidence on institutions and development using a conditional convergence specification, rather than a levels regression. One remaining issue concerns whether the convergence specification can identify long-run effects with sufficient precision for the approach to be informative.

24.3.4 Interpreting errors in growth regressions

The development of the relationship between cross-country growth regressions and neoclassical growth theories in section 24.3.2 illustrates the practice, common in the literature, of deriving a deterministic growth relationship and then appending an error term in an *ad hoc* way to capture all aspects of the growth process omitted from the model. One problem with this practice is that some types of errors often have important implications for the asymptotic behavior of the estimator used in the subsequent empirical analysis. Binder and Pesaran (1999) conduct an exhaustive study of this question and conclude, *inter alia*, that if one generalizes the assumption of a constant rate of technical change so that technical change

follows a random walk, the induced non-stationarity in many of the levels series raises attendant unit root questions.

Beyond such issues of asymptotics, the *ad hoc* addition of regression errors described above leaves unanswered the question of the substantive economic assumptions implicitly made by a researcher. Brock and Durlauf (2001a) address this issue using the concept of "exchangeability" and many criticisms of growth regressions can be interpreted as claims that exchangeability has been violated. Loosely, their argument is that researchers working with regressions such as (24.11) typically think of the errors ε_i as interchangeable across observations, so that different patterns of realized errors would be equally likely to be observed if the realizations were permuted across countries. That is, the information available to a researcher about the countries is not informative about the error terms.

This idea can be formalized as F-conditional exchangeability, defined as:

$$\mu\left(\varepsilon_1 = a_1, \ldots, \varepsilon_N = a_N \,|F_1 \ldots F_N\right) = \mu\left(\varepsilon_{\rho(1)} = a_1, \ldots, \varepsilon_{\rho(N)} = a_N \,|F_1 \ldots F_N\right), \tag{24.12}$$

where, for each observation i, F_i is the associated information set available to the researcher and $\rho()$ is an operator that permutes the N indices. In the growth context, F_i may include knowledge of a country's history or culture as well as any more purely "economic" variables that are known. Omitted regressors then, for example, induce exchangeability violations as these regressors are elements of F_i. Parameter heterogeneity similarly leads to non-exchangeability.

Brock and Durlauf argue that exchangeability can be an organizing principle to connect substantive social science knowledge with the error structure. This suggests that it would be good empirical practice if researchers were to question whether or not the errors in their model are genuinely exchangeable and, if not, to determine whether the violation invalidates the purposes for which the regression is being used. As subject-specific knowledge is needed to evaluate the plausibility of exchangeability: this cannot be done in an algorithmic fashion, but instead requires judgments by the analyst.[5]

24.4 Statistical models of the growth process

Although the initial focus of empirical work in this field was the convergence hypothesis, the primary focus of more recent work has been the identification of potential growth determinants. This work may be divided into three main categories, which we discuss in turn in the next three subsections. Section 24.4.1 discusses the analysis of whether specific determinants affect growth, focusing on alternative ways to address the uncertainty about which explanatory variables should be included in a model. Section 24.4.2 explores methods to account for parameter heterogeneity and summarizes some of the relevant evidence. Section 24.4.3 focuses on the analysis of nonlinearities and multiple regimes in the growth process. Models of poverty traps and endogenous growth are often highly nonlinear, or associated with multiple steady-states in the growth process,

with important implications for econometric practice. Observe that in each case, while the associated analyses are often motivated by formal theories, operationally they represent efforts to develop statistical growth models that are consistent with particular specification tests.

24.4.1 Specifying explanatory variables in growth regressions

The first point to emphasize is the sheer number of growth determinants that have been proposed; the number of potential growth determinants now approaches the number of countries available. The table in Appendix B of Durlauf *et al.* (2005) lists many of them, with references to studies that represent either the first use of the variable or an especially well-known use of the variable. That table contains 145 different regressors, the vast majority of which have been found to be significant at conventional levels in at least one study. One reason why so many alternative variables have been identified is due to questions of measurement. For example, even given a specific claim that political freedom might affect growth, there could be many ways to measure such freedoms. But even taking this into account, the multiplicity of possible theories is striking. Durlauf *et al.* organize the empirical literature into 43 distinct growth "theories" (that is, conceptually distinct growth determinants) and it would not be difficult to add further examples.

Moreover, this list does not consider interactions between variables or nonlinear transformations of variables, even though both are often used. The range of possibilities hints at one of the fundamental problems with empirical growth research: a lack of consensus on which growth determinants ought to be included in a statistical model. In this section, we discuss attempts to address this question and to limit the degree of arbitrariness otherwise present.

To fix ideas, let S_i denote the set of regressors always included by the researcher while R_i denotes the set of additional candidate regressors, so that:

$$\gamma_i = \psi S_i + \pi R_i + \varepsilon_i, \tag{24.13}$$

is the putative growth regression. The inclusion of a variable in S does not mean the researcher is certain that it influences growth, only that it is to be included in all models considered. If one takes the regressors that comprise R as fixed, then statements about elements of ψ are straightforward. A frequentist approach to inference will compute an estimate of the parameter ψ with an associated distribution that depends on the data-generating process (DGP). Bayesians would compute a posterior probability density of ψ given the researcher's prior, the data, and the assumption that the linear model is correctly specified. Designating the available data as D and a particular model as m, this posterior may be written as $\mu(\psi | D, m)$.

While extant growth theories can be used to identify candidates for R, the fundamental problem in developing statistical statements about either $\hat{\psi}$ or $\mu(\psi | D, m)$ is that there do not exist good theoretical reasons to favour one particular model and exclude others. As Brock and Durlauf (2001a) point out, growth theories are typically "open-ended" in the sense that different theories are often compatible with one another, rather than mutually exclusive. For example, a theory that institutions matter is not logically inconsistent with a theory that emphasizes the role

of geographic characteristics. A set of K potential growth theories, all of which are logically compatible with combinations of one another, implies that there exist $2^K - 1$ potential specifications of the form (24.13), each one of which corresponds to a particular combination of theories.

One approach to this model uncertainty is to examine robustness with respect to variation in the model specification. This is the idea behind the classic Levine and Renelt (1992) paper which, building on Leamer (1978, 1983) and Leamer and Leonard (1983), used extreme bounds analysis to assess growth determinants. For a model $m \in M$ within the space of possible models, the growth process is specified as:

$$\gamma_i = \psi_m S_i + \pi_m R_{i,m} + \varepsilon_{i,m}, \tag{24.14}$$

where the m subscripts reflect the model specific nature of the parameters and associated errors. Let $\hat{\psi}_m$ denote the point estimate of ψ for every $m \in M$ and let the vector S be composed of a variable of interest, s_I, and other variables which are included in all the specifications considered. Motivated by Leamer (1983), Levine and Renelt (1992) use the following rule: there is strong evidence that s_I affects growth if (and only if) the sign of the associated regression coefficient $\hat{\psi}_{I,m}$ is constant and the coefficient estimate is statistically significant across all $m \in M$. In their analysis, the vector S includes the constant term, initial income, the investment share of GDP, the secondary school enrollment rate, and the population growth rate, as suggested by the augmented Solow model. The possible models are distinguished by alternative combinations of between one and three variables, taken from a set of seven; these correspond to alternative choices of $R_{i,m}$. Applying their rule, they conclude that the only robust growth determinants are initial income and the share of investment in GDP.

These two findings are confirmed in subsequent work by Kalaitzidakis, Mamuneas and Stengos (2000), who allow for potential nonlinearities in (24.14) by considering models of the form:

$$\gamma_i = \psi_m S_i + f_m\left(\pi R_{i,m}\right) + \varepsilon_{i,m}, \tag{24.15}$$

where $f(\cdot)$ is a function allowed to vary across specifications of R. Like Levine and Renelt, they find that initial income and physical capital investment rates are robust determinants of growth, but also find that inflation volatility and a measure of exchange rate distortions are robust, providing an example of how failing to account for nonlinearity in one set of variables can mask the importance of another. A related exercise by Minier (2007) allows for nonlinearities in a parametric way (including squared and interaction terms) and also examines what happens when the Levine–Renelt sample is restricted to the lowest 75% of countries when ranked by initial income, which broadly corresponds to a sample of developing countries. She shows that a wider range of variables is found to be robust, including several fiscal indicators that Levine and Renelt had classed as fragile. An open question here is the extent to which certain kinds of nonlinearity, such as quadratic terms, may be highly sensitive to outliers. Temple (2000b) discussed how an extreme bounds analysis could be combined with robust estimation methods.

More fundamentally, as explained in Brock and Durlauf (2001a) and Brock, Durlauf and West (2003), even a sophisticated extreme bounds approach is somewhat problematic when viewed from a decision-theoretic perspective. Suppose, for example, that interest in ψ_l derives from country i's consideration of a policy change in which a variable $s_{i,l}$ will be increased by one unit. Let $El\left(s_{i,l}, m\right)$ represent the policy maker's expected loss associated with a policy indicator in country i, and suppose that she is only interested in the case where the increase in the indicator will raise growth, so that the policy change is sensible only if $\hat{\psi}_{l,m} > 0$. One can approximate a t-statistic rule, requiring that the coefficient estimate for s_l be statistically significant, as:

$$El\left(s_{i,l}+1, m\right) - El\left(s_{i,l}, m\right) = \left(\hat{\psi}_{l,m} - 2sd\left(\hat{\psi}_{l,m}\right)\right) > 0, \tag{24.16}$$

where $sd\left(\hat{\psi}_{l,m}\right)$ is the estimate of the standard deviation associated with $\hat{\psi}_{l,m}$ and the required significance level is assumed to correspond to a t-statistic of 2. As odd as it seems, this is the form of the loss function implicitly assumed when t-statistics are used to make policy decisions. Extreme bounds analysis requires that (24.16) holds for every $m \in M$ so that $El\left(s_{i,l}\right)$, the expected loss for a policy maker when conditioning only on the policy variable, must have the property that:

$$El\left(s_{i,l}+1\right) - El\left(s_{i,l}\right) > 0 \Rightarrow El\left(s_{i,l}+1, m\right) - El\left(s_{i,l}, m\right) > 0 \ \forall m, \tag{24.17}$$

which means that the policy maker must have minimax preferences with respect to model uncertainty. That is, she will make the policy change only if it yields a positive expected payoff under the least favorable model in M. Such extreme risk aversion seems hard to justify, notwithstanding claims that individuals do indeed assess uncertainty about models in different ways to the uncertainty that arises within models.[6]

Even when one moves away from decision-theoretic considerations, extreme bounds analysis encounters substantial problems.[7] One practical criticism is developed carefully in Hoover and Perez (2004). Using simulations, they show that an extreme bounds analysis can easily lead to the conclusion that many growth determinants are fragile even when they are part of the DGP. Intuitively, adding more and more irrelevant variables to such an analysis always has the potential to overturn any specific finding, including relationships that are part of the true DGP. Hoover and Perez also find that the procedure has poor power properties, in the sense that some regressors that do not matter may spuriously appear to be robust. The first concern, that extreme bounds analysis is excessively conservative, had already led Sala-i-Martin (1997a, 1997b) to propose less demanding criteria. These were justified in essentially heuristic terms, with their statistical properties remaining somewhat uncertain. Again using simulations, Hoover and Perez (2004) found that these newer robustness criteria, although less demanding, could again have poor size properties, in the sense that "true" growth determinants are still likely to fail to be identified.

Dissatisfaction with extreme bounds analysis and its close relatives has led some authors to advocate more systematic methods for model selection. Hendry and Krolzig (2004) and Hoover and Perez (2004) both employ the general-to-specific modeling methodologies associated with the research program of David Hendry, in order to select one version of (24.13) out of the model space. Essentially, these papers use algorithms which select a particular regression model from a space of possible models, through comparisons based on a set of statistical tests. The attractiveness of this approach is closely linked to that of the broader Hendry research program (see Hendry, 1995). We do not provide an extended evaluation here, but note that relying solely on model selection procedures does not possess a clear decision-theoretic justification, which makes it harder to evaluate the output of the procedure in terms of the objectives of a researcher. That said, automated procedures have the important virtue that they can identify sets of models that are well supported by the available data, and may be especially useful as a preliminary step in model-building.

In our judgment, the most promising approach to model uncertainty is the use of model averaging in the Bayesian tradition, and especially the methods developed by Adrian Raftery and co-authors (for example, Raftery, Madigan and Hoeting, 1997). Versions of these methods have been applied to growth data in Brock and Durlauf (2001a), Brock *et al.* (2003), Ciccone and Jarocinski (2007), Durlauf, Kourtellos and Tan (2008), Fernandez, Ley and Steel (2001a), Masanjala and Papageorgiou (2005) and Sala-i-Martin, Doppelhofer and Miller (2004), among others. The basic idea is to treat the identity of the "true" growth model as an unobservable variable about which the researcher is inevitably uncertain.[8] In order to account for this, each element m in the model space M is associated with a posterior model probability $\mu(m|D)$. By Bayes' rule,

$$\mu(m|D) \propto \mu(D|m)\,\mu(m), \tag{24.18}$$

where $\mu(D|m)$ is the likelihood of the data given the model and $\mu(m)$ is the prior model probability. These model probabilities are used to eliminate the dependence of parameter analysis on a specific model. For frequentist estimates, averaging is done across the model-specific estimates $\hat{\psi}_m$ to produce an estimate $\hat{\psi}$ via:

$$\hat{\psi} = \sum_m \hat{\psi}_m \mu(m|D), \tag{24.19}$$

whereas, in the Bayesian context, the dependence of the posterior probability measure of the parameter of interest, $\mu(\psi|D,m)$, on the model choice is eliminated via standard conditional probability arguments, that is:

$$\mu(\psi|D) = \sum_{m\in M} \mu(\psi|D,m)\mu(m|D). \tag{24.20}$$

Brock *et al.* (2003) argue that the strategy of constructing posterior probabilities that are not model-dependent is especially appropriate when the objective of the statistical exercise is to evaluate alternative policy questions, such as whether to

change an element of S_i by one unit. This assumes that the ultimate goal of the exercise is to estimate a parameter, rather than to identify the "best" growth model.

Bayesian model averaging is still relatively new, and many practical questions arise. The implementation of the approach in economics has often closely followed the early work by Raftery (1995) and Raftery *et al.* (1997). One issue concerns the specification of priors on parameters within a model. In line with Raftery's approach, Brock and Durlauf (2001a), Brock *et al.* (2003), and Sala-i-Martin *et al.* (2004) assume a diffuse prior on the model specific coefficients. This has the advantage that, when the errors are normal with known variance, the posterior expected value of ψ, conditional on the data D and model m, is the ordinary least squares (OLS) estimator $\hat{\psi}_m$. One disadvantage of this approach is that, since the diffuse prior on the regression parameters is improper, one has to be careful that the posterior model probabilities associated with the prior are interpretable. But as long as the posterior model probabilities include an appropriate penalty for model complexity, we do not see any conceptual problem in interpreting this approach as strictly Bayesian. Brock and Durlauf (2001a), Brock *et al.* (2003), and Sala-i-Martin *et al.* (2004) all compute posterior model probabilities using Bayesian information criterion (BIC)-adjusted likelihoods. Fernandez *et al.* (2001a) and Masanjala and Papageorgiou (2005) employ proper priors and therefore avoid any such concerns.[9] So far there is only limited evidence that use of improper versus proper priors has important consequences in practice. Masanjala and Papageorgiou compare results using proper priors with the improper priors we have described, and find that the choice is unimportant in their application. Arguably the most important evidence that the conventional approach is problematic can be found in Ciccone and Jarocinski (2007), and we will discuss their study in detail at the end of this section.

Other work has examined the effects of different proper priors. Letting Z_i denote $\left(S_i, R_{i,m}\right)$ and $\eta_m = \begin{pmatrix} \psi_m \\ \pi_m \end{pmatrix}$, Fernandez *et al.* (2001b) propose the use of the Zellner (1986) g-prior:

$$\mu\left(\eta_m \left| m, \sigma_{\varepsilon,m}\right.\right) \propto N\left(0, \sigma^2_{\varepsilon,m}\left(gZ'_mZ_m\right)^{-1}\right), \tag{24.21}$$

with $g = 1/\max\left\{n, k_m^2\right\}$, n denoting the number of observations and k_m denoting the number of regressors in model m. Ley and Steel (2008) extend this analysis by considering the performance of this within-model prior for different model space priors; the model space priors all assume that each variable appears in the true model with equal probability and that variable inclusions exhibit conditional independence as described above. They conclude that, for growth contexts, models of interest typically involve a sufficiently large number of growth determinants such that $k_m^2 > n$, so that $g = k_m^{-2}$. They additionally argue that the frequentist/Bayesian hybrid employed by Sala-i-Martin *et al.* (2004) is well approximated by the $g = n^{-1}$ case and therefore may be criticized on the grounds that this value of g is generally inappropriate. A different approach to within-model parameter priors is proposed by Eicher, Papageorgiou and Raftery (2008). They suggest the use of what Kass and

Wasserman (1995) called a unit information prior; the prior is implicitly defined to ensure that posterior model probabilities are well approximated by the Bayesian information or Schwarz criterion. This paper concludes that the combination of a unit information prior for within-model probabilities and a uniform prior across models produces superior performance against a range of alternatives.

A distinct approach to within-model priors is developed by Magnus, Powell and Prufer (2008), who employ the distinction between variables that are included in all models, S_i, and variables that are model-specific, $R_{i,m}$. For each model they propose estimating a regression based on S_i and $e_{i,m}$, the residual of $R_{i,m}$ when projected against S_i. A Laplace prior is assigned to the $e_{i,m}$ parameters, which corresponds to the idea that a researcher is ignorant as to whether the absolute value of the t-statistic (computed at population values) is greater than 1. They argue that this prior has the advantage that it is not dependent on an arbitrary choice of a parameter, such as occurs because of the need to set g in (24.21).

There is also no consensus on the appropriate specification of the prior model probabilities $\mu(m)$. In the model averaging literature, the usual assumption has been to assign equal prior probabilities to all models in M. This corresponds to assuming that the prior probability that a given variable appears in the "true" model is 0.5 and that the probability that one variable appears in the model is independent of whether others appear. Sala-i-Martin *et al.* (2004) consider modifications of this prior, in which the probability that a given variable appears in the true model is $p < 0.5$ while preserving the assumption that the inclusion probabilities for each variable are independent. The Sala-i-Martin *et al.* probabilities may be written as:

$$p^{\#(m)}\left(1-p\right)^{k-\#(m)}, \tag{24.22}$$

where $\#(m)$ denotes the number of regressors in model m. This prior can be generalized by treating (24.21) as the conditional probability of a model given p and then assigning a prior to p, an idea developed in Brown, Vannucci and Fearn (1998) and applied to growth regressions by Ley and Steel (2008).

The conditional independence assumption may be unappealing given collinearity between regressors. One reason for this is that the different growth regressors are sometimes included as proxies for a common growth theory. Durlauf *et al.* (2008) address this by using dilution priors, due to George (1999), which downweight models that contain potentially "redundant" variables, as when a dataset contains multiple proxies for the same underlying economic concept. This is done by multiplying (24.21) by the determinant of the correlation matrix for the included variables in a given model, which reweights model probabilities so as to downweight those with redundant variables.

The issue of redundant variables is part of a wider set of conceptual problems which arise when a researcher uses a prior which treats all models as equally likely. Brock and Durlauf (2001a), Brock *et al.* (2003) and Durlauf *et al.* (2008) criticize the widespread use of prior model probabilities which assume that the inclusion of one variable should be independent of the inclusion of another. The conceptual problem is analogous to the "red bus/blue bus" problem in discrete choice theory.

Clearly some regressors are similar, such as alternative measures of trade openness, whereas other regressors are quite disparate, such as measures of geography versus institutional quality.

To address this, Brock *et al.* (2003) propose a tree structure to organize model uncertainty for linear growth models. First, they argue that growth models suffer from theory uncertainty. Hence, one can identify alternative classes of models based on what growth theories are included. Second, for each specification of a body of theories to be embedded, they argue there is specification uncertainty. A given set of theories requires determining whether the theories interact, whether they are subject to threshold effects or other types of nonlinearity, and so on. Third, for each theory and model specification, there is measurement uncertainty; to say that climate affects growth does not specify the relevant empirical proxies, such as the number of sunny days or average temperature. Finally, each choice of theory, specification and measurement is argued to suffer from heterogeneity uncertainty, which means that it is unclear which sub-sets of countries obey a common linear model. Brock *et al.* (2003) argue that one should assign priors that account for the interdependence implied by this structure in assigning model probabilities.

We now briefly summarize some of the main findings of model averaging studies. Sala-i-Martin *et al.* (2004) find that four variables have posterior model inclusion probabilities above 0.9, namely initial income, the fraction of GDP from mining, the number of years the economy has been open,[10] and the fraction of the population following Confucianism. Fernandez *et al.* (2001a) also find that four variables have posterior model inclusion probabilities above 0.9, substantially overlapping with Sala-i-Martin *et al.* (2004) despite working with a different model space: initial income, the fraction of the population following Confucianism, life expectancy, and the share of equipment investment in GDP.[11] These findings appear to be somewhat dependent on details of the way in which priors are assigned within and across the model space.[12] Eicher *et al.* (2008) work with the same dataset as Fernandez *et al.* (2001a) and find that the combination of a unit information within-model prior and a uniform model space prior generates 16 different growth variables whose posterior inclusion probabilities are 0.9 or greater. Interestingly, if one reduces the variable inclusion probability so that the expected number of variables in a model is seven (which is the prior used by Sala-i-Martin *et al.*, 2004), only four variables have posterior inclusion probabilities above 0.9; these are the same as those identified by Fernandez *et al.* (2001a).

Durlauf *et al.* (2008) have applied model averaging to an unbalanced panel based on three time periods spanning 1965–94, with a focus on evaluating the robustness of various fundamental growth determinants. They confirm the importance of initial income and investment, and also find a role for population growth and two macroeconomic variables, the share of government consumption (net of defense and education spending) in GDP and the rate of inflation. Their approach differs from those above in that the conventional BIC approximation is applied in the context of two-stage least squares (2SLS), rather than OLS. The development of a rigorous combination of model averaging and instrumental variable methods is an interesting area for further work.

In other applications, Brock and Durlauf (2001a) and Masanjala and Papageorgiou (2005) have employed model averaging to study the reason for the poor growth performance of sub-Saharan Africa. Both papers identify some important differences between Africa and the rest of the world in terms of the relevant growth determinants. The study of Brock *et al.* (2003) takes this idea further by exploring the use of growth regressions in the evaluation of policy recommendations. Specifically, the paper assesses the question of whether a policy maker should favor a reduction of tariffs for sub-Saharan African countries. The analysis assumes that the policy maker has a specific set of mean-variance preferences with respect to the effects of a change in current policies. At first glance, the analysis supports a tariff reduction: it shows that a policy maker with these preferences should be in favor, unless the policy maker has a strong prior that sub-Saharan African countries obey a growth process distinct from the rest of the world. In the latter case, there is sufficient uncertainty about the relationship between tariffs and growth for African countries that a change in trade policy cannot be justified. In statistical terms, this result is a consequence of the strong prior belief in the possibility of heterogeneity. The prior implies that the growth experiences of non-African countries will have little effect on the precision of estimates of marginal effects that are constructed using data for sub-Saharan Africa.

To date, perhaps the most important critique of the Bayesian approach, at least as applied to growth data, is that developed in Ciccone and Jarocinski (2007). Their central point is that agnostic empirical approaches, such as model averaging, appear to be sensitive to modest changes in the data. One of their examples is based on Sala-i-Martin *et al.* (2004) and its application of model averaging to 1960–96 growth determinants, using Penn World Table (PWT) version 6.0 data for output levels and growth rates. When Ciccone and Jarocinski update those results with the revised data provided in PWT version 6.1, they find that the two versions of the PWT lead to disagreement on 13 of 25 determinants of 1960–96 growth that emerge using one version of the data or the other. When they carry out a further exercise, now using the latest PWT 6.2 data for 1960–96, they again find scope for considerable disagreement. They illustrate the potential concerns using a Monte Carlo study, which confirm that the Bayesian approach can be sensitive to data revisions that are modest by the historical standards of revisions to the PWT. Their results imply that a priority for future research should be the development of methods which are less sensitive to small changes in the data, perhaps by reformulating the priors on model coefficients or explicitly allowing for mismeasured data. In this respect, it is worth noting that the growth literature has made relatively little use of the methods for simultaneous model selection and outlier identification that were developed by Hoeting, Raftery and Madigan (1996).

24.4.2 Parameter heterogeneity

The estimation of linear growth models, at best an approximation to the true law of motion of an economy, has generated unease about the statistical foundations of the exercise. It is difficult to sustain the claim that the data for very

different countries are realizations of a common DGP, and many of the modeling assumptions and procedures of the empirical growth literature can appear arbitrary. In the well-known question posed by Harberger (1987): "What do Thailand, the Dominican Republic, Zimbabwe, Greece and Bolivia have in common that merits their being put in the same regression analysis?"

The extent to which this objection is fundamental remains an open question, but there seems to be agreement that, when studying growth, it will be difficult to recover a DGP even if one exists, and the prospects for recovering causal effects are clearly weak. The shortcomings of the relevant economic theory, as well as those of the data and econometric analysis, are considerable. Those who will be satisfied only with the specification and estimation of a structural model, in which parameters are either "deep" and invariant to policy, or correspond to precisely defined causal effects within a coherent theoretical framework, are bound to be disappointed. The more appropriate goal for the growth literature is less ambitious: investigating whether or not particular hypotheses have any support in the data and whether it is possible to rule out some possible claims about the world, or at least shift the burden of proof from one side of a debate to another. In practice, growth researchers are looking for patterns and systematic tendencies that, in combination with historical analysis, case studies, and relevant theoretical models, can increase our understanding of the growth process. A related goal, more difficult than it may appear at first sight, is to communicate the degree of support for any patterns identified by the researcher.

The issue raised by Harberger is essentially that of parameter heterogeneity. Why should we expect disparate countries to lie on a common regression surface? Of course, this criticism could be made of most empirical work in social science: whether the data points reflect the actions and characteristics of individuals and firms, or the aggregations of their choices that are used in macroeconometrics. It is the small sample sizes available to growth researchers that limit the scope for addressing this problem, and mean that Harberger's remark retains some force. In other contexts, an appropriate response would be to use a model that has sufficient flexibility to be a good approximation. But this approach will often be fragile when the sample is rarely greater than 100 observations, as is the case when studying economic growth using cross-country data.

If parameter heterogeneity is present, the consequences are potentially serious, except in the special case where the slope parameters vary randomly across units, and are distributed independently of the variables in the regression and the disturbances. In this case, the coefficient estimate should be an unbiased estimate of the mean of the parameter distribution. However, the assumption of independence will often be unwarranted. For example, when estimating the relationship between growth and investment, the marginal effect of investment will almost certainly be correlated with aspects of the economic environment that should also be included in the regression, such as political stability or the protection of property rights.

Some researchers have allowed greater flexibility in the functional form of their models, often beginning with the canonical Solow regression which, for

comparison purposes, we restate:

$$\gamma_i = k + \beta \log y_{i,0} + \pi_n \log (n_i + g + \delta) + \pi_K \log s_{K,i} + \pi_H \log s_{H,i} + \varepsilon_i. \quad (24.23)$$

For example, Liu and Stengos (1999) estimate a semiparametric partially linear version of this model, namely:

$$\gamma_i = k + f_\beta(\log y_{i,0}) + \pi_n \log (n_i + g + \delta) + \pi_K \log s_{K,i} + f_{\pi_H}(\log s_{H,i}) + \varepsilon_i, \quad (24.24)$$

where $f_\beta(\cdot)$ and $f_{\pi_H}(\cdot)$ are arbitrary functions except for variance smoothness requirements. They find that the value of $f_\beta(\log y_{i,0})$ is only negative when initial per capita income exceeds about \$1,800; below that level, there is less evidence for the conditional convergence effect predicted by the Solow model. Banerjee and Duflo (2003) use a similar approach to study nonlinearity in the relationship between changes in inequality and growth, estimating a version of (24.24) where Solow-type variables and some additional variables enter in a linear way, supplemented by a nonlinear function $f_G(G_{i,t} - G_{i,t-5})$, where $G_{i,t}$ is the Gini coefficient.

Using an alternative method, Durlauf, Kourtellos and Minkin (2001) estimate a version of the augmented Solow model that allows the parameters to vary across countries as functions of initial income:

$$\begin{aligned}\gamma_i = {} & k(y_{i,0}) + \beta(y_{i,0}) \log y_{i,0} + \pi_n(y_{i,0}) \log (n_i + \delta + g) \\ & + \pi_K(y_{i,0}) \log s_{K,i} + \pi_H(y_{i,0}) \log s_{H,i} + \varepsilon_i. \end{aligned} \quad (24.25)$$

Hence each initial income level defines a distinct Solow regression, and thereby shifts the emphasis away from nonlinearity and towards parameter heterogeneity. This study indicates considerable parameter heterogeneity, especially among the poorer countries, and confirms the Liu and Stengos (1999) finding that $\beta(y_{i,0})$ is positive for low $y_{i,0}$ values and negative for higher ones. Durlauf *et al.* (2001) also find that $\pi_K(y_{i,0})$ fluctuates greatly over the range of $y_{i,0}$ values in their sample. The extension by Kourtellos (2003a) uncovers systematic heterogeneity in the parameters on initial literacy and initial life expectancy. A varying coefficient approach is also employed in Mamuneas, Savvides and Stengos (2006), who consider a model in which the coefficient on human capital is allowed to vary with the level of human capital and a measure of trade openness. Constancy of the human capital coefficient is rejected across a range of specifications.

At a minimum, it makes sense for empirical researchers to test for neglected parameter heterogeneity, either using interaction terms or by carrying out diagnostic tests. As an alternative, some authors have used panel data to identify parameter heterogeneity without the imposition of a functional relationship between parameters and various observable variables. An important early contribution along these lines is Canova and Marcet (1995). Defining $s_{i,t}$ as the logarithm of the ratio of a country's per capita income to the time t international aggregate value, and using data either on the regions of Europe or 17 western European countries, they

estimate models of the form:

$$s_{i,t} = a_i + \rho_i s_{i,t-1} + \varepsilon_{i,t}. \tag{24.26}$$

The long-run forecast of $s_{i,t}$ is given by $\frac{a_i}{1-\rho_i}$, with $1 - \rho_i$ being the rate of convergence towards that value. Restricting the parameters a_i and ρ_i to be constant across i gives a standard β-convergence test and yields an estimated annual rate of convergence of approximately 2%, similar to other findings in the literature. But allowing for heterogeneity in these parameters produces a "substantial" and statistically significant dispersion of the implied long-run $s_{i,t}$ forecasts. The positive correlation of those forecasts with the initial values of $s_{i,t}$ implies a dependence of long-run outcomes on initial conditions that contradicts the convergence hypothesis. For the country-level data, differences in initial conditions explain almost half the cross-sectional variation in long-run forecasts. This shows how key findings can be sensitive to the treatment of parameter heterogeneity, and we return to this issue when we discuss panel data models in section 24.5.

24.4.3 Nonlinearity and multiple regimes

We now discuss research that has attempted to disentangle the roles of heterogeneous structural characteristics and initial conditions in determining growth outcomes. These papers employ a variety of statistical methods, but there is considerable agreement in their findings. Many of them indicate the existence of convergence clubs even after accounting for the role of structural characteristics. We have discussed some of this work in our companion chapter on convergence (Chapter 23 in this volume), and here we concentrate on the wider implications of multiple regimes for the statistical methods that should be adopted.

One of the first contributions to this literature was Durlauf and Johnson (1995). They used classification and regression tree (CART) methods to search for nonlinearities.[13] More specifically, the CART procedure identifies sub-groups of countries that obey a common linear growth model based on the Solow variables. These sub-groups are identified by initial income and literacy; a typical sub-group l is defined by countries whose initial income lies within the interval $\vartheta_{l,y} \leq y_{i,0} < \bar{\vartheta}_{l,y}$ and whose literacy rate L_i lies in the interval $\vartheta_{l,L} \leq L_i < \bar{\vartheta}_{l,L}$. The number of sub-groups and the boundaries for the variable intervals that define them are chosen by an algorithm that trades off model complexity (the number of sub-groups) and goodness of fit. Because the procedure uses rules to sequentially split the data into finer and finer sub-groups, it organizes the data into a tree structure, where the branches of the tree ultimately divide the sample into groups of countries that follow distinct regimes.

Durlauf and Johnson (1995) also test the null hypothesis of a common growth regime against the alternative hypothesis of a growth process with multiple regimes. Taking Mankiw *et al.* (1992) as their starting point, and using income per capita and the literacy rate as possible threshold variables, Durlauf and Johnson reject the single regime model. This finding has been confirmed in subsequent research by Papageorgiou and Masanjala (2004). They estimate a version of the

Solow model that is based on a constant elasticity of substitution (CES) production function, building on Duffy and Papageorgiou (2000). By using the Hansen (2000) approach to sample splitting and threshold estimation, they find statistically significant evidence of thresholds in the data. The estimated thresholds divide the sample into four distinct growth regimes that are broadly consistent with those found by Durlauf and Johnson.[14] Relative to the regression tree approach, the Hansen methods have the significant advantage of allowing inference on the level of the estimated threshold.

Another closely related analysis is that of Tan (2004). He employs a procedure known as GUIDE (generalized, unbiased interaction detection and estimation), due to Loh (2002), to identify sub-groups of countries which obey a common growth model. Relative to CART, the GUIDE algorithm has two advantages. First, the algorithm explicitly looks for interactions between explanatory variables when identifying splits. Second, the penalties for model complexity are supplemented with some within-model testing, which reduces the tendency for CART procedures to produce an excessive number of splits in finite samples. Tan (2004) finds strong evidence that measures of institutional quality and ethnic fractionalization define convergence clubs across a wide range of countries. He also finds some evidence that geographic characteristics distinguish the growth process for sub-Saharan Africa from the rest of the world.

Further research has corroborated the evidence of multiple regimes using alternative statistical methods, including projection pursuit.[15] Desdoigts (1999) uses these methods to identify groups of countries with relatively homogeneous growth experiences based on the characteristics and initial conditions of each country. The idea is to find the orthogonal projections of the data into low dimensional spaces that best display some interesting feature of the data; this can be seen as a generalization of principal components analysis. When using principal components analysis, a researcher will typically retain only the components needed to account for "most" of the variation in the data. Similarly, in projection pursuit methods, a researcher will consider as many dimensions as needed to account for "most" of the clustering in the data. Some evidence of their utility can be found in Kourtellos (2003b). Unlike Desdoigts, Kourtellos uses projection pursuit to construct models of the growth process. Formally, he estimates models of the form:

$$\gamma_i = \sum_{l=1}^{L} f_l \left(y_{i,0}\beta_l + X_i\psi_l + Z_i\pi_l \right) + \varepsilon_i. \tag{24.27}$$

Each element in the summation represents a distinct projection. Kourtellos uncovers evidence of two steady-states, including one that corresponds to countries with low initial income and low initial human capital.

Another approach to multiple regimes is employed by Bloom, Canning and Sevilla (2003). This is based on the observation that if long-run outcomes are determined by fundamental forces alone, the relationship between exogenous variables and income levels ought to be unique. If initial conditions play a role there will be multiple relationships, one for each basin of attraction defined by the initial

conditions. If there are two (stochastic) steady-states, and large shocks are sufficiently infrequent,[16] the system will, under suitable regularity conditions, exhibit an invariant probability measure that can be described by a "reduced form" model in which the long-run behavior of $\log y_{i,t}$ depends only on the exogenous variables, m_i, such as:

$$\log y_{i,t} = \log y_1^* (m_i) + u_{1,i,t} \text{ with probability } p(m_i), \tag{24.28}$$

and:

$$\log y_{i,t} = \log y_2^* (m_i) + u_{2,i,t} \text{ with probability } 1 - p(m_i), \tag{24.29}$$

where $u_{1,i,t}$ and $u_{2,i,t}$ are independent, zero mean deviations from the steady-state log means $\log y_1^*(m_i)$ and $\log y_2^*(m_i)$ respectively, and $p(m_i)$ is the probability that country i is in the basin of attraction of the first of the two steady-states. From the perspective of the econometrician, $\log y_{i,t}$ thus obeys a mixture process. The two steady-states associated with (24.28) and (24.29) might be interpreted as a low-income regime or poverty trap, and a high-income or growth regime, respectively. Bloom *et al.* (2003) estimate a linear version of this model using 1985 income data from 152 countries, with the absolute latitude of the country as the fundamental exogenous variable. They are able to reject the null hypothesis of a single regime model in favor of the alternative of a model with two regimes: a high-income steady-state in which income is independent of absolute latitude, and a low-income ("agricultural") steady-state in which income is increasing in absolute latitude. In addition, the probability of being in the high-income steady-state is found to be increasing in absolute latitude.

Adding extra complexity to this model could well be constrained by the small number of countries available. More generally, the empirical investigation of multiple steady-states raises some complex problems for standard methods. One response is to draw more heavily on structural theoretical models as a framework for understanding the data, as in Graham and Temple (2006). Another possibility would be to exploit time series variation in a single country, in order to identify jumps from one equilibrium or steady state to another. But in either case, it is clear that these forms of analysis would have to proceed under strong assumptions, some of which will be difficult to test.

24.5 Time series methods, panel data and event studies

Our discussion now explores alternative ways of modeling growth: time series models, the use of panel data, and studies based on discrete "events" which draw on panel data methods. At the risk of stating the obvious, choices on research design involve significant trade-offs, which depend partly on statistical considerations and partly on the economic context. This means that attempts at universal prescriptions are misguided, and we will try to show the desirability of matching techniques to the economic question at hand. One example, to be discussed below, would be the choice between panel data methods and the estimation of separate

time series regressions for each country. The use of panel data is likely to increase efficiency and allow richer models to be estimated, but at the expense of potentially serious biases if the parameter homogeneity assumptions are incorrect. This trade-off between robustness and efficiency is another running theme of our survey. The scientific solution would be to base the choice of estimation method on a context-specific loss function, but this is clearly a difficult task, and in practice more subjective decisions are involved.

Section 24.5.1 examines the econometric issues that arise in the use of time series data to study growth, emphasizing some of the drawbacks of this approach. Section 24.5.2 discusses the many issues that arise when panel data are employed, an increasingly popular approach to growth questions. We consider the estimation of dynamic models in the presence of fixed effects, and alternatives to standard procedures. Section 24.5.3 describes another increasingly popular approach, namely the use of "event studies" to analyze growth behavior, based on studying responses to major events such as political reform or changes in trade policy.

24.5.1 Time series approaches

At first glance, the most natural way to understand growth would be to examine time series data for each country in isolation. In practice, however, a time series approach runs into substantial difficulties. One key constraint is the available data. For many developing countries, some of the most important data are only available on an annual basis, with limited coverage before the 1960s. Moreover, the listing of annual data in widely used sources and online databases can be misleading. For example, population figures are often based primarily on census data, while measures of average educational attainment are often constructed by interpolating between census observations using school enrollments. The true extent of information in the time series variation may be less than appears at first glance, and conventional standard errors will be misleading.

Some key growth determinants display relatively little time variation. Even where a variable appears to show significant variation, this may not correspond to the concept the researcher originally had in mind. An example would be political stability. Since Barro (1991), researchers have sometimes used the incidence of political revolutions and coups as a measure of political instability. The interpretation of such an index clearly varies depending on the length of the time period used to construct it. If the hypothesis of interest relates to underlying political uncertainty (say, the *ex ante* probability of a transfer of power) then time series observations on political instability would need to be averaged over a long time period. The variation in political instability at shorter horizons casts light on a different hypothesis, namely the direct impact of revolutions and coups, rather than on the effects of *ex ante* political uncertainty.

There are other significant problems with the time series approach. The hypotheses of most interest to growth theorists are mainly about the evolution of potential output, not deviations from potential output, whether business cycles or larger-scale output collapses. Since measured output is a noisy indicator of potential output, it is easy for the econometric modeling of a growth process to be

contaminated by short-run dynamics. These problems are likely to be even more serious in developing countries, where large slumps or crises are not uncommon, and output may deviate for long periods from any previous structural trend. As Pritchett (2000a) emphasizes, output often behaves very differently in developing countries compared to Organization for Economic Cooperation and Development (OECD) member countries, and a major collapse in output is not a rare event. There may be no underlying trend in the sense commonly understood, and conventional time series methods should be applied with caution.

The problem of short-run output instability extends further. It is easy to construct examples where the difference between observed output and potential output is correlated with variables that move up and down at high frequencies, with inflation being one obvious example (Temple, 2000a). At a minimum, this means that any time series or panel data analysis should distinguish carefully between short-run and long-run effects.

Nevertheless, despite these problems, there are some hypotheses for which time series variation may be informative. Jones (1995) and Kocherlakota and Yi (1997) show how time series models might be used to discriminate between different growth theories. More specifically, they develop a statistical test of endogenous growth models based on regressing growth on lagged growth and a lagged policy variable (or the lagged investment rate, as in Jones). Exogenous growth models predict that the coefficients on the lagged policy variable should sum to zero, indicating no long-run growth effect of permanent changes in this variable. In contrast, some endogenous growth models would imply that the sum of coefficients should be non-zero. A simple time series regression then provides a direct test. More formally, as in Jones (1995), for a given country i one can investigate a dynamic relationship for the growth rate $\gamma_{i,t}$, where:

$$\gamma_{i,t} = A(L)\gamma_{i,t-1} + B(L)z_{i,t} + \varepsilon_{i,t}, \tag{24.30}$$

where z is the policy variable or growth determinant of interest, and $A(L)$ and $B(L)$ are lag polynomials assumed to be compatible with stationarity. The hypothesis of interest is whether $B(1) \neq 0$. If the sum of the coefficients in the lag polynomial $B(L)$ is significantly different from zero, this implies that a permanent change in the variable z will affect the growth rate indefinitely. As Jones (1995) explicitly discusses, this test is best seen as indicating whether a policy change affects growth over a long horizon, rather than firmly identifying or rejecting the presence of a long-run growth effect in the theoretical sense of that term. The theoretical conditions under which policy variables affect the long-run growth rate are strict, and many endogenous growth models are best seen as new theories of potentially sizeable level effects.[17]

A related idea is that of Granger causality, where the hypothesis of interest would be the explanatory power of lags of $Z_{i,t}$ for $\gamma_{i,t}$ conditional on lagged values of $\gamma_{i,t}$. Blomstrom, Lipsey and Zejan (1996) carry out Granger causality tests for investment and growth using panel data with five-year sub-periods. They find strong evidence that lagged growth rates have explanatory power for investment rates,

but weaker evidence for causality in the more conventional direction from investment to growth. In a similar vein, Campos and Nugent (2002) find that, once Granger causality tests are applied, the evidence that political instability affects growth may be weaker than usually believed.

A familiar objection to the more ambitious interpretations of Granger causality is that much economic behavior is forward-looking (see, for example, Bils and Klenow, 2000, on the forward-looking nature of educational investments). The movements of stock markets are another obvious instance where temporal sequences can be misleading about causality. Nevertheless, it could be argued that evidence on timing has been under-utilized in the growth literature to date, especially in panel data studies.

An underlying assumption of most studies is that timing patterns and effects will be similar across units such as countries or regions. Potential heterogeneity has only sometimes been acknowledged, as in the observation of Campos and Nugent (2002) that their results are heavily influenced by the African countries in the sample. The potential importance of these factors is also established in Binder and Brock (2004) who, by using panel methods to allow for heterogeneity in country-specific dynamics, find feedbacks from investment to growth beyond those that appear in Blomstrom *et al.* (1996).

Since testing for Granger causality using panel data requires a dynamic model, the use of a standard fixed effects estimator is likely to be inappropriate when individual effects are present. We discuss this further in section 24.5.2. In the context of investment and growth, a comprehensive examination of the associated econometric issues has been carried out by Bond, Leblebicioglu and Schiantarelli (2004). Their work shows that these issues are more than technicalities: unlike Blomstrom *et al.* (1996), they find strong evidence that investment has a causal effect on growth.

24.5.2 Panel data

As we emphasized above, the prospects for reliable generalizations in empirical growth research are often constrained by the limited number of countries available. This constraint makes parameter estimates imprecise, and limits the extent to which researchers can apply more sophisticated methods, such as semiparametric estimators. A natural response to this constraint is to use the within-country variation to multiply the number of observations. Using different episodes within the same country is ultimately the only practical substitute for somehow increasing the number of countries. To the extent that important variables change over time, this appears the most promising way to sidestep many of the problems that face growth researchers. Moreover, as the years pass and more data become available, the prospects for informative work of this kind can only improve.

We first discuss the implementation and advantages of panel data estimators in more detail, and then some of the technical issues that arise in the context of growth. We will use T to denote the number of time series observations in a panel of N countries or regions. At first sight, T should be relatively high in this context, because of the availability of annual data. But the concerns about

time series analysis raised above continue to apply. Important variables are either measured at infrequent intervals, or show little year-to-year variation. Moreover, variation in annual growth rates may give misleading answers about the longer-term growth process. For this reason, growth research using panel data has typically averaged data over five- or ten-year periods. Given the lack of data before 1960, this implies that growth panels not only have relatively few cross-sectional units, but also low values of T, often just five or six once lagged values have been included as explanatory variables or instruments.[18]

Most of the estimated models have been based on the hypothesis of conditional convergence, namely that countries converge to parallel equilibrium growth paths, the levels of which are a function of a few variables. As we saw in section 24.3, a corollary is that an equation for growth (essentially the first difference of log output) should contain some dynamics in lagged output. In this case, the growth equation can be rewritten as a dynamic panel data model in which current output is regressed on controls and lagged output, as in Islam (1995). In statistical terms this rewritten model is identical in all respects, except that the coefficient on initial output (originally β) is now $1 + \beta$:

$$\log y_{i,t} = (1 + \beta) \log y_{i,t-1} + \psi X_{i,t} + \pi Z_{i,t} + \alpha_i + \mu_t + \varepsilon_{i,t}. \tag{24.31}$$

This regression is a panel analogue to the cross-section regression (24.11), but now includes a country-specific effect α_i and a time-specific effect μ_t. The inclusion of time effects is important in the growth context, not least because the means of the log output series will typically increase over time, given productivity growth at the world level. Inclusion of a country-specific effect allows permanent differences in the level of income between countries that are not captured by $X_{i,t}$ or $Z_{i,t}$. In principle, one can also allow the parameters $1+\beta$, ψ, and π to differ across countries or regions.

Standard random effects estimators require that the individual effects α_i are distributed independently of the explanatory variables, and this requirement is clearly violated for a dynamic panel such as (24.31) by construction, given the dependence of $\log y_{i,t}$ on α_i. Hence the vast majority of panel data growth studies use a fixed effects (within-group) estimator. Given their popularity, it is important to understand how these estimators work. In a fixed effects regression there is a full set of country-specific intercepts, one for each country, and inference proceeds conditional on the particular countries observed, a natural choice in this context. Identification of the slope parameters, usually constrained to be the same across countries, relies on variation over time within each country. The "between" variation, namely the variation across countries in the long-run averages of the variables, is not used.

The key strength of this method, familiar from the microeconometric literature, is the ability to address one form of unobserved heterogeneity: any omitted variables that are constant over time will not bias the estimates, even if these omitted variables are correlated with the explanatory variables. Intuitively, the country-specific intercepts can be seen as picking up the combined effects of all

such variables. This is the usual motivation for using fixed effects in the growth context, as discussed in Islam (1995), Caselli, Esquivel and Lefort (1996) and Temple (1999). In more recent work, fixed effects estimators have been used in studying the effects of distinct events or "treatments," such as democratization or trade reform. We will discuss this approach in section 24.5.3.

A particular motivation for the use of fixed effects arises from the Mankiw *et al.* (1992) implementation of the Solow model. As discussed in section 24.3, their version of the model implies that one determinant of the level of the steady-state growth path is the initial level of efficiency ($A_{i,0}$) and cross-section heterogeneity in this variable should usually be regarded as unobservable. Islam (1995) explicitly develops a specification in which this term is treated as a fixed effect, while world growth and common shocks are incorporated using time-specific effects.

The use of panel data methods to address unobserved heterogeneity can bring substantial gains in robustness, but is not without costs. There are times when the question of interest precludes a fixed-effects approach, and sometimes the limitations of the data will make it uninformative. Some variables of interest are measured at only one point in time. Others are highly persistent, and this dependence implies that the amount of useful information in the within-country variation will be limited. At one extreme, some explanatory variables of interest are essentially fixed factors, like geographic characteristics. Here the only available variation is "between-country," and empirical work will have to be based on cross-sections or pooled cross-section time series. Alternatively, a two-stage hybrid of these methods can be used, in which a panel data estimator is used to obtain estimates of the fixed effects, which are then explicitly modeled in a second stage as in Hoeffler (2002).

A common failing of panel data studies based on within-country variation is that researchers do not pay enough attention to the dynamics of adjustment, and the important distinction between short-run and long-run effects. There are many panel data papers on human capital and growth that test only whether a change in school enrollment or years of schooling has an immediate effect on aggregate productivity, which seems an implausible hypothesis. It would be more natural to consider education as having a lagged effect, especially once various possible externalities are considered. Another example, given by Pritchett (2000a), is the use of panels to study inequality and growth. All too often, changes in the distribution of income are implicitly expected to have an immediate impact on growth. Yet many of the relevant theoretical papers highlight long-run effects, associated with the political process for example, and there is a strong presumption that much of the short-run variation in measures of inequality is due to measurement error. In these circumstances, it is hard to see how the available within-country variation can shed much useful light, at least until better data become available.

There is also a more general problem. Since the fixed effects estimator ignores between-country variation, the reduction in bias typically comes at the expense of higher standard errors. Another reason for imprecision is that either of the devices used to eliminate the country-specific intercepts – the within-groups transformation or first-differencing – will tend to exacerbate the effect of measurement error.[19] As a result, it is common for researchers using panel data models with fixed

effects, especially in the context of small T, to obtain imprecise sets of parameter estimates. Given the potentially unattractive trade-off between robustness and efficiency, Barro (1997), Temple (1999), Pritchett (2000a) and Wacziarg (2002) all argue that the use of fixed effects in empirical growth models has to be approached with care. The price of eliminating the misleading component of the between variation – namely, the variation due to unobserved heterogeneity – is that all the between variation is lost. This is costly, because growth episodes within countries inevitably look a great deal more alike than growth episodes across countries, and therefore offer less identifying variation. Restricting the analysis to the within variation eliminates one source of bias, but makes it harder to identify growth effects with any degree of precision. Many of the explanatory variables currently used in growth research are either highly stable over time, or tending to trend in one direction. Without useful identifying variation in the time series data, the within-country approach is in trouble. Moreover, growth is quite volatile at short horizons. It will typically be hard to explain this variation using predictors that show little variation over time, or that are measured with substantial errors. The result has been a number of panel data studies suggesting that a given variable "does not matter," when a more accurate interpretation is that its effect cannot be identified using the data at hand.

Depending on the sources of heterogeneity, even simple recommendations, such as including a complete set of regional dummies, can help to alleviate the biases associated with omitted variables (Temple, 1998). More than a decade of growth research has identified a host of fixed factors that could be used to substitute for country-specific intercepts. A growth model that includes these variables can still exploit the panel structure of the data, and the explicit modeling of the country-specific effects is directly informative about the sources of persistent income and growth differences.

In practice, the literature has focused on another aspect of using panel data estimators to investigate growth. Nickell (1981) showed that within-groups estimates of a dynamic panel data model can be badly biased for small T, even as N goes to infinity. The direction of this bias is such that, in a growth model, output appears less persistent than it should (the estimate of β is too low) and the rate of conditional convergence will be overestimated. The Nickell bias explains why the within-groups estimator is often avoided when estimating dynamic models. The most widely-used alternative is to difference the model to eliminate the fixed effects, and then use 2SLS or generalized method of moments (GMM) to address the correlation between the differenced lagged dependent variable and the induced MA(1) error term. To see the need for instrumental variable procedures, first-difference (24.31) to obtain:

$$\Delta \log y_{i,t} = (1+\beta)\Delta \log y_{i,t-1} + \Delta X_{i,t}\psi + \Delta Z_{i,t}\pi + \Delta \mu_i + \varepsilon_{i,t} - \varepsilon_{i,t-1}, \quad (24.32)$$

and note that (absent an unlikely error structure) the $\log y_{i,t-1}$ component of $\Delta \log y_{i,t-1}$ will be correlated with the $\varepsilon_{i,t-1}$ component of the new composite error term, as is clearly seen by considering equation (24.31) lagged one period.

Hence, at least one of the explanatory variables in the first-differenced equation will be correlated with the disturbances, and instrumental variable procedures are required.

Arellano and Bond (1991), building on work by Holtz-Eakin, Newey and Rosen (1988), developed the GMM approach to dynamic panels in detail, including specification tests and methods suitable for unbalanced panels. Caselli *et al.* (1996) applied their estimator in the growth context and obtained a much faster rate of conditional convergence than found in cross-section studies, consistent with the view that OLS estimates, by ignoring country effects, will yield an upward bias on the lagged dependent variable.

The GMM approach is typically based on using lagged levels of the series as instruments for lagged first differences. If the error terms in the levels equation (ε_{it}) are serially uncorrelated then $\Delta \log y_{i,t-1}$ can be instrumented using $\log y_{i,t-2}$ and as many earlier lagged levels as are available. This corresponds to a set of moment conditions that can be used to estimate the first-differenced equation by GMM. Bond (2002) and Roodman (2006) provide especially accessible introductions to the theory and application of this approach.

In principle, this strategy can alleviate biases due to measurement error and endogenous explanatory variables. In practice, many researchers are sceptical that lags, or "internally generated" instruments, are appropriate choices for instruments. It is easy to see that a variable such as educational attainment may influence output with a considerable delay, so that the exclusion of lags from the growth equation can look arbitrary. More generally, the GMM approach relies on a lack of serial correlation in the error terms of the growth equation (before differencing). This assumption can be tested using the methods developed in Arellano and Bond (1991), and can also be relaxed by an appropriate choice of instruments, but will sometimes be restrictive.

In practice, many applications of these methods have used "too many" moment conditions. The small-sample performance of the GMM panel data estimators is known to deteriorate as the number of moment conditions grows relative to the cross-section dimension of the panel. In that case, the coefficient estimates can be severely biased, and a further consequence is that the power of Sargan-type tests of overidentifying restrictions may collapse, as shown in Bowsher (2002). When tests of the overidentifying restrictions yield p-values near unity, this is an important warning sign that too many moment conditions are in use, and this problem can be seen relatively frequently in the literature. This can be avoided by using only a sub-set of the available lags as instruments, or summing moment conditions over time, while retaining enough overidentifying restrictions to ensure that Sargan-type tests will have some power. Roodman (2007) discusses these issues in more detail.

Another concern is that the explanatory variables may be highly persistent, as is clearly true of output. Lagged levels can then be weak instruments for first differences, and the GMM panel data estimator is likely to be severely biased in short panels. Bond, Hoeffler and Temple (2001) illustrate this point by comparing the Caselli *et al.* (1996) estimates of the coefficient on lagged output with OLS and

within-group estimates. Since the OLS and within-group estimates of β are biased in opposing directions then, leaving aside sampling variability and small-sample considerations, a consistent parameter estimate should lie between these two extremes, as discussed in Nerlove (1999, 2000). Formally, when the explanatory variables other than lagged output are strictly exogenous, we have:

$$p\lim \hat{\beta}_{WG} < p\lim \hat{\beta} < p\lim \hat{\beta}_{OLS}, \tag{24.33}$$

where $\hat{\beta}$ is a consistent parameter estimate, $\hat{\beta}_{WG}$ is the within-groups estimate and $\hat{\beta}_{OLS}$ is the estimate from a pooled OLS regression. For the dataset and model used by Caselli *et al*. (1996), this large-sample prediction is not valid, which raises a question mark over the reliability of the first-differenced GMM estimates. The problem may be one of weak instruments, and unless this can be resolved, it is not difficult to imagine circumstances in which the within-groups estimator, or bias-corrected versions of it, may be preferable to the GMM approach.

One device that can be informative in short panels is to make more restrictive assumptions about the initial conditions. If the observations at the start of the sample are distributed in a way that is representative of steady-state behavior, in a sense that will be made precise below, efficiency gains are possible. Assumptions about the initial conditions can be used to derive a "system" GMM estimator, of the form developed and studied by Arellano and Bover (1995) and Blundell and Bond (1998), and also discussed in Ahn and Schmidt (1995) and Hahn (1999). In this estimator, not only are lagged levels used as instruments for first differences, but lagged first differences are used as instruments for levels, which corresponds to an extra set of moment conditions. Blundell and Bond (1998) provide Monte Carlo evidence that this estimator is more robust than the Arellano–Bond method in the presence of highly persistent series. As also shown by Blundell and Bond, the necessary assumptions can be seen in terms of an extra restriction, namely that the deviations of the initial values of $\log y_{i,t}$ from their long-run (steady-state) values are not systematically related to the individual effects.[20] For simplicity, we focus on the case where there are no explanatory variables other than lagged output. The required assumption on the initial conditions is that, for all $i = 1, \ldots, N$, we have:

$$E\left[\left(\log y_{i,1} - \bar{y}_i\right)\alpha_i\right] = 0, \tag{24.34}$$

where the $\bar{y}_i$ are the long-run values of the $\log y_{i,t}$ series and are therefore functions of the individual effects α_i and the autoregressive parameter β. This assumption on the initial conditions ensures that:

$$E\left[\Delta \log y_{i,2}\alpha_i\right] = 0, \tag{24.35}$$

and this, together with the mild assumption that the changes in the errors are uncorrelated with the individual effects:

$$E\left[\Delta\varepsilon_{i,t}\alpha_i\right] = 0, \tag{24.36}$$

implies $T-2$ extra moment conditions of the form:

$$E\left[\Delta \log y_{i,t-1}(\alpha_i + \varepsilon_{i,t})\right] = 0 \quad \text{for } i = 1, \ldots, N \text{ and } t = 3,\ 4, \ldots, T. \tag{24.37}$$

Intuitively, as is clear from the new moment conditions, the extra assumptions ensure that the lagged first difference of the dependent variable is a valid instrument for untransformed equations in levels, since it is uncorrelated with the composite error term in the levels equation. The additional moment conditions build in some insurance against weak identification, because if the series are persistent and lagged levels are weak instruments for first differences, it may still be the case that lagged first differences will have some explanatory power for levels.[21] Nevertheless, the analysis of Bun and Windmeijer (2007) indicates that weak instrument problems can emerge even for the system GMM estimator, especially when the variance of the country effects is high relative to the variance of the transitory shocks, which may well be the case for growth data.

Moreover, the extra moment conditions are based on assumptions about the initial conditions that are unlikely to command universal assent. In principle, these assumptions can be tested using the incremental Sargan statistic (or C statistic) associated with the additional moment conditions. Yet the validity of the restriction should arguably be evaluated in wider terms, based on some knowledge of the historical forces giving rise to the observed initial conditions. This point, that key statistical assumptions should not always be evaluated only in statistical terms, is one that we will return to later, when discussing the wider application of instrumental variable (IV) methods.

Alternatives to GMM have been proposed. Kiviet (1995, 1999) derives an analytical approximation to the Nickell bias that can be used to construct a bias-adjusted within-country estimator for dynamic panels. The simulation evidence reported in Judson and Owen (1999) and Bun and Kiviet (2001) suggests that this estimator performs well relative to standard alternatives when N and T are small. More recently, Bun and Carree (2005) have developed an alternative bias-adjusted estimator. One serious limitation of the currently available bias-adjusted estimators, relative to GMM, is that they do not address the possible correlation between the explanatory variables and the disturbances due to simultaneity and measurement error. Nevertheless, there is a clear case for implementing these estimators, at least as a complement to other methods.

A further issue that arises when estimating dynamic panel data models is that of parameter heterogeneity. If a slope parameter such as β varies across countries, and the relevant explanatory variable is serially correlated, this will induce serial correlation in the error term. If we focus on a simple case where a researcher wrongly assumes homogeneity in the coefficient on lagged output, or $\beta_i = \beta$ for all $i = 1, \ldots, N$, then the error process for a given country will contain a component that resembles $(\beta_i - \beta) \log y_{i,t-1}$. Hence there is serial correlation in the errors, given the persistence of output. The estimates of a dynamic panel data model will be inconsistent even if GMM methods are applied. This problem was analyzed in more general terms by Robertson and Symons (1992) and Pesaran and Smith (1995)

and has been explored in depth for the growth context by Lee, Pesaran and Smith (1997, 1998). Since an absence of serial correlation in the disturbances is usually a critical assumption for the GMM approach, parameter heterogeneity can be a serious concern. Some of the possible solutions, such as regressions applied to single time series, or the pooled mean group estimator developed by Pesaran, Shin and Smith (1999), have limitations in studying growth for reasons already discussed. An alternative solution is to split the sample into groups that are more likely to share similar parameter values. Groupings by regional location or the initial level of development are a natural starting point.

Perhaps the state of the art in analyzing growth using panel data and allowing for parameter heterogeneity is represented by Phillips and Sul (2003). They allow for heterogeneity in parameters not only across countries, but also over time. Temporal heterogeneity is rarely investigated in panel studies, but may be important.

One drawback of many current panel studies is that some of the necessary decisions, and perhaps especially the construction of the time series observations, can appear arbitrary. There is no inherent reason why five or ten years represent natural spans over which to average observations. Similarly, there is arbitrariness with respect to which time periods are aggregated. A useful endeavor would be the development of tools to ensure that panel findings are robust under alternative ways of assembling the panel from the raw data; it is also possible that the field could draw more heavily on the econometric literature on time aggregation than it does at present.

More fundamentally, the empirical growth literature has not fully addressed the question of the appropriate time horizons over which growth models should be assessed. For example, it remains unclear when business cycle considerations, or instances of output collapses, may be safely ignored. While cross-section studies that examine growth over 30–40-year periods might be exempt from these considerations, it is less clear that panel studies employing five-year averages are genuinely informative about medium-run growth dynamics. As more data become available with the passage of time, concerns over the scope for arbitrary choices can only increase. It will also be important to develop robust methods for inference about long-run effects.

24.5.3 The event study approach

Although we have focused on the limitations of panel data methods, it is clear that the prospects for informative work of this kind should improve over time. The addition of further time periods is valuable in itself, and the history of developing countries in the 1980s and 1990s offers various events that introduce richer time series variation into the data. These events include waves of democratization, macroeconomic stabilization, financial liberalization and trade reform, and panel data methods can be used to investigate their consequences for growth. This can proceed in a similar way to event studies in the empirical finance literature. In event studies, researchers look for systematic changes in asset returns after a discrete event, such as a profits warning. In other fields, before-and-after studies like this have proved an informative way to gauge the effects of inflation stabilization,

as in Easterly (1996), and the consequences of the debt crisis for investment, as in Warner (1992).

The obvious analogue for growth econometrics is to study the time paths of variables such as output growth, investment and total factor productivity (TFP) growth, before and after discrete events such as democratizations. When using fixed effects combined with a binary indicator to capture discrete events, the logic of the approach is similar to the differences-in-differences estimator in the literature on program evaluation. Examples include the work of Giavazzi and Tabellini (2005) on economic and political liberalizations, Henry (2000, 2003) on stock market liberalization, Papaioannou and Siourounis (2007) and Rodrik and Wacziarg (2005) on democratizations, and Wacziarg and Welch (2003) on trade reforms. Depending on the context, one can also study the response of other variables in a way that is informative about the channels of influence. For example, in the case of trade reform, it is natural to study the response of the trade share, as in the work of Wacziarg and Welch.

The rigor of this method should not be exaggerated. As with any other approach to empirical growth, one has to be cautious about inferring a causal effect. This is clear from drawing explicitly on the literature on treatment effects and program evaluation.[22] In the study of growth, "treatments" such as democratization are clearly not exogenously assigned, but are events that have arisen endogenously. This means, for example, that treatment and control groups may differ systematically, either in terms of time-invariant unobservables, or in factors that vary over time. Methods based on fixed effects can address the first of these considerations, but allowing for the second is more complicated. To illustrate the problem, Papaioannou and Siourounis (2007) draw a useful analogy between democratizations and "Ashenfelter's dip" in the program evaluation literature. It is possible that countries experiencing a downturn or weak economic performance are especially likely to democratize, in which case the estimated effect of democratization risks conflating the true effect with the effects of a separate recovery from the pre-treatment "dip."

Moreover, in growth applications, the treatment effects are highly likely to be heterogeneous across countries and over time. They may depend, for example, on whether a policy change is seen as temporary or permanent, as Pritchett (2000a) observes. In these circumstances, the ability to quantify even an average treatment effect is strongly circumscribed. It may still be possible to identify the direction of effects, and here the limited number of observations does have one advantage. With a small number of cases to examine, it is easy for the researcher to present a graphical analysis that allows readers to gauge the extent of heterogeneity in responses, and the overall pattern. Another useful and informative approach, adopted by Papaioannou and Siourounis (2007), is to estimate a model that allows the treatment effect to vary over time, using the methods developed in Laporte and Windmeijer (2005).

There is one remaining problem to note. When growth researchers look at the effects of discrete events, they typically study the effects on serially correlated outcomes such as output or investment. A particular concern in cross-country samples

is that the errors may then be serially correlated, and the standard errors unreliable. Using simulations, Bertrand, Duflo and Mullainathan (2004) showed that differences-in-differences estimators are potentially highly vulnerable to this problem, to the extent that "placebo" interventions are often found to have effects that are statistically significant. This could well be a major concern for the corresponding growth studies carried out to date. In samples with the cross-section dimensions associated with cross-country data, some of the available solutions for calculating panel-robust standard errors may also face problems.

24.6 Endogeneity and instrumental variables

In this section, we consider the use of instrumental variables in cross-section and time-series contexts. One obvious criticism of growth regressions is that they do little to establish directions of causation. As well as reverse causality, there is the standard problem that two variables may be correlated but jointly determined by a third. Variables such as growth and political stability could be seen as jointly determined equilibrium outcomes associated with, say, a particular set of institutions. The usual response has been the use of instrumental variables, for reasons discussed in section 24.6.1, but there are some grounds for caution in their application. These include the difficulty of establishing credible exclusion restrictions (section 24.6.2) and the problems raised by heterogeneous effects in small samples (section 24.6.3).

24.6.1 Concepts of endogeneity

There are many instances in growth research when explanatory variables are clearly endogenously determined in an economic sense. The most familiar example would be a regression that relates growth to the share of investment in GDP. This may tell us that the investment share and growth are associated, but stops short of identifying a causal effect, or explaining why investment varies; presumably it is endogenous to a range of economic variables. When variables are endogenously determined in the economic sense, there is also a strong chance that they will be endogenous in the statistical or technical sense, namely correlated with the disturbances in the structural equation for growth. To give an example, consider what happens if political instability lowers growth, but slower economic growth feeds back into political instability. The OLS estimator will conflate these two effects and yield an inconsistent estimate of the causal effect of instability.[23]

Views on the importance of these considerations differ greatly. One position is that the whole growth research project effectively capsizes before it has even begun. Mankiw (1995) and Wacziarg (2002) have suggested an alternative and more positive view. According to them, one should accept that reliable causal statements are almost impossible to make, but use the partial correlations of the growth literature to rule out some possible hypotheses about the world. Wacziarg uses the example of the negative partial correlation between corruption and growth found by Mauro (1995). Even if shown to be robust, this correlation does not establish that somehow reducing corruption will be followed by higher growth rates. But it does make

it harder to believe some of the earlier suggestions, rarely based on evidence, that corruption could be actively beneficial.

Given the likelihood that variables are inter-related, one response is to model as many as possible of the variables that are endogenously determined. One prominent example is Tavares and Wacziarg (2001), who estimate structural equations for various channels through which democracy could influence development. This approach has some important advantages in both economic and statistical terms. It can be informative about underlying mechanisms in a way that much empirical growth research is not. From a purely statistical perspective, if the structural equations are estimated jointly by methods such as three-stage least squares (3SLS) or full information maximum likelihood (FIML), this is likely to bring efficiency gains. That said, systems estimation is not necessarily the best route: it has the important disadvantage that specification errors in one of the structural equations could contaminate the estimates obtained from the others. Importantly, these specification errors could include invalid exclusion restrictions, a possibility that is often hard to rule out.

24.6.2 Exclusion restrictions

The most common response to endogeneity has been the application of instrumental variable procedures to a single structural equation, with growth as the dependent variable. Appendices C and D in Durlauf *et al.* (2005) describe a wide range of other instrumental variables that have been proposed for the Solow variables and other growth determinants respectively, where the focus has been on the endogeneity of particular variables. Whether these instruments are genuinely plausible is another matter. In our view, the belief that it is easy to identify valid instrumental variables in the growth context is often mistaken. Many applications of instrumental variable procedures in the empirical growth literature are undermined by a failure to address properly the question of whether these instruments are valid, in the sense of being uncorrelated with the error term in a growth regression. When the instrument is invalid, instrumental variables estimates will be inconsistent. Not enough is currently known about the consequences of "small" departures from validity, but there are circumstances in which the 2SLS bias is worse than the OLS bias, especially if the instruments are "weak." It is certainly possible to envisage circumstances under which ordinary least squares would be preferable to instrumental variables on, say, a mean square error criterion.

A common misunderstanding, perhaps based on confusing the economic and statistical versions of "exogeneity," is that predetermined variables, such as geographical characteristics, are inevitably strong candidates for instruments. There is, however, nothing in the predetermined nature of these variables to preclude a direct effect on growth, or the possibility that they are correlated with omitted growth determinants, and hence with the error term. Even if we take the extreme example of geographic characteristics, there are many channels through which these could affect growth, and therefore many ways in which they could be correlated with the disturbances in a growth model. Brock and Durlauf (2001a) use this type of reasoning to criticize the use of instrumental variables in growth economics.

Since growth theories are often mutually compatible, the validity of an instrument requires a positive and explicit argument that it cannot be a direct growth determinant or correlated with an omitted growth determinant. For many of the instrumental variables that have been proposed, such an argument is difficult to construct.

Discussions of the validity of instruments inevitably suffer from some degree of imprecision because of the need to make qualitative and subjective judgments. When one researcher claims that it is implausible that a given instrument is valid, unless this claim is made on the basis of a joint model of the instruments and the variable of original interest, another researcher can always reject the assertion as unpersuasive. To be clear, this element of subjectivity does not mean that arguments about validity are pointless.[24] Rather, one must recognize that not all statistical questions can be adjudicated on the basis of formal tests.

To see how different instruments might be assigned different levels of plausibility, we consider some examples. Hall and Jones (1999) use various indicators of Western European influence as instruments for openness to trade and institutional quality. As subsequent authors, including Acemoglu (2005), have pointed out, these indicators of Western European influence may have affected long-run development through a variety of channels, in which case their usefulness as instruments appears doubtful at best. The case for exclusion is easier to make for the measure of Western European influence constructed by Acemoglu *et al.* (2001), namely the mortality rates of colonial settlers. Glaeser *et al.* (2004) discuss some of the relevant issues in more detail.

As an example where instrument validity may be relatively plausible, consider Cook (2002). He employs measures of the damage caused by World War II as instruments for various growth regressors, such as saving rates. The validity of Cook's instruments again relies on the orthogonality of World War II damage with omitted post-war growth determinants. It may be that levels of wartime damage had consequences for post-war growth performance in other respects, such as institutional change. Nevertheless, that argument would clearly be more involved, and speculative, than would be necessary for some other examples in the growth literature.

To be clear, this discussion is nowhere near sufficient to conclude that one set of instruments is valid and another is not. Our central point is that exclusion restrictions need to rest on careful and explicit arguments. In particular, it is not enough to appeal to a variable being predetermined. The fact that a variable may be exogenous from an economic point of view is not enough to ensure that it is uncorrelated with the disturbances in the structural equation being estimated. This implies that historical information has a vital role to play in evaluating the plausibility of exclusion restrictions.

This discussion of instrumental variables indicates another important, albeit neglected, issue in empirical growth analysis: the relationship between model specification and instrumental variable selection. One cannot discuss the validity of particular instruments independently from the choice of the specific growth determinants under study and decisions about how to specify their relationship with growth. As we noted earlier, an important research question is whether model

uncertainty and instrumental variable selection can be integrated simultaneously into methods for model averaging and model selection. The recent work of Hendry and Krolzig (2005) on automated methods includes an ambitious approach to systematic model selection for simultaneous equation models, in which identifying restrictions are primarily determined by the data.

24.6.3 Instrumental variables and heterogeneous effects

Another issue that arises in applying instrumental variable methods to cross-country data is the possible heterogeneity in the effects of the instrument, and in the marginal effect of the explanatory variable that is instrumented. This is closely related to the idea of "local" average treatment effects. Stock and Watson (2004, sec. 11.7) provide a useful discussion of the issues in the context of 2SLS. Assume that the parameters in the first stage and second stage of 2SLS vary across countries, and are distributed independently of the variables (and instruments) in the model and the error terms. It can then be shown that the probability limit of the 2SLS estimate of the coefficient on the endogenous explanatory variable is not the average causal effect, but a weighted average of the effects for individual countries. The weighted average gives most weight to the countries for which the instrument has the largest effect on the endogenous explanatory variable. A corollary is that, when heterogeneity is present, the estimated effect depends on the choice of instrument. A further consequence is that claims for the exogeneity of the instruments become harder to sustain.

We can illustrate the potential importance of this by considering some of the most influential papers that apply IV methods to cross-country data, using the "levels regressions" approach discussed in section 24.3.3 above. In particular, Acemoglu *et al.* (2001), Frankel and Romer (1999), and Hall and Jones (1999) all study the determinants of income levels using IV methods. The dependent variable is a measure of (log) GDP per capita or per worker, and the explanatory variables include one or more regressors that may determine income levels, but that are themselves likely to be endogenous to the level of development.

What direction of bias should be expected when estimating such models by OLS? The usual expectation would be that policy variables like institutional quality "improve" (that is, move in the direction of promoting development) as GDP per capita increases. Under this view of the world, an OLS estimate of the effect of variables like institutions is likely to overstate their importance. The OLS slope coefficient will be biased away from zero, and correcting for this using IV should lead to a parameter estimate closer to zero, sampling variability aside. But the papers of Acemoglu *et al.* (2001), Frankel and Romer (1999) and Hall and Jones (1999) all have in common the opposite result. Somewhat surprisingly, the IV estimate associated with the variable of interest, such as the quality of institutions, is typically larger in magnitude than the OLS estimate.

There are a number of possible explanations. One is sampling variability, while another is measurement error. But if we take the view that development is likely to encourage improvements in (say) institutions, so that OLS estimates of their effect on output per worker are biased away from zero, the required extent of

measurement error is unlikely to be trivial. It has to be large enough to more than offset the effect of the simultaneity bias acting in the other direction.

A more sceptical view is that the IV coefficient may be larger because either (i) the effects may be heterogeneous; or (ii) the exclusion restrictions used in these papers are not genuinely valid; or some combination of the two. One interesting perspective on the IV results in the cross-country literature is that the instruments might have a more powerful effect on the endogenous explanatory variable (such as institutions) in those countries where the explanatory variable has an especially powerful effect on development outcomes. To give a concrete example, this would be the case if the Acemoglu *et al.* (2001) instrument, namely mortality rates of colonial settlers, had greatest influence on institutional development in sub-Saharan Africa, and if the marginal effect of institutions on development outcomes is most powerful in Africa. Were this true, the estimated effect of institutions will be larger than the average causal effect, because the IV estimate gives more weight to the causal effect for countries where the instrument has greatest influence. This does not invalidate the finding that institutions matter, but does make it harder to generalize about the extent to which they matter.

This is admittedly a speculative hypothesis, but there is some possible supporting evidence in Table 4 of Acemoglu *et al.* (2001). The 2SLS coefficient on institutions is roughly halved when African countries are excluded from the sample, although still precisely estimated. The sensitivity of the 2SLS estimate suggests that the effects of institutions differ substantially across countries. A deeper and more rigorous investigation would be possible when there is at least one additional instrument, so that estimates can be compared across different instrument sets. If the effects of policy are homogeneous across countries, the estimated effect should be the same regardless of the choice of instrument (abstracting from sampling variability). That invariance no longer holds under heterogeneous effects. Then, as we have seen, it is likely that the IV estimate will be influenced by the choice of instrument, and the estimated effect will no longer relate to the whole population.

24.7 Other econometric issues

In this section we consider a range of questions that arise in growth econometrics from the properties of data and errors. Starting with data issues, section 24.7.1 examines how one may handle outliers in growth data. Section 24.7.2 examines the problem of measurement error. This is an important issue since there are good reasons to believe that the quality of the data is sometimes poor for less developed economies. In section 24.7.3 we consider the case where data are missing. Turning to issues of the properties of model errors, section 24.7.4 examines the analysis of heteroskedasticity in growth contexts. Finally, section 24.7.5 addresses the problem of cross-section error dependence.

24.7.1 Outliers

Empirical growth researchers often work with small datasets and estimate relatively simple models. In these circumstances, OLS regressions are almost meaningless

unless they have been accompanied by systematic investigation of the data, including the sensitivity of the results to outlying observations. There are many reasons why some observations may be unrepresentative. It is possible for variables to be measured with error for that particular region or country. Alternatively, the model specified by the researcher may omit a relevant consideration, and so a group of observations will act as outliers. It is inherent in least squares estimators that they are highly sensitive to unrepresentative observations, and the dangers of using OLS were forcibly expressed by Swartz and Welsch (1986, p. 171): "In a world of fat-tailed or asymmetric error distributions, data errors, and imperfectly specified models, it is just those data in which we have the least faith that often exert the most influence on the OLS estimates."

Some researchers respond to this concern by using leverage measures or single-case diagnostics such as Cook's distance statistic. There are well-known problems with these approaches, because where more than one outlier is present, the extent of the influence of one observation can easily be hidden by the presence of another (the "masking" effect). By far the best response is to use a more robust estimator, such as least trimmed squares, at least as a preliminary way of investigating the data.[25] These issues are discussed in more detail in Temple (1998, 2000b).

24.7.2 Measurement error

We now turn to a more general discussion of measurement error. It is clear that measurement errors are likely to be pervasive, especially in data that relate to developing countries, yet relatively few empirical studies of growth consider the impact of measurement error in any detail. This rather casual approach often appeals to the best-known statistical result, which applies to a bivariate model where the independent variable is measured with error.[26] The estimate of the slope coefficient will be biased towards zero, even in large samples, because measurement error induces a covariance between the observable form of the regressor and the error term. This attenuation bias is well known, but sometimes misleads researchers into suggesting that measurement error will only mask effects, a claim that is not true in general. When there are multiple explanatory variables, but only one is measured with error, then typically all the parameter estimates will be biased. Some parameter estimates may be biased away from zero and, although the direction of the bias can be estimated consistently, this is rarely done. When several variables are measured with error, the assumption that measurement error only hides effects is even less defensible.

Where measurement error is present, the coefficients are typically not identified unless other information is used. The most popular solution is to use instrumental variables, if a separate instrument can be found which is likely to be independent of the measurement error. A more complex solution, which does not need an additional variable, is to exploit higher-order sample moments to construct IV estimators, as in Dagenais and Dagenais (1997) and Arcand and Dagenais (2005). The reliability of these procedures in small samples is uncertain, since the use of higher-order moments could make them sensitive to outliers.

Sometimes partial identification is possible, in the sense that bounds on the extent of measurement error can be used to derive consistent estimates of bounds on the slope parameters. Although it can be difficult for researchers to agree on sensible bounds on the measurement error variances, there are easier ways of formulating the necessary restrictions, as discussed by Klepper and Leamer (1984). Their reverse regression approach was implemented by Persson and Tabellini (1994) and Temple (1998), but has rarely been used by other researchers. Another strategy is to investigate sensitivity to varying degrees of measurement error, based on method of moments corrections. Again, this is easy to implement in linear models, and should be applied more routinely than it is at present. Temple (1998) provides a discussion of both approaches in the context of the Mankiw *et al*. (1992) model.

24.7.3 Missing data

Some countries rarely appear in growth datasets, partly by design: it is common to leave out countries with small populations, oil producers, and transition economies. These are countries that seem especially unlikely to lie on a regression surface common to the majority of the OECD member countries or the developing world. Other countries are left out for different reasons. When a nation experiences political chaos, or lacks economic resources, the collection of national accounts statistics will be a low priority. In other cases, countries appear in some studies but not in others, depending on the availability of particular variables of interest.

Missing data can be a serious problem. If a researcher started from a representative dataset and then deleted countries at random, this would typically increase the standard errors but not lead to biased estimates. More serious difficulties arise if countries are missing in a non-random or systematic way, because then parameter estimates are likely to be biased. This problem is given relatively little attention in mainstream econometrics textbooks, despite a large body of research in the statistics literature. A variety of solutions are possible, with the simplest being one form or another of imputation, with an appropriate adjustment to the standard errors. Hall and Jones (1999) and Hoover and Perez (2004) are among the few empirical growth studies to implement this. It may be especially useful when countries are missing from a dataset because a few variables are not observed for their particular cases. It is then easy to justify using other available information to predict the missing data, and thereby exploit the additional information contained in the variables that are observed. Alternative approaches to missing data are also available, based on likelihood or Bayesian methods, which can be extended to handle missing observations.

24.7.4 Heteroskedasticity

It is common in cross-section regressions for the underlying disturbances to have a non-constant variance. As is well known, the coefficient estimates remain unbiased, but OLS is inefficient and the estimates of the standard errors are biased. Most empirical growth research simply uses the heteroskedasticity-consistent standard errors developed by Eicker (1967) and White (1980). These estimates of the standard

errors are consistent but not unbiased, which suggests that alternative solutions to the problem may be desirable. For datasets of the size found in cross-country empirical work, the alternative estimators developed by MacKinnon and White (1985) are likely to have better finite sample properties, as discussed in Davidson and MacKinnon (1993) and supported by simulations in Long and Ervin (2000).

There are at least two other concerns with the routine application of White's heteroskedasticity correction as the only response to heteroskedasticity. The first is that by exploiting any structure in the variance of the disturbances, using weighted least squares, it may be possible to obtain efficiency gains. The second and more fundamental objection is that heteroskedasticity can often arise from serious model misspecification, such as omitted variables or neglected parameter heterogeneity. Evidence of heteroskedasticity should then prompt revisions of the model for the conditional mean, rather than mechanical adjustments to the standard errors. See Zietz (2001) for further discussion and references.

24.7.5 Cross-section error dependence

An unresolved issue in growth econometrics is the treatment of cross-section dependence in model errors. This dependence may have important consequences for inference. As noted by DeLong and Summers (1991) in the growth context, failure to account for cross-sectional error correlation can lead to inaccurate standard errors. Furthermore, there are several reasons to expect cross-sectional error dependence to be present when studying growth. For example, countries that are geographically close together, or trading partners, may well experience common shocks. Output growth may often be related to the growth of large, leading countries within a particular region or world.

The general issue of error dependence has been a focus of recent research, in the context of panel data and panel time series estimators in particular. Whether the effect of dependence is sizeable in practice remains an open question, but one that might be addressed using ideas developed in Baltagi, Song and Koh (2003) and Driscoll and Kraay (1998), among others.

In the context of growth regressions, work on cross-section dependence may be divided into two strands. One concerns tests to identify the presence of cross-section dependence. Pesaran (2004) develops tests that do not rely on any prior ordering; this framework in essence sums the cross-section sample error correlations in a panel and evaluates whether they are consistent with the null hypothesis that the population correlations are zero. Specifically, and recalling that N denotes the cross-section dimension and T the time dimension, he proposes a cross-section dependence statistic CD:

$$CD = \sqrt{\frac{2T}{N(N-1)}} \left(\sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \hat{\rho}_{i,j} \right), \tag{24.38}$$

where $\hat{\rho}_{i,j}$ is the sample correlation between $\varepsilon_{i,t}$ and $\varepsilon_{j,t}$. Pesaran gives conditions under which this statistic converges to a Normal (0,1) random variable (as N and T become infinite) under the null hypothesis of no cross-section correlation. This

test statistic is based on earlier work by Breusch and Pagan (1980) and appears to possess good finite sample properties in comparison to this earlier work. Using a country-level panel, Pesaran (2004) strongly rejects the null of no cross-section dependence for the world as a whole, and within several geographic groupings.

The CD test need not be consistent for some alternatives of interest, however. With this in mind, Pesaran, Ullah and Yamagata (2008) develop a bias-adjusted version of the Breusch and Pagan Lagrange multiplier (LM) test statistic for cross-section error independence, for panels with strictly exogenous regressors and normally distributed errors. This approach retains some power in some circumstances where the CD test does not, but is less robust to departures from normality and the presence of regressors that are only weakly exogenous.

The second strand of research on cross-section error dependence has constructed empirical models that take it explicitly into account. One approach relies on formulating a statistical model of the dependence. Phillips and Sul (2003) model the error term in a growth panel as:

$$\varepsilon_{i,t} = \delta_i \theta_t + u_{i,t}, \tag{24.39}$$

where θ_t and $u_{i,t}$ are independent random variables and $u_{i,t}$ is assumed to be i.i.d. across countries and across time. Pesaran (2006) develops an alternative estimation strategy based on a generalized form of this error structure, one in which θ_t may be a vector. While Phillips and Sul consider how to account for error dependence in a generalized least squares (GLS)-type structure, Pesaran considers ways to filter the individual observations in order to eliminate the dependence. From the perspective of growth dynamics, (24.39) suffers from the problem that it does not account for aspects of the error process associated with growth. In order to account for cross-section dependence in convergence analysis, Phillips and Sul (2007a, 2007b) study the case where δ_i is replaced with $\delta_{i,t}$ in (24.39), arguing that transition dynamics produce time varying coefficients of this type as less advanced economies catch up to more advanced ones.

Another possibility when analyzing error dependence is to treat the problem as one of spatial correlation. This issue has been much studied in the regional science literature, and statisticians in this field have developed spatial analogues of many time series concepts (see Anselin, 2001, 2006, for an overview). Spatial methods may yet have an important role to play in growth econometrics. However, when these methods are adapted from the spatial statistics literature, they raise the problem of identifying the appropriate notion of space. One can imagine many reasons for cross-section correlation. If one is interested in technological spillovers, it may well be the case that in the space of technological proximity, the United Kingdom is closer to the United States than is Mexico. Put differently, unlike the time series and spatial cases, there is no natural cross-section ordering to elements in the standard growth datasets. Following language due to Akerlof (1997), countries are perhaps best thought of as occupying some general socioeconomic-political space defined by a range of factors; spatial methods then require a means to identify their locations.

One approach is pursued by Conley and Ligon (2002). In their analysis, they attempt to construct estimates of the spatial covariation of the residuals ε_i in a cross-section. In order to do this, they construct different measures of socioeconomic distance between countries. They separately consider geographic distance (measured between capital cities) and measures of the costs of transportation between these cities. Once a distance metric is constructed, these are used to construct a residual covariance matrix. Estimation methods for this procedure are developed in Conley (1999). Conley and Ligon (2002) find that allowing for cross-section dependence in this way is relatively unimportant in terms of appropriate calculation of standard errors for growth model parameters. Their methods could be extended to allow for comparisons of different variables as the source for cross-section correlation, as in Conley and Topa (2002) in the context of residential neighborhoods. A valuable generalization of this work would be the modeling of cross-section dependence as a function of multiple variables. Such an analysis would allow further progress on the measurement of distances in socioeconomic space, which may arise through multiple channels.

An alternative approach is to build spillover effects directly into the structure of an empirical model. Easterly and Levine (1997) is an example of a study which incorporates a direct effect of the growth of neighboring countries, but such examples remain rare. Some of the relevant issues have been highlighted in the theoretical literature on social interactions, inspired by empirical problems such as the measurement of peer effects in schools. While a structural approach has advantages, the presence of spillovers has consequences for identification that are not easily resolved, for the reasons explained in Manski (1993) and subsequently discussed in Brock and Durlauf (2001b). These consequences have yet to be fully explored in the context of empirical growth studies. Binder and Pesaran (2001) and Brock and Durlauf (2001b) analyze identification and estimation problems for intertemporal environments that are particularly relevant to the growth context.

24.8 Conclusions: the future of growth econometrics

In this section, we offer some closing thoughts on the most promising directions for empirical growth research. We explicitly draw on previous contributions along these lines, many of which deserve wider currency. It is especially interesting to compare the current state of the field against the verdicts offered in the early survey by Levine and Renelt (1991).

A dominant theme will be that the empirical study of growth requires an eclectic approach, and that the field has been harmed by a tendency for research areas to evolve independently, without enough interaction.[27] This is not simply a question of using a variety of statistical techniques. It also suggests the need for a closer connection between theory and evidence, a willingness to draw on ideas from areas such as trade theory, and more attention to particular features of the countries under study, including the historical context.

Pritchett (2000a) has listed three questions for growth researchers to address:

- What are the conditions that initiate an acceleration of growth or the conditions that set off sustained decline?
- What happens to growth when policies – trade, macroeconomic, investment – or politics change dramatically in episodes of reform?
- Why have some countries absorbed and overcome shocks with little impact on growth, while others seem to have been overwhelmed by adverse shocks?

Although this research agenda is almost ten years old, it retains considerable relevance, not least because it focuses attention on substantive economic issues rather than technicalities. The importance of the first of Pritchett's questions is evident from the many instances where countries have moved from stagnation to growth and vice versa. Hausmann, Pritchett and Rodrik (2005) explicitly model transitions to fast growth ("accelerations") and make clear the scope for informative work of this kind. The second question we have discussed in section 24.5.3, and research in this vein is increasingly prominent. Here, one of the major challenges will be to relax the (sometimes only implicit) assumption that policies are randomly assigned, and to find ways of carrying out inference that are robust in small samples. The third question has been addressed in an important paper by Rodrik (1999).

In all three cases, it is clear that econometric work should be informed by detailed studies of individual countries, such as those collected in Rodrik (2003). Too much empirical growth research proceeds without enough attention to the historical and institutional context. For example, a newcomer to this literature might be surprised at the paucity of work that integrates growth regression findings with, say, the known consequences of the 1980s debt crisis. Another reason for advocating case studies is that much of the empirical growth literature essentially isolates only reduced-form partial correlations. These can be useful, but it is clear that we often need to move beyond this. A partial correlation is more persuasive if it can be supported by theoretical arguments. The two combined are more persuasive if there is evidence of the intermediating effects or mechanisms that are emphasized in the relevant theory. There is plenty of scope for informative work that tries to isolate the mechanisms by which variables such as financial depth, inequality, and political institutions shape the growth process. Wacziarg (2002), in particular, highlights the need for a "structural" growth econometrics, one that aims to recover channels of causation.

A more extreme view is that growth econometrics should be supplanted by the calibration of theoretical models. Klenow and Rodriguez-Clare (1997) emphasize the potential of such an approach. The analysis of Mankiw *et al.* (1992) can be seen partly as a comparison of estimated parameter values with those associated with specific theoretical models, but relatively little of the empirical work that has followed has achieved a similarly close connection between theory and evidence. This has been a recurring criticism of the literature since at least Levine and

Renelt (1991). It would be premature to say that econometric approaches should be entirely replaced by calibration or "quantitative theory," but the two methods could inform each other more often than at present. Calibrated models can help to interpret parameter estimates, not least in comparing the magnitude of the estimates with the implications of plausible models. At the same time, the partial correlations identified in growth econometrics can help to act as a discipline on model-building and can also indicate where model-based quantitative investigations are most likely to be fruitful. This role for growth econometrics is likely to be especially useful in areas where the microeconomic evidence used to calibrate structural models is relatively weak, or standard behavioral assumptions may be flawed.

The need for a tighter connection between theory and evidence is especially apparent in certain areas. Most empirical growth papers are based on the one-sector, closed-economy Solow model, which leaves out aspects of interdependence that are surely important. Howitt (2000) has shown that standard empirical growth models can be reinterpreted in the light of a multi-country theoretical model with a role for technology diffusion. More generally, there is a need for researchers to develop frameworks that are consistent with international flows of goods, capital and knowledge. These issues are partly addressed by the theoretical analyses of Barro, Mankiw and Sala-i-Martin (1995) and Howitt (2000), and empirical work that builds on such ideas deserves greater prominence. Here especially, research that draws on the quantitative implications of specific theoretical models, as in the work of Eaton and Kortum (1999, 2001) on technology diffusion and the role of imported capital goods, could be an important advance.

The neglect of open economy models is just one example of the narrowness with which empirical growth models are often conceived. Much of the empirical literature uses a theoretical framework that was originally developed to explain the long-run growth experiences of the US and other developed nations. This framework is routinely applied to study developing countries, while incorporating few of their distinctive features. A list of these could include the potentially important roles of agricultural employment, dualism, and structural change; a relatively large informal sector, which often accounts for a substantial share of total employment; and periods of extensive state involvement in production, sometimes reflecting the legacy of nationalist movements and many years of socialist economic policies.

The narrowness of focus in existing studies has many limitations. For example, the conventional use of one-sector models depends on unrealistic assumptions about aggregation. It also prevents many relevant and interesting questions from even being asked, including the role of changes in sectoral and occupational structure in productivity growth. Given the scope for more general and more informative models, empirical growth researchers have really only scratched the surface, with a few recent exceptions. Temple (2005, 2006) and Temple and Wößmann (2006) discuss some of the relevant issues, and provide further references.

Some of these issues are closely linked to an especially important research agenda, namely the need to distinguish between different types of growth and

their distributional consequences. For example, the general equilibrium effects of productivity improvements in agriculture may be very different to those in services and industry. Identifying the nature of "shared growth" will require more detailed attention to particular features of developing countries. It will also require an effort to understand how these influence the forms taken by growth, and their distributional consequences. Given that the main source of income for the poor is usually labor income, there is a need to integrate theoretical and empirical growth models with theory and evidence from labor economics, in order to study how growth and labor markets interact. Agénor (2004) and Temple (2005) consider some of the relevant issues. Partly because of the weaknesses of data on income distribution, too little work in growth econometrics has differentiated between types of growth, even though the policy relevance of these questions is clear.

Ideally, research along these various lines will utilize not only statistical methods, but also the power of case studies in generating hypotheses, and in deepening our understanding of the economic, social and political forces at work in determining growth outcomes. Case studies may be especially valuable in at least two areas. The first of these is the study of technology transfer. As emphasized in the survey by Klenow and Rodriguez-Clare (1997), we do not know enough about why some countries are more successful than others in climbing the "ladder" of product quality and technological complexity. What are the relative contributions of human capital, foreign direct investment and trade? In recent years some of these issues have been intensively studied at the microeconomic level, especially the role of foreign direct investment and trade, but there remains work to be done in relating firm and sector-level evidence to aggregate implications.

A second area where case studies may be especially valuable is the study of political economy, in its modern sense. It is a truism that economists, particularly those considering development, have become aware of the need to account for the two-way interaction between economics and politics. A case can be made that the theoretical literature has outpaced the empirical literature in this regard. Analytical case studies of individual countries, drawing on both economic theory and political science, would help to close this gap.

Thus far, we have highlighted a number of limitations of existing work, and directions in which further research seems especially valuable. Some of the issues we have considered were highlighted much earlier by Levine and Renelt (1991). The extent to which limitations have stubbornly persisted over time might lead to pessimism over the long-term prospects of this literature.[28] This also shows that our prescriptions for future research could seem rather pious, since the improvements we recommend are easier said than done. But the literature has also evolved in some interesting and unpredictable ways, and we will end our review by considering some areas in which genuine progress has been made, and where further progress appears likely.

One reason for optimism is the potential of recently developed model averaging methods. These help to address the model selection and robustness issues that have been identified as a major weakness of cross-country growth research since at least Levine and Renelt (1992). By framing the problem explicitly in terms of model

uncertainty, the Bayesian approach can consider many candidate explanatory variables simultaneously, and the extent of their robustness to changes in specification. Researchers can then communicate the degree of support for a particular hypothesis with more faith that the results do not depend on arbitrary modeling choices. Perhaps the main open questions about these methods are those identified by Ciccone and Jarocinski (2007). From their analysis, it is clear that current approaches to Bayesian model averaging may have significant limitations of their own. The development of methods to overcome these should be a research priority.

Another reason for optimism is that the quality of available data is likely to improve over time. The development of new and better data has clearly been one of the main achievements of the empirical growth literature since the early 1990s, and one that was not foreseen by critics of the field. Researchers have developed increasingly sophisticated proxies for drivers of growth that previously appeared resistant to statistical analysis. One approach, pioneered in the growth literature by Knack and Keefer (1995) and Mauro (1995), has been the use of country-specific ratings compiled by international agencies. Such data increasingly form the basis for measures of corruption, government efficiency, and protection of property rights. More recent work, such as that of Kaufmann, Kraay and Zoido-Lobaton (1999a, 1999b) and Kaufmann, Kraay and Mastruzzi (2003), has established unusually comprehensive measures of various aspects of institutional quality. Similarly, research in political science, notably the POLITY project at the University of Maryland, has developed a range of indicators of political institutions that have already played an important role in empirical growth studies.

As more variables become available, the construction of proxies is likely to make increasing use of latent variable methods. These aim to reduce a set of observed variables to a smaller number of indicators that are seen as driving the majority of the variation in the original data, and that could represent some underlying variable of interest. For example, the extent of democracy is not directly observed, but is often obtained by applying factor analysis or extracting principal components from various dimensions of political freedom. There are obvious dangers with this approach, but the results can be effective proxies for concepts that are otherwise hard to measure.[29] Using latent variables makes especially good sense under one view of the proper aims of growth research. It is possible to argue that empirical growth studies will never give good answers to precise hypotheses, but can be informative at a broader level. For example, a growth regression is unlikely to tell us whether the growth effect of inflation is more important than the effect of inflation uncertainty, because these two variables are usually highly correlated. It may even be difficult to distinguish the effects of inflation from the effects of sizeable budget deficits.[30] Instead, a growth regression might be used to address a less precise hypothesis, such as the growth dividend of macroeconomic stability, broadly conceived. In this context, it is natural to use latent variable approaches to measure the broader concept.

Another valuable development is likely to be the creation of rich panel datasets at the level of regions within countries. Regional data offer greater scope for

controlling for some variables that are hard to measure at the country level, such as cultural factors. By comparing experiences across regions, there may also be scope for identifying events that correspond more closely to natural experiments than those found in cross-country data. Work such as that by Besley and Burgess (2000, 2002, 2004), using panel data on Indian states, shows the potential of such an approach. In working with such data more closely, one of the main challenges will be to develop empirical frameworks that incorporate movements of capital and labor between regions: clearly, regions within countries should only rarely be treated as closed economies. Shioji (2001) is an example of how analysis using regional data can take this into account.

Even with better data, at finer levels of disaggregation, the problem of omitted variables can only be alleviated, not resolved. It is possible to argue that the problem applies equally to historical research and case studies, but at least in these instances, the researcher may have some grasp of important forces that are difficult to quantify. Since growth researchers naturally gravitate towards determinants of growth that can be analyzed statistically, there is an ever-present danger that the empirical literature, even taken as a whole, yields a rather partial and unbalanced picture of the forces that truly matter. Even a growth model with high explanatory power, in a statistical sense, has to be seen as a rather provisional set of ideas about the forces that drive growth and development.

This brings us to our final points. We once again emphasize that empirical progress on the major growth questions requires attention to qualitative sources such as historical narratives and studies by country experts. One example we have given concerns the validity of instrumental variables: understanding the historical experiences of various countries seems critical for determining whether exclusion restrictions are plausible. In this regard work such as that of Acemoglu *et al.* (2001, 2002) is exemplary. More generally, nothing in the empirical growth literature suggests that issues of long-term development can be disassociated from the historical and cultural factors that fascinated commentators such as Max Weber, and the examination of these factors must rely at least partly on case studies, or risk missing some of the most interesting and important issues.

These questions have been asked for many decades, and the quest to understand the wealth of nations is as old as the discipline of economics itself. In contrast, growth econometrics is an area of research that is still in its infancy. Researchers in this field have shown flexibility in responding to the specific challenges and questions that arise in this context. They have introduced a number of statistical methods into applied economics, including classification and regression tree algorithms, robust estimation, threshold models and Bayesian model averaging, all of which appear to have wider utility. As with any new literature, especially one tackling questions as complex as these, it is easy to identify significant limitations of the existing evidence, and of the tools that are currently applied. Yet it seems clear to us that significant progress has been and continues to be made, even from the vantage point of our (2005) review. We therefore see good reasons for continued optimism.

Acknowledgments

This chapter updates and extends our earlier survey, Durlauf *et al.* (2005). Durlauf thanks the University of Wisconsin and National Science Foundation for financial support. Johnson thanks the Department of Economics, University of Wisconsin for its hospitality in Fall 2003, during which some of the preparation for this chapter was completed. Temple thanks the Leverhulme Trust for financial support under the Philip Leverhulme Prize Fellowship scheme. Finally, we thank Stephen Bond and William Brock for useful discussions.

Notes

1. See Temple (2000b) and Brock and Durlauf (2001a) for a conceptual discussion of this issue.
2. This independence assumption is sometimes defended either on theoretical grounds or because the parameter estimates are consistent with those predicted by the augmented Solow model.
3. Given the role it plays in the analysis of convergence, the initial income variable $\log y_{i,0}$ is usually distinguished from the other Solow variables.
4. Other early studies include Baumol (1986), DeLong (1988), Grier and Tullock (1989), Kormendi and Meguire (1985) and Marris (1982).
5. Note that while some failures of exchangeability call into question the interpretation of the regression, this is not always the case. For example, a heteroskedastistic error, while violating exchangeability, does not undermine the interpretation of the point estimates of the parameters. See Draper *et al.* (1993) for further discussion of the role of exchangeability in empirical work.
6. See the discussion in Brock *et al.* (2003) of the Ellsberg paradox.
7. For further discussion of extreme bounds analysis, see Temple (2000b) and the references therein.
8. In this discussion, we will assume that one of the models in the model space M is the correct specification of the growth process. When none of the model specifications is the correct one, this naturally affects the interpretation of the model averaging procedure.
9. Fernandez, Ley and Steel (2001b) provide a general analysis of proper model specific priors for model averaging exercises.
10. Sachs and Warner (1995) use this variable as an index of overall openness of an economy.
11. The posterior inclusion probabilities of single variables ignores their interdependence and so may be criticized for reasons similar to those we have raised with respect to model space priors that assume, for inclusion in a given model, conditional independence across variables. Doppelhofer and Weeks (2007) propose ways to measure the jointness of variable inclusion. Letting k and l denote the events "variable r_k appears in the true model" and "variable r_l appears in the true model," and using $\bar{k}$ and $\bar{l}$ to denote the complements of these events, the authors propose the jointness statistic

$$J_{k,l} = \log\left(\frac{\mu\left(k\,|l,D,M\right)}{\mu\left(\bar{k}\,|l,D,M\right)}\cdot\frac{\mu\left(\bar{k}\,\middle|\,\bar{l},D,M\right)}{\mu\left(k\,\middle|\,\bar{l},D,M\right)}\right)$$

to measure the degree of dependence between two candidate variables. The authors find that positive dependence is a common feature of the candidate growth determinants studied by Sala-i-Martin *et al.* (2004).

12. Here we are being imprecise in referring to within-model priors for Sala-i-Martin *et al*. (2004), but note that, following Ley and Steel (2008), their analysis is interpretable in this way.
13. A detailed discussion of regression tree methods appears in Breiman *et al*. (1984). The technical appendix of Durlauf and Johnson (1995) presents a treatment tailored to the specific question of identifying multiple regimes in growth models.
14. Motivated by the debate over trade openness and growth, Papageorgiou (2002) applies Hansen's (2000) methods to the Durlauf and Johnson (1995) data, with the trade share added to the set of variables on which sample splits may occur.
15. Projection pursuit methods are developed in Friedman and Tukey (1974) and Friedman (1987). Appendix A of Desdoigts (1999) provides a useful primer.
16. The assumed rarity of large shocks implies that movements between basins of attraction of each of the steady-states are sufficiently infrequent that they can be ignored in estimation. This assumption is consistent with, for example, the Bianchi (1997) and Paap and van Dijk (1998) findings that there is relatively little mobility within the cross-country income distribution.
17. See Temple (2003) for more discussion of this point and the long-run implications of different growth models.
18. This is true of the many published studies that have used version 5.6 of the Penn World Tables. Now that more recent data are available, there is more scope for estimating panels with a longer time dimension.
19. See Arellano (2003, pp. 47–51) for a more formal treatment of this issue.
20. Note that the long-run values of log output are evolving over time when time-specific effects are included in the model.
21. An alternative approach would be to use small-sample bias adjustments for GMM panel data estimators, such as those described in Hahn, Hausman and Kuersteiner (2001).
22. This connection with the treatment effect literature is sometimes explicitly made, as in Giavazzi and Tabellini (2005), Papaioannou and Siourounis (2007) and Persson and Tabellini (2003). The connection helps to understand the limitations of the evidence, but the scope for resolving the associated identification problems may be limited in cross-country datasets.
23. Although this "reverse causality" interpretation of endogeneity is popular and important, it should be remembered that a correlation between an explanatory variable and the error term can arise for other reasons, including omitted variables and measurement error. As we discuss, it is important to bear a general interpretation of the error term in mind when judging the plausibility of exclusion restrictions in instrumental variable procedures.
24. Put differently, one does not require a precise definition of what makes an instrument valid in order to debate whether a given instrument is valid or not. To take an example due to Taylor (1998), the absence of a precise definition of money does not weaken my belief that the currency in my wallet is a form of money, whereas the computer on which this paper is written is not. To claim such arguments cannot be made is known as the Socratic fallacy.
25. This estimator should not be confused with trimmed least squares and other methods based on deleting observations with large residuals in the OLS estimates. A residual-based approach is inadequate for obvious reasons.
26. This and the following discussion assume classical measurement error. Under more general assumptions, it is usually even harder to identify the consequences of measurement error for parameter estimates.
27. To give a specific example, the macroeconomic literature on international technology differences only rarely acknowledges relevant work by trade economists, including estimates of the Heckscher–Ohlin–Vanek model that suggest an important role for technology differences. See Acemoglu (2008) and Klenow and Rodriguez-Clare (1997) for more discussion.

28. Only now are researchers beginning to engage with some of the issues they raised, such as the varying conditions under which it is appropriate to use international rather than national prices in making productivity comparisons and constructing capital stocks.
29. A relevant question, not often asked, is how high the correlation between the proxy and the true predictor has to be for the estimated regression coefficient on the proxy to be of the "true" sign. Krasker and Pratt (1986, 1987) have developed methods that can be used to establish this under surprisingly general assumptions.
30. As Sala-i-Martin (1991) has argued, various specific indicators of macroeconomic instability should perhaps be seen as symptoms of some deeper, underlying characteristic of a country.

The Econometrics of Finance and Growth

Thorsten Beck

Abstract

This chapter reviews different econometric methodologies to assess the relationship between financial development and growth. It illustrates the identification problem, which is at the center of the finance and growth literature, using the example of a simple ordinary least squares estimation. It discusses cross-sectional and panel instrumental variable approaches to overcome the identification problem. It presents the time series approach, which focuses on the forecast capacity of financial development for future growth rates, and differences-in-differences techniques that try to overcome the identification problem by assessing the differential effect of financial sector development across states with different policies or across industries with different needs for external finance. Finally, it discusses firm- and household-level approaches that allow analysts to dig deeper into the channels and mechanisms through which financial development enhances growth and welfare, but pose their own methodological challenges.

25.1 Introduction

Economists have discussed over the past 100 years whether or not financial development has a causal impact on economic development. Theory suggests that effective financial institutions and markets that help overcome market frictions introduced by information asymmetries and transaction costs can foster economic growth through several channels. Specifically, they help (i) ease the exchange of goods and services by providing payment services, (ii) mobilize and pool savings

from a large number of investors, (iii) acquire and process information about enterprises and possible investment projects, thus allocating society's savings to its most productive use, (iv) monitor investments and exert corporate governance, and (v) diversify and reduce liquidity and intertemporal risk. However, other models show that higher returns from better resource allocation may depress saving rates, resulting in overall growth rates actually slowing with more effective financial markets and institutions.[1]

While the finding of a positive correlation between indicators of financial development and economic growth cannot settle this debate, advances in computational capacity and availability of large cross-country datasets with relatively large time dimensions have enabled researchers to rigorously explore the relationship between financial development and economic growth. Further, as more disaggregated datasets have become available, the finance and growth literature has proceeded from using country-level data, to using industry- and firm-level data, to more recently using household data. While the cross-country literature has developed more sophisticated models to address biases introduced by measurement error, reverse causation and omitted variables, the progress to firm- and household-level data allows not only additional ways to address these biases, but also tests of the specific channels through which finance might enhance economic growth.

The econometrics of finance and growth can be summarized in the following simple regression model:

$$g(i,t) = y(i,t) - y(i,t-1) = \alpha + \beta_i f(i,t) + C(i,t)\gamma_i + \mu(i) + \varepsilon(i,t), \qquad (25.1)$$

where y is the log of real GDP per capita or of another measure of welfare, g is the growth rate of y, f is an indicator of financial development, C is a set of conditioning information, μ and ε are error terms, i is the observational unit – be it a country, an industry, a firm or a household – and t is the time period. While ε is a white-noise error with a mean of zero, μ is a country-specific element of the error term that does not necessarily have a mean of zero. The explanatory variables are measured either as an average over the sample period or as an initial value. The sign and significance of the coefficient β_i is at the center of the debate. As discussed in the remainder of this chapter, the estimate of β_i can be biased for a variety of reasons, among them measurement error, reverse causation and omitted variable bias. While the cross-country literature assumes $\beta_i = \beta$, with some research supporting this assumption (Loayza and Ranciere, 2006), the time series literature does not impose this restriction. Further, several industry- and firm-level studies test whether β varies across industries or firms with different characteristics, utilizing interaction terms.

This chapter is concerned with an unbiased, consistent and efficient estimator of β_i.[2] In this context, we abstract from a number of other problems in the finance and growth literature. First, this chapter does not cover problems arising from the lack of appropriate data, although we are concerned about measurement error in the financial indicators and the bias this introduces in the estimation. Second, while

we are concerned about the bias introduced by the potential reverse causation from growth to finance, we are not concerned about this reverse causation *per se*, that is, we do not discuss in depth the literature focusing on the impact of economic growth on financial development and bidirectional causality. Finally, this chapter does not intend to be a fully-fledged survey of the empirical finance and growth literature, as is Levine (2005), but rather focuses on studies with methodological contributions.

While this chapter is concerned about estimating the relationship between finance and growth, some remarks about measuring financial development might be useful. While the theoretical literature links specific functions of the financial system to economic growth, data limitations have forced researchers to focus on variables capturing the size, activity or efficiency of specific financial institutions or markets. The first generation of papers in the finance and growth literature have built on aggregate data on financial institutions, mainly banks, available for 30–40-year periods for a large number of developed and developing countries. Such indicators include monetization variables, such as the ratio of M2 or M3 to gross domestic product (GDP), or financial depth indicators, such as the ratio of private credit (outstanding claims of financial institutions on the private sector) to GDP. Later papers have added indicators of the size and liquidity of stock markets, albeit available for fewer countries and shorter time periods. Indicators for the efficiency and competitiveness of financial systems, non-bank financial institutions such as institutional investors and, most importantly, the outreach of financial systems, are available for only a few countries and often do not have a time dimension.[3] Within-country studies allow researchers to utilize more micro-based data or focus on specific policy interventions or reforms.

The remainder of the chapter is structured as follows. Section 25.2 illustrates the identification problem, which is at the center of the finance and growth literature, using the example of a simple ordinary least squares (OLS) estimation of regression (25.1). Section 25.3 discusses instrumental variable (IV) approaches using cross-sectional and panel data. Section 25.4 discusses time series approaches, and section 25.5 differences-in-differences techniques. Section 25.6 discusses the use of firm- and household-level data and the methodological challenges this implies. Section 25.7 concludes and looks forward to new research directions.

25.2 Correlation versus causality: the identification problem

Goldsmith (1969) was the first to empirically show the positive correlation between financial development and GDP per capita, using data on the assets of financial intermediaries relative to GNP and data on the sum of net issues of bonds and securities plus changes in loans relative to GNP for 35 countries over the period 1860–1963. Such a correlation, however, does not control for other factors that are associated with economic growth and might thus be driven by other country characteristics correlated with both finance and growth. Second, such a correlation does not provide any information on the direction of causality between finance and growth. The early finance and growth literature has therefore used standard

cross-country OLS regressions that build on an augmented Barro growth regression as in (25.1), with data for each country averaged over the sample period, assuming $\beta_i = \beta$ and $\gamma_i = \gamma$ for all countries, and including the lagged dependent variable as a control variable:

$$g(i) = y(i,t) - y(i,t-1) = \alpha + \beta f(i) + C(i)\gamma + \delta y(i,t-1) + \varepsilon(i). \tag{25.2}$$

Unlike regression (25.1), regression (25.2) has thus only a cross-country, but not a time series, dimension. The log of initial income per capita is included to control for convergence predicted by the Solow–Swan growth models. Including other country characteristics, such as initial levels of human or physical capital, and policy variables, such as government consumption or trade openness, in a set of conditioning information allows testing for an independent partial correlation of finance with growth. The coefficient β is of interest for finance and growth researchers, who interpret a positive and significant coefficient as evidence for a positive partial correlation between finance and growth.

Running this cross-country regression for a sample of 77 countries over the period 1960–89, King and Levine (1993) found a positive and significant relationship between several financial development indicators and GDP per capita growth. Their study focuses mostly on monetization indicators and indicators measuring the size and relative importance of banking institutions. Using initial values of financial development confirms their finding. Levine and Zervos (1998) expanded the analysis to include measures of stock market development and found a positive partial correlation of both stock market and bank development with GDP per capita growth over the period 1976–94.[4] Interestingly, they found a positive and significant link between liquidity of stock markets – as measured by a turnover indicator or value traded to GDP – and economic growth, but no robust relationship between the size of stock markets and economic growth. The empirical relationship between finance and growth, however, is not only statistically, but also economically, significant. Levine and Zervos found that a one standard deviation change in stock market liquidity and banking sector development explains an annual GDP per capita growth difference of 0.8 and 0.7 percentage points, respectively, adding up to a total difference in GDP per capita of 31% over the 18-year sample period.

OLS estimates, however, are only consistent if the following orthogonality conditions hold:

$$E[C(i)'\varepsilon(i)] = 0; \quad E[y(i,t-1)'\varepsilon(i)] = 0; \quad E[f(i)'\varepsilon(i)] = 0. \tag{25.3}$$

A violation of this condition can arise for several reasons. First, the presence of an unobserved country-specific effect $\mu(i)$ – as in regression (25.1) – results in a positive correlation of the lagged dependent variable with the error term as, unlike the error term $\varepsilon(i)$, $\mu(i)$ does not have a mean of zero, so that:

$$E[y(i,t-1)'(\mu(i) + \varepsilon(i))] \neq 0. \tag{25.4}$$

Omitted variable bias can also arise if other explanatory variables are correlated with the unobserved country-specific effect or if explanatory variables that should

be included in regression (25.2) are (i) not included and (ii) correlated with included explanatory variables, so that:

$$E[C(i)'(\mu(i) + \varepsilon(i))] \neq 0. \tag{25.5}$$

Second, reverse causation from GDP per capita growth to financial development or another explanatory variable could violate the orthogonality condition and thus bias the estimator of β if $\varepsilon(i)$ and $\nu(i)$ are correlated with each other, as would occur if:

$$f(i) = \lambda y(i, t-1) + \nu(i). \tag{25.6}$$

Third, one of the explanatory variables could be mismeasured, so that:

$$f^*(i) = f(i) + u(i), \tag{25.7}$$

where f^* is the true level and f is the measured level of financial development. This could result in attenuation bias if the measurement error is correlated with f.

Several simple approaches to overcome these biases have been suggested. First, controlling for other country traits and policies can help minimize the omitted variable bias and allow testing for the robustness of the finance and growth link (Levine and Renelt, 1992). However, the number of observations, and thus degrees of freedom, severely limits this approach in a typical cross-country regression. Second, several studies have used initial values of financial development, rather than values averaged over the same period as GDP per capita growth. If the true time span over which an improvement in financial development results in higher growth is shorter than the sample period used in the regression, then using initial values might reduce biases stemming from reverse causation. On the other hand, using initial values does not correct for biases introduced by omitted variables, measurement error or the inclusion of the lagged dependent variable, and implies a loss of information to be used in the estimation. Third, using panel regressions with fixed country effects would eliminate any time-invariant omitted variable bias and time-invariant measurement bias. However, the correlation between the transformed lagged dependent variable and the transformed error term will make the fixed-effect estimator biased, and this bias is only eliminated as the number of time periods goes towards infinity, which is certainly not the case for the typical growth regression with fewer than 40 annual data points. Finally, fixed-effect regressions also have the conceptual shortcoming that they effectively limit the analysis to within-country variation in growth and financial development by differencing-out cross-country variation.

25.3 The IV approach

The classical approach in cross-country growth regressions to overcome the biases related to OLS is to identify an instrument that helps isolate that part of the variation in the endogenous variable that is not associated with reverse causation,

omitted variables and measurement error. Following the seminal work by La Porta *et al.* (1997, 1998), who identified variation in countries' legal origin as an historical exogenous factor explaining current variation in countries' level of financial development, an extensive literature has utilized this variable to extract the exogenous component of financial development.

To overcome biases related to the inclusion of the lagged dependent variable and omitted variable bias, while at the same time controlling for reverse causation and measurement error, researchers have utilized dynamic panel regressions using lagged values of the explanatory endogenous variables as instruments. Finally, to control for country heterogeneity in the finance–growth relationship, researchers have utilized pooled mean group estimators. We will discuss each methodology in turn.

25.3.1 Cross-sectional regressions

Underlying IV estimation is the following specification:

$$g(i) = y(i,t) - y(i,t-1) = \alpha_1 + \beta_1 f(i) + C(i)\gamma_1 + \delta_1 y(i,t-1) + \varepsilon(i) \tag{25.8}$$

$$f(i) = \alpha_2 + Z(i)\beta_2 + C(i)\gamma_2 + \delta_2 y(i,t-1) + \nu(i) \tag{25.9}$$

$$f^*(i) = f(i) + u(i), \tag{25.10}$$

where C are the included exogenous and Z the excluded exogenous control variables; the latter are also referred to as IVs which allow us to extract the exogenous component of $f(i)$ that is not correlated with $\varepsilon(i)$, that is, $E[Z(i)'\varepsilon(i)] = 0$, and $E[Z(i)'u(i)] = 0$.[5] Estimating regression (25.8) with instruments can help alleviate biases arising from reverse causation, omitted variables and measurement error.

Regression (25.8) is typically estimated with a two-stage least squares (2SLS) estimator. Unlike the OLS estimator, the 2SLS estimator only uses the variation in the explanatory variables that is correlated with the instrument and therefore uses less information than the OLS estimator. If OLS is consistent, it is therefore more efficient than IV, whereas if OLS is inconsistent, the IV estimator is both consistent and efficient.[6]

The 2SLS estimator can also be derived as a generalized method of moments (GMM) estimator that minimizes a set of orthogonality conditions (Hansen, 1982). In the case where there are more excluded exogenous than endogenous variables, a weighting matrix has to be used. While the 2SLS estimator uses a weighting matrix constructed under the assumption of homoskedasticity, the weighting matrix of the GMM estimator is constructed as the inverse of the variance-covariance matrix, thus assigning different weights to the orthogonality condition, according to their variances. While the 2SLS estimator is thus consistent, it is inefficient as it does not use all the available information. On the other hand, the GMM estimator relies on asymptotic characteristics and therefore suffers from a finite-sample bias as the optimal weighting matrix is a function of fourth moments (Hayashi, 2000).[7]

Using legal origin as an instrument for financial development, Levine (1998, 1999) finds a positive relationship between finance and economic growth. Researchers have also used other historical and exogenous country characteristics

as instruments for financial development, such as settler mortality and latitude, to proxy for geographic conditions, ethnic fractionalization, religious composition of the population, and years since independence (McCraig and Stengos, 2005). Guiso, Sapienza and Zingales (2004) use sub-national variation in historical bank restriction indicators across 20 Italian regions and its 103 provinces as IVs to assess the impact of financial development and competition on economic growth and other real sector outcomes.

IV regressions depend on the quality of the IVs, independent of whether 2SLS or GMM is applied. As discussed above, these instruments are typically exogenous country characteristics, such as geographic traits, or based on historical experience, such as legal origin. The challenge is to identify the economic mechanisms through which the IVs influence the endogenous variable – financial development – while at the same time assuring that the instruments are not correlated with growth directly. An extensive literature has discussed the historic determinants of financial sector development and the channels through which, for example, legal origin has helped shape current financial sector development,[8] but there are also several formal econometric conditions to be fulfilled in order for an instrument to be valid. First, the exogenous variables cannot be correlated with error terms, that is, $E[Z(i)'\varepsilon(i)] = 0$ (orthogonality or exogeneity condition). Second, the excluded exogenous instruments have to explain the variation in the endogenous variables after controlling for the included exogenous variables, that is, the F-test for $Z(i)$ in (25.9) is rejected at conventional levels (relevance condition).

The orthogonality condition is typically tested with the Sargan (1958) test of overidentifying restrictions (OIR) if there are more instruments than explanatory variables, that is: $\hat{\varepsilon}'Z(Z'Z)^{-1}Z'\hat{\varepsilon}/\widehat{\sigma^2}$, where $\widehat{\sigma^2} = (\hat{\varepsilon}'\hat{\varepsilon})/n$ and $\hat{\varepsilon}$ is the vector of residuals from estimating regression (25.8). This test can easily be calculated from a regression of the IV regression residuals on included and excluded exogenous variables. It is distributed as χ^2 with $(J - K)$ degrees of freedom under the null hypothesis that the residuals are not correlated with the exogenous variables, where J is the number of instruments and K is the number endogenous variables.[9] Hansen's (1982) J-test is a generalization of the Sargan OIR test to the GMM context and is the value of the GMM objective function evaluated at the efficient GMM estimator: $\hat{\varepsilon}'Z(Z'\hat{\Omega}Z)^{-1}Z'\hat{\varepsilon}$, where $\hat{\Omega}$ is the estimated variance-covariance matrix of the residuals from regression (25.8). As with the Sargan test, Hansen's test is distributed as χ^2 with $(J - K)$ degrees of freedom.

The test of OIR, however, is relatively weak. First, the test only assesses the validity of any additional instruments, that is, it cannot be performed if the number of excluded exogenous variables is the same as the number of endogenous variables. Further, the test tends to reject the null hypothesis of valid instruments too often in small samples (Murray, 2006). Most importantly, the test over-rejects if the instruments are weak, that is, if they do not explain the endogenous variables in the first stage.

The second condition of instrument relevance can be tested in different ways. First, one can use an F-test of the joint significance of the instruments in (25.9);

the critical values of this F-test for IV estimation, however, are larger than for OLS estimation; for the case of a single endogenous variable, Staiger and Stock (1997) show, using Monte Carlo simulations, that for most specifications and independent of the degrees of freedom, a critical value of 10 is sufficient to reject the null hypothesis, and Stock and Yogo (2005) derive critical values for this F-test for the case of several endogenous variables, with the critical values increasing with the number of instruments.[10] Second, one can use a partial R^2 of the first-stage regression (25.9) that takes into account the intercorrelation among the instruments (Shea, 1997). Specifically, Godfrey (1999) shows that this statistic for endogenous regressor *i* is:

$$\frac{\hat{\sigma}_i^{OLS}}{\hat{\sigma}_i^{IV}}\left[\frac{\left(1-R_{IV}^2\right)}{\left(1-R_{OLS}^2\right)}\right],$$

where $\hat{\sigma}_i$ is the estimated asymptotic variance of the coefficient *i*. This measure thus tests for the relevance of the individual instruments, unlike the F-test, which tests for the overall relevance.

Weak instruments can bias the IV results towards OLS and turn them inconsistent. Further, weak instruments can result in an over-rejection of the overidentification test discussed above. If instruments are both invalid and irrelevant, the bias thus increases in a multiplicative way.[11]

Most of the cross-country finance and growth papers utilizing IVs find that the IV estimator of β_1 is higher than the OLS estimator.[12] Manipulating regressions (25.8), (25.9) and (25.10), one can show that this implies:

$$\hat{\delta}_2 + \hat{\rho}\frac{\widehat{\sigma(\upsilon)}}{\widehat{\sigma(\varepsilon)}} < \hat{\beta}_1\left(1-\hat{\beta}_1\hat{\delta}_2\right)\frac{\widehat{\sigma(u)}}{\widehat{\sigma(\varepsilon)}}, \tag{25.11}$$

where ρ is the correlation between ε and υ, and the other parameters are taken from regressions (25.8), (25.9) and (25.10). There are several possible explanations for this finding and thus for inequality (25.11) to hold (Kraay and Kaufman, 2002). First, there could be negative reverse causation ($\delta_2 < 0$), which would bias the OLS estimator of the β_1 coefficient downwards. Given empirical studies showing the positive relationship between economic and financial development, this explanation seems rather unlikely (Harrison, Sussman and Zeira, 1999). A second explanation that makes inequality (25.11) hold is that omitted variables are correlated with growth and finance with opposite signs ($\rho < 0$), an explanation for which, again, little evidence exists. A third – and most commonly adopted – explanation relies on attenuation bias, where measurement error in financial development ($\widehat{\sigma(u)}$) biases the OLS estimate downwards and makes inequality (25.11) hold. Critically, however, if the IVs are positively correlated with omitted variables and the exclusion condition is thus violated, the IV estimator of β_1 is biased upwards. This is of concern, as a few IVs, such as historical country traits, have been

used for many different institutional variables in the context of growth regressions (Pande and Udry, 2006). Specifically, legal origin has been shown to be associated with an array of institutional arrangements, ranging from financial markets over general regulatory approaches, to labor market institutions. A significant correlation between institutional variables left out of the regressions and the IVs can therefore also result in an upwardly biased IV estimator of β_1.

25.3.2 Dynamic panel analysis

While the cross-sectional IV regressions address biases related to omitted variables, reverse causation and measurement error, they do face several limitations. First, cross-country studies using cross-sectional IV regressions typically control only for the endogeneity and measurement error of financial development, but not of other explanatory variables entering the growth regressions. Second, in the presence of country-specific omitted variables, the lagged dependent variable is correlated with the error term if it is not instrumented.

As an alternative to cross-sectional IV regressions, researchers have therefore used dynamic panel regressions of the following format:

$$g(i,t) = \alpha + \beta f(i,t) + C^{(1)}(i,t)\gamma_1 + C^{(2)}(i,t)\gamma_2 + \delta y(i,t-1) + \mu(i) + \lambda(t) + \varepsilon(i,t), \tag{25.12}$$

where $C^{(1)}$ represents a set of exogenous explanatory variables, $C^{(2)}$ a set of endogenous explanatory variables, and λ a vector of time dummies. Note that β is still assumed to be constant across countries, a restriction that we will relax further below.

Unlike the cross-sectional regressions, which use external instruments, that is, variables that are completely external to the second-stage regression, the dynamic panel regressions use internal instruments, that is, lagged realizations of the explanatory variables. While this method does not control for full endogeneity, it does control for weak exogeneity, which means that current realizations of f or variables in $C^{(2)}$ can be affected by current and past realizations of the growth rate, but must be uncorrelated with future realizations of the error term. Thus, under the weak exogeneity assumption, future innovations of the growth rate do not affect current financial development.

In order to address the different biases in regression (25.12), Arellano and Bond (1991) suggest first-differencing the regression equation to eliminate the country-specific effect, as follows:[13]

$$\Delta g(i,t) = \beta \Delta f(i,t) + \Delta C^{(1)}(i,t)\gamma_1 + \Delta C^{(2)}(i,t)\gamma_2 + \delta \Delta y(i,t-1) + \Delta\lambda(t) + \Delta\varepsilon(i,t), \tag{25.13}$$

where $\Delta x(t) = x(t) - x(t-1)$. This procedure solves the omitted variable bias, as described above, but introduces a correlation between the new error term, $\Delta\varepsilon(i,t)$, and the lagged dependent variable, $\Delta y(i,t-1)$. To address this correlation and the endogeneity and measurement problems, Arellano and Bond suggest using lagged

values of the explanatory variables in levels as instruments for current differences of the endogenous variables. Under the assumptions that there is no serial correlation in the error term ε and that the explanatory variables f and $C^{(2)}$ are weakly exogenous, one can use the following moment conditions to estimate regression (25.13):

$$\begin{aligned} E[f(i,t-s)'\Delta\varepsilon(i,t)] &= 0, \quad \text{for each } t = 3,\ldots,T, s \geq 2 \\ E\left[C^{(2)}(i,t-s)'\Delta\varepsilon(i,t)\right] &= 0, \quad \text{for each } t = 3,\ldots,T, s \geq 2 \\ E[y(i,t-s)'\Delta\varepsilon(i,t)] &= 0, \quad \text{for each } t = 3,\ldots,T, s \geq 2. \end{aligned} \tag{25.14}$$

Using these moment conditions, Arellano and Bond propose a two-step GMM difference estimator. In the first step, the error terms are assumed to be both independent and homoskedastic across countries and over time, while in the second step, the residuals obtained in the first step are used to construct a consistent estimate of the variance-covariance matrix, thus relaxing the assumptions of independence and homoskedasticity. Simulations, however, have shown very modest efficiency gains from using the two-step as opposed to the one-step estimator, while the two-step estimator tends to underestimate the standard errors of the coefficient given that the two-step weight matrix depends on estimated parameters from the one-step estimator (Bond and Windmeijer, 2002).

There are several conceptual and econometric shortcomings with the difference estimator. First, by first-differencing we lose the pure cross-country dimension of the data. Second, differencing may decrease the signal-to-noise ratio, thereby exacerbating measurement error biases (see Griliches and Hausman, 1986). Finally, Alonso-Borrego and Arellano (1999) and Blundell and Bond (1998) show that, if the lagged dependent and the explanatory variables are persistent over time, that is, have very high autocorrelation, then the lagged levels of these variables are weak instruments for the regressions in differences.[14] Simulation studies show that the difference estimator has a large finite-sample bias and poor precision.

To address these conceptual and econometric problems, Arellano and Bover (1995) suggest an alternative estimator that combines the regression in differences with the regression in levels. Using Monte Carlo experiments, Blundell and Bond (1998) show that the inclusion of the level regression in the estimation reduces the potential biases in finite samples and the asymptotic imprecision associated with the difference estimator. Using the regression in levels, however, does not directly eliminate the country-specific effect μ. Lagged differences of the explanatory variables can be used as instruments for the levels of the endogenous explanatory variables under the assumption that the correlation between μ and the levels of the explanatory variables is constant over time, such that:

$$\begin{aligned} E[f(i,t+p)'\mu(i)] &= E[f(i,t+q)'\mu(i)], \quad \text{for all } p \text{ and } q \\ E\left[C^{(2)}(i,t+p)'\mu(i)\right] &= E\left[C^{(2)}(i,t+q)'\mu(i)\right], \quad \text{for all } p \text{ and } q. \end{aligned} \tag{25.15}$$

Under this assumption, lagged differences are valid instruments for the regression in levels, and the moment conditions for the regression in levels are as follows:

$$
\begin{aligned}
E[\Delta f(i,t-s)'(\varepsilon(i,t)+\mu(i))] &= 0, \quad \text{for each } t=3,\ldots,T, s=2 \\
E\left[\Delta C^{(2)}(i,t-s)'(\varepsilon(i,t)+\mu(i))\right] &= 0, \quad \text{for each } t=3,\ldots,T, s=2 \\
E[\Delta y(i,t-s)'(\varepsilon(i,t)+\mu(i))] &= 0, \quad \text{for each } t=3,\ldots,T, s=2. \qquad (25.16)
\end{aligned}
$$

The system thus consists of the stacked regressions in differences and levels, with the moment conditions in (25.14) applied to the first part of the system, the regressions in differences, and the moment conditions in (25.16) applied to the second part, the regressions in levels.[15] As with the difference estimator, the model is estimated in a two-step GMM procedure.

The consistency of the GMM estimator depends both on the validity of the instruments (exclusion condition) and the assumption that the error term, ε, does not exhibit serial correlation. Arellano and Bond (1991) propose two tests to examine these assumptions. The first is a Sargan test of OIR, which is constructed in a similar manner to the cross-sectional test discussed above. In the context of the system estimator, one can also compute a "difference-in-Sargan" test, the C-statistic (Eichenbaum, Hansen and Singleton, 1988), to test the orthogonality condition of a sub-set of instruments, such as the instruments applied to the level regressions. The C-statistic is computed as the difference of two Sargan/Hansen statistics, the one for the regression using the full set of instruments and the one using a smaller set of instruments. The C-statistic is distributed as χ^2 with the degrees of freedom equal to the number of instruments dropped from the second regression.

The second test examines the assumption of no serial correlation in the error terms, specifically whether the differenced error term is second-order serially correlated as, by construction, the error term $\Delta\varepsilon(i,t)$ from the difference regression is first-order serially correlated and we cannot use the error terms from the regression in levels since they include the country-specific effect μ. This test is based on the standardized average residual autocovariances and, under the null hypothesis of no second-order serial correlation, has a standard normal distribution.

Rousseau and Wachtel (2000) use the difference estimator with annual data over the period 1980–95 across 47 countries and find a positive link between indicators of bank and stock market development and economic growth.[16] Using five-year averages over the period 1960–95 across 74 countries, Beck, Levine and Loayza (2000) and Levine, Loayza and Beck (2000) use both the difference and the system estimator and find a positive and significant relationship between indicators of financial intermediary development and GDP per capita growth, with the specification tests referred to above confirming the validity of both instruments and econometric model.[17] Beck *et al.* (2000) also find that the effect of finance on growth is through productivity growth, while there is no robust relationship between financial development and capital accumulation when controlling for biases due to simultaneity, omitted variables and measurement error.

The dynamic panel estimators have typically been applied to panels with few time periods and many countries. Further, the instrumental variable matrix Z is typically constructed with separate columns for instruments in different time periods, resulting in a quadratic increase in the number of columns of Z as the number of time periods increases (Roodman, 2007). This results in an overfit of the endogenous variables, biasing the coefficient estimates towards OLS estimates and biasing the Sargan/Hansen test for joint validity of the instruments towards over-accepting the null hypothesis (Bowsher, 2002). In order to avoid overfitting, one can limit the number of lags used in the difference regression or combine instruments into smaller sets, effectively imposing the constraint that instruments of each lag distance have the same coefficient when projecting regressors onto instruments (Beck and Levine, 2004; Roodman, 2007). In this case, the orthogonality conditions for the difference regressions are:

$$\begin{aligned} E[f(i,t-s)'\Delta\varepsilon(i,t)] &= 0, \quad \text{for each } s \geq 2 \\ E\left[C^{(2)}(i,t-s)'\Delta\varepsilon(i,t)\right] &= 0, \quad \text{for each } s \geq 2 \\ E[y(i,t-s)'\Delta\varepsilon(i,t)] &= 0, \quad \text{for each } s \geq 2, \end{aligned} \tag{25.17}$$

and the orthogonality conditions for the levels regressions are:

$$\begin{aligned} E[\Delta f(i,t-s)'(\varepsilon(i,t)+\mu(i))] &= 0, \quad \text{for each } s \geq 2 \\ E\left[\Delta C^{2}(i,t-s)'(\varepsilon(i,t)+\mu(i))\right] &= 0, \quad \text{for each } s \geq 2 \\ E[\Delta y(i,t-s)'(\varepsilon(i,t)+\mu(i))] &= 0, \quad \text{for each } s \geq 2. \end{aligned} \tag{25.18}$$

Given that data on financial sector indicators for a broad cross-section of countries are only available for a 25–40-year period, most studies split the sample period into non-overlapping five-year periods, thus controlling for business cycle effects, while at the same time having a reasonable number of time periods. An alternative to splitting the sample period into a number of five-year periods is to utilize overlapping five-year periods, as proposed by Bekaert, Harvey and Lundblad (2005), thus allowing researchers to increase the number of time periods in the panel. In order to control for the MA(4) character of the data, the weighting matrix of the GMM estimator has to be adjusted accordingly.

Both the cross-sectional and the dynamic panel regressions discussed up to now assume a homogeneous relationship between finance and growth across countries, that is, $\beta_i = \beta$. At the other extreme, the time series approach, discussed in the next section, assumes complete country heterogeneity, but relies on a sufficiently large time series of data. When both cross-country and time series dimension are sufficiently large, Pesaran, Smith and Im (1995) show that a consistent mean coefficient across countries is the unweighted average of the coefficients from independent country regressions (mean group (MG) estimator). The pooled mean group (PMG) estimator, introduced by Pesaran, Shin and Smith (1999), is in between

these two extremes of cross-country and time series approaches, as it imposes the same coefficient across countries on the long-run coefficients, but allows the short-run coefficients and intercepts to be country-specific. Loayza and Ranciere (2006) use the PMG estimator on a sample of 75 countries and annual data over the period 1960–2000 and find a positive long-run relationship between financial development and growth, while the mean short-run coefficient on current financial development enters negatively.[18] Using the Hausman test that compares the MG with the PMG model, they cannot reject the hypothesis that the long-run coefficients on finance are the same in a cross-country panel growth regression. This is also evidence that the assumption that $\beta_i = \beta$ in the cross-country estimations discussed so far is a valid one, as long as the focus is on the long-term relationship between financial development and economic growth.

25.4 The time series approach

The use of higher-frequency data, often limited to one or a few countries, and the concept of causality are the main differences between the time series approach and the cross-country approach discussed in the previous section. First, the time series approach relies on higher-frequency data, mostly yearly, to gain econometric power, while the cross-country approach typically utilizes multi-year averages.[19] Further, the time series approach relaxes the somewhat restrictive assumption of the finance–growth relationship being the same across countries, that is, $\beta_i = \beta$, and allows country heterogeneity of the finance–growth relationship; most studies therefore focus their analysis on a few countries with long time series data. The time series approach also directly addresses biases introduced by the persistence and potential unit root behavior of financial development, as we will see in the following.

Second, and more importantly, different causality concepts underlie the two approaches. The time series approach relies on the concept of Granger causality, as first developed by Granger (1969). A time series X is said to Granger-cause Y if, controlling for lagged Y values, lagged X values provide statistically significant information about the current value of Y. Granger causality tests are tests of forecast capacity; that is, to what extent does one series contain information about the other series? Unlike the cross-country panel regressions discussed earlier, this concept therefore does not control for omitted variable bias by directly including other variables or by controlling with instrumental variables. Rather, by including a rich lag structure, which is lacking in the cross-sectional approach, the time series approach hopes to capture omitted variables. The cross-country approach, on the other hand, estimates the empirical relationship between finance and growth controlling for the different biases discussed in section 25.2, including the omitted variable bias, by extracting an exogenous component of finance that is related to growth only through finance.

In the context of the finance and growth literature, finance is said to Granger-cause GDP per capita if the inclusion of past values of finance in a regression of GDP per capita on its lags and the conditioning information set reduces the mean

squared error *mse*. Formally:

$$mse[y(t+s)/y(t), y(t-1), \ldots] > mse[y(t+s)/y(t), y(t-1), \ldots, f(t), f(t-1), \ldots], \tag{25.19}$$

where the null hypothesis of no Granger causality is typically tested using F-tests on current and lagged values of f. Most studies test for bidirectional Granger causality using the following vector autoregression (VAR) system:

$$Y(t) = \alpha_1 Y(t-1) + \alpha_2 Y(t-2) + \cdots + \alpha_j Y(t-j) + \mu(t), \tag{25.20}$$

where Y is a vector comprising both GDP per capita and finance, as well as possibly other macroeconomic variables, and μ is a vector of error terms. Jung (1986) finds evidence for Granger causality from finance to GDP per capita for a sample of 56 countries, with some evidence of reverse Granger causality in the case of developed countries.

Testing for Granger causality between finance and GDP per capita using a levels VAR has the shortcoming that both finance and GDP per capita are non-stationary variables in most countries, as shown by standard tests for unit roots, such as the augmented Dickey–Fuller (ADF) and Phillips and Perron (PP) tests, but stationary in first differences. However, only if two (or more) non-stationary series are co-integrated, that is, if some linear combination of the series is stationary, can one use a levels VAR to test for Granger causality (Toda and Phillips, 1993, 1994). Co-integration thus implies a long-run equilibrium relationship between finance and GDP per capita. As in the case of Granger causality, cointegration does not directly control for omitted variable or measurement biases, but rather exploits the long time series of data to assess whether there is a stable relationship between these two variables.

If the vector Y is cointegrated, regression (25.20) can be rewritten in the vector error correction (VEC) form (Engle and Granger, 1987):

$$\Delta Y(t) = \alpha_1 \Delta Y(t-1) + \alpha_2 \Delta Y(t-2) + \cdots + \gamma \delta' Y(t-1) + \mu(t), \tag{25.21}$$

where the vector γ of error correction coefficients (loading factors) indicates the direction and speed of adjustment of the respective dependent variable to temporary deviations from the long-run relationship, while δ is the cointegrating vector. If there exists a non-zero cointegrating vector such that $\delta' Y(t)$ is stationary, the variables in Y are considered cointegrated. Testing for cointegration of the vector $Y(t)$ therefore is equivalent to a test that $\delta' Y(t)$ is stationary. If we can reject the null hypothesis that $\delta' Y(t)$ is stationary, we can also reject the null hypothesis that $Y(t)$ is cointegrated. In the case of two variables, this implies testing the residuals from a regression of $y(1,t)$ on $y(2,t)$ or $y(2,t)$ on $y(1,t)$ for stationarity. While the standard ADF test can be applied, the critical values are not the same as the test is performed on estimated residuals (Engle and Yoo, 1987). If there is no unit root, the two variables are cointegrated. In the case of more than two variables, inferences on the number and coefficients of the cointegrating vectors can be based

on Johansen's (1991) full information maximum likelihood approach. Johansen (1988) and Johansen and Juselius (1990) show that the maximum likelihood estimator of γ and δ can be derived as a solution of a generalized eigenvalue problem, and likelihood ratio tests, based on these eigenvalues, can be used to test hypotheses on the number of cointegrating vectors.[20] The number of linear independent cointegrating vectors is equal to the rank of the matrix δ. Alternatively, one can test the hypothesis of a specific known cointegrating vector (Horvath and Watson, 1995), as done by Neusser and Kugler (1998).

Demetriades and Hussein (1996) and Luintel and Khan (1999) use the VEC specification and test for weak exogeneity of finance to GDP per capita by testing the null hypothesis that the corresponding loading factor in the GDP per capita regression in (25.21) is zero, while they follow Toda and Phillips' (1993) suggestion and use the product of the loading factor and the cointegrating parameter to test for long-run causality. While Demetriades and Hussein (1996) find evidence for bidirectional causality and reverse causation from income to finance across a sample of 16 developing countries with at least 27 annual observations, with results varying substantially from country to country, Luintel and Khan (1999) find consistent evidence for bidirectional causality across a sample of ten developing countries with at least 36 years of data.

In the case of a cointegrating relationship between finance and GDP per capita, however, a levels VAR as in (25.20) can be used to test for short-term Granger causality, with conventional F-test statistics applying (Toda and Phillips, 1993, 1994; Sims, Stock and Watson, 1990),[21] and the VEC representation in (25.21) to estimate the adjustment speed γ. Rousseau and Wachtel (1998) use both the VAR specification of (25.20) and the VEC specification of (25.21) to determine the direction of causality between economic and financial development for five industrialized countries for the period 1870–1929. Specifically, using the VEC specification of (25.21), they find a cointegrating relationship for all five countries, while Granger causality tests suggest that finance leads GDP per capita in all five countries.[22] In addition, Neusser and Kugler (1998) apply the Granger and Lin (1995) test to measure the strength of causality from finance to GDP per capita at frequency zero, that is, in the long term, which is a function of the correlation of the errors in a bivariate VEC model and the adjustment coefficient vector γ.

In order to gain degrees of freedom, as unit root and cointegration tests have low power in the case of short time series, several studies have expanded the time series approach to panel data (Neusser and Kugler, 1998; Christopoulos and Tsionas, 2004). Averaging individual Dickey–Fuller unit root tests yields the Im, Pesaran and Shin (2003) test, while combining p-values from individual ADF tests yields the Maddala and Wu (1999) test, both of which allow testing for a unit root in panels. To establish cointegration relationships in a panel, Pedroni (1997) suggests estimating the cointegrating regression by OLS separately for each country before a unit root test similar to the PP test is applied to the stacked residuals. Further, the VEC specification (25.21) can be extended to a panel with country-specific fixed effects to test for both long- and short-run relationships between finance and GDP per capita. Christopoulos and Tsionas (2004) find evidence for cointegration and

long-run Granger causality from finance to GDP per capita for a sample of ten developing countries for the period 1970–2000, both for individual countries and for the panel. Unlike other studies in the time series tradition, they also confirm their findings by applying dynamic panel regression techniques using lagged values as instruments in the panel version of (25.21).

Using Geweke's (1982) measure of linear dependence, Calderon and Liu (2003) compute the relative strength of Granger causality from finance to GDP per capita, from GDP per capita to finance and the instantaneous feedback between finance and GDP per capita. Specifically, using variance-covariance matrices calculated under different restrictions on the system (25.20) allows calculating a measure of the overall strength of the relationship between the two variables and the three different sources. They find a stronger effect from finance to GDP per capita than for the reverse effect for developing countries, which increases when they average data over longer time periods. While they consider the linear decomposition in the context of panel regressions, with data averaged over five-year periods, they do not assess the finance–GDP per capita relationship at different frequencies.

25.5 Differences-in-differences estimations

While the cross-country IV approach focuses on identifying instruments to overcome the different biases found in an OLS regression, and the time series approach focuses on the forecast capacity of finance in a VAR including GDP per capita, the differences-in-differences technique can be understood as a "smoking gun" or controlled treatment approach. Specifically, traditional differences-in-differences estimation consists of comparing the difference between the treatment and the control groups before and after a treatment, such as a policy change, thus controlling for other confounding influences on growth.[23]

The seminal paper in this literature is Jayartne and Strahan (1996), who exploit the fact that states across the US deregulated intrastate branch restrictions at different times over the period 1970–1995 and relate this policy change to subsequent state-level growth. In this case the treatment and control groups are in flux; at any point in time, the treatment group consists of states that have deregulated, while the control group consists of those states that have not deregulated yet. By controlling for state- and year-specific effects, this approach effectively measures the impact of deregulation on state-level growth relative to the average state-level growth rate over the sample period and relative to the average growth rate in the US in this specific year. The specification is:

$$g(i,t) = \alpha(i) + \lambda(t) + \beta d(i,t) + C(i,t)\gamma + \delta y(i,t-1) + \varepsilon(i,t), \quad i = 1,\ldots,49; \\ t = 1976,\ldots,1994, \tag{25.22}$$

where $\alpha(i)$ is a vector of state dummies, $\lambda(t)$ a vector of year dummies, $C(i,t)$ a vector of time-varying state characteristics and d the treatment variable, which is branch deregulation in the case of Jayaratne and Strahan (1996), who found a positive and significant coefficient β, thus suggesting that branch deregulation led

to higher growth.[24] They also find evidence for a large economic effect of branch deregulation, explaining an annual growth difference of at least 0.5 percentage points, compared to an average annual growth rate across states of 1.6%. Consistent with cross-country results, they also find evidence that the finance–growth nexus worked through improved lending efficiency rather than more lending and investment.

The differences-in-differences estimator reduces, but does not eliminate, the biases of reverse causation and omitted variables. Specifically, any omitted variable has to be time-variant in order to bias the results, because otherwise it would be picked up by the state dummies. Further, by considering sub-national variation, differences-in-differences estimation is less subject to biases introduced by unobserved heterogeneity across countries and measurement error is reduced as the focus is on one specific policy measure, implemented in the same way but at different times across sub-national units.[25] On the other hand, the events in different states, such as branch deregulation, were not independent from each other, but rather came in waves, which might bias the estimate of β (Huang, 2008). Further, the concern of reverse causation can only be addressed by utilizing instrumental variables or by showing that the decision to implement the policy change across states is not correlated with future growth rates, as was done by Jayaratne and Strahan (1996).

Apart from the problem of endogeneity, serial correlation of the error terms in differences-in-differences estimations can lead to underestimation of standard errors, as shown by Bertrand, Duflo and Mullainathan (2004).[26] This problem increases with the number of time periods and the persistence of the dependent variable and is exacerbated by the fact that the treatment variable, for example, branch deregulation, shows little change across states, at most one change from zero to one. Using Monte Carlo simulation, Bertrand, Duflo and Mullainathan show that collapsing data to before and after-treatment[27] or allowing for correlation within states (clustering) are solutions that resolve the problem of underestimated standard errors.

Going even more local, Huang (2008) uses county-level data from contiguous counties only separated by a state border in cases where one state deregulated at least three years earlier than the other. This helps reduce concerns of omitted variables, as one can assume a very similar structure of two contiguous counties and also helps reduce concerns of reverse causation, as expected higher future growth of a specific county is unlikely to affect state-level political decisions.[28, 29]

A somewhat related differences-in-differences approach is suggested by Rajan and Zingales (1998), who conjecture that the effect of financial development should vary by sector or industry according to the financing need of each sector or industry. They thus assess the finance and growth link by focusing on a specific channel through which financial development should foster economic development, that is, the channeling of society's savings to industries with the highest demand for external finance. Specifically, they use variation across industries in their dependence on external finance and variation across countries in their level of financial development to assess the impact of finance on industry growth, and apply the

following specification:[30]

$$g(i,k) = \alpha(i) + \lambda(k) + \beta(External(k)^{*}f(i)) + \gamma Share(i,k) + (Industry(k)^{*}Country(i))\delta + \varepsilon(i,k), \quad (25.23)$$

where g is growth of value added in industry k in country i; α and λ are vectors of country and industry dummies; *Share* is the initial share of industry k's value added in total manufacturing value added of country i; *External* is the external dependence of industry k; f is a measure of financial development in country i; *Industry* is a vector of other industry characteristics that do not vary across countries; and *Country* is a vector of other country characteristics that do not vary across industries. By including industry and country specific effects, the coefficient β measures the differential growth impact of financial development on high-dependence industries relative to low-dependence industries. When redefining this exercise in terms of a controlled experiment, we could see industries (rather than states) as the treated objects, some of which (high external dependence) are subjected to the treatment of financial development. In a sample of 41 countries and 36 manufacturing industries, Rajan and Zingales (1998) find robust evidence for a significant and positive β, which is even stronger when focusing on young firms in the computation of external dependence. To gauge the economic significance, Rajan and Zingales assess the growth difference between the industries at the 75th and 25th percentiles of external dependence in the countries at the 75th and 25th percentiles of their financial development indicator. Their results suggest that the annual growth difference between Machinery (75th percentile of external dependence) and Beverages (25th percentile of external dependence) is 1.3 percentage points higher in Italy (75th percentile financial development) than in Philippines (25th percentile financial development). This compares to an average industry growth rate of 3.4%, and thus is a relatively large effect.

As in the case of Jayaratne and Strahan (1996), regression (25.23) does not control for biases due to omitted variables or reverse causation. Rajan and Zingales (1998) address concerns about the endogeneity of the treatment, that is, of financial development, by focusing on the smallest 50% of industries in terms of initial value added in each country, as it is less likely that the financial sector develops in response to the smallest industries. They address the omitted variable bias by including other interaction terms between industry and country characteristics that can explain cross-country, cross-industry growth variation and utilizing instrumental variables for financial development.[31] Critically, the differences-in-differences estimator depends on the assumption that there are industry-inherent characteristics that do not vary across countries and that they are properly measured by the data in the US (von Furstenberg and von Kalckreuth, 2006, 2007).

25.6 Firm- and household-level approaches

While the three approaches discussed so far, cross-country instrumental variable regressions, VAR models and differences-in-differences estimation, have tried to

address the different biases resulting from the standard OLS cross-country growth regression, a fourth approach has used disaggregated firm and, more recently, household-level data to assess the impact of access to financial services on firm growth and household welfare. The advantage of using micro-level data is that it allows more clearly the disentangling and testing of the mechanisms and channels through which financial development enhances economic growth. A disadvantage is that it focuses on the direct effect of finance on firm growth and household welfare but commonly does not consider spillover effects on other firms and households and therefore does not allow for individual effects to be added up to an aggregate growth effect.[32]

Further, as in the case of cross-country regressions, biases due to omitted variables, measurement error and reverse causation have to be addressed. This section discusses several studies using micro-data that assess whether easier access to finance is associated with faster firm growth and higher household welfare. Unlike the previous section, this section does not introduce new methodologies, but rather discusses methodological challenges stemming from the use of micro-, as opposed to country-level data.

25.6.1 Firm-level approaches

The different approaches discussed in this section consist of relating firm-level growth or investment to country-level financial development measures. As in the case of cross-country regressions, however, this implies controlling for biases stemming from reverse causation and omitted variables. A first approach, suggested by Demirgüç-Kunt and Maksimovic (1998), compares firm growth to an exogenously given benchmark. Specifically, they calculate for each firm in an economy the rate at which it can grow, using (i) only its internal funds or (ii) its internal funds and short-term borrowing, based on the standard "percentage of sales" financial planning model (Higgins, 1977). Given a set of simplifying assumptions, the external financing needs *EFN* at time t of a firm growing at rate $g(t)$ is given by:[33]

$$EFN(t) = g(t)^{*}Assets(t) - [1 - g(t)]^{*}Earnings(t)^{*}b(t), \tag{25.24}$$

where $b(t)$ is the fraction of the firm's earnings that are retained for reinvestment at time t. Assuming that the firm retains all its earnings, that is, $b(t) = 1$, the internally financed growth rate $IG(t)$ is the maximum growth rate that can be financed with internal resources only, that is:

$$IG(t) = ROA(t)/[1 - ROA(t)]. \tag{25.25}$$

Demirgüç-Kunt and Maksimovic (1998) then regress the percentage of firms in a country that grow at rates exceeding $IG(t)$ on financial development, other country characteristics and averaged firm characteristics in a simple OLS set-up and show, for a sample of 8,500 firms across 30 countries, that the proportion of firms growing beyond the rate allowed by internal resources is higher in countries with better developed banking systems and more liquid stock markets.[34]

An alternative approach to assess the impact of access to finance on firm growth is the use of firm-level survey data, as done by Beck, Demirgüç-Kunt and Maksimovic (2005), who use firm-level survey data for over 4,000 firms in 54 countries to run the following regression:

$$g(i,k) = \alpha + \beta_1 o(i,k) + \beta_2 f(i) + \beta_3 o(i,k)^* f(i) + C^{(1)}(i,k)\gamma_1 + C^{(2)}(i)\gamma_2 + \varepsilon(i,k), \tag{25.26}$$

where g is sales growth of firm k in country i over the period 1996–99, $C^{(1)}$ is a set of firm-level control variables, $C^{(2)}$ is a set of country-level control variables, o is the financing obstacle as reported by the firm and f is a country-level financial development indicator. The financing obstacle is the response by the firm to the question of whether financing is an obstacle to its operation and growth, and responses are coded as no obstacle (1) minor obstacle (2), moderate obstacle (3), and major obstacle (4). While β_1 indicates the relationship between the reported financing obstacle and firm growth, β_3 indicates whether this relationship varies across countries with different levels of financial development. Beck, Demirgüç-Kunt and Maksimovic find a negative and significant coefficient on β_1 and a positive and significant coefficient on β_3, suggesting that firms reporting higher financing obstacles experience slower sales growth, but that this relationship is less strong in countries with better developed financial systems. Further, using triple interaction terms, they show that the mitigating effect of financial development on the relationship between financing obstacles and firm growth is stronger for small firms than for large firms.

Another methodology consists of assessing the relationship between country-level financial development and firms' financing constraints derived from a structural investment model, such as the Euler equation (Love, 2003; Laeven, 2003). Specifically, the Euler equation derives the optimal investment decision as the point where the marginal cost of today's investment is equal to the discounted marginal cost of postponing investment until the next period, which includes the marginal product of capital, the adjustment cost and the price of investment tomorrow. In the absence of credit market constraints, firms' investment decisions should thus be independent of firms' cashflow holdings, while the investment decisions of credit constrained firms should be a positive function of available cash. Financial sector development, on the other hand, should reduce the dependence of firms' investment on cash holdings. To test for the presence of credit market constraints and the impact of financial development on the relationship between credit market constraints and investment, the following regression is used:

$$\begin{aligned} I(k,t) = {} & \alpha(k) + \lambda(t) + \beta_1 Cash(k,t-1) + \beta_2 Cash(k,t-1)^* f(i,t) \\ & + C^{(1)}(k,t)\gamma_1 + C^{(2)}(k,t-1)\gamma_2 + \varepsilon(i,k,t), \end{aligned} \tag{25.27}$$

where I is investment, $\alpha(k)$ is a vector of firm dummies, $\lambda(t)$ a vector of time dummies, *Cash* is liquid assets relative to total assets, $C^{(1)}$ and $C^{(2)}$ are sets of current and lagged firm-level control variables, such as investment-to-capital ratios

and sales-to-capital ratios, and the i refers to countries. The existence of credit constraints implies $\beta_1 > 0$, while the alleviating role of financial sector development implies $\beta_2 < 0$. As regression (25.27) poses similar problems in terms of the different biases identified in section 25.2 for cross-country growth regressions, most studies use the dynamic panel techniques suggested by Arrellano and Bond (1991) and Arrellano and Bover (1995) to control for these biases. Using data for 5,000 firms across 36 countries, Love (2003) shows that financial development reduces firms' dependence on cash holdings for investment, while Laeven (2003) shows, for a sample of 400 firms across 13 countries, that financial liberalization helped reduce small firms' financing dependence on internal cash, while it adversely affected large firms' financing possibilities. The effect of financial development and liberalization is also economically significant. Love (2003) shows that firms' financing constraints – as measured by the cost of capital – in countries with low levels of financial development are twice as high as in countries with average levels of financial development, while Laeven (2003) shows that financial liberalization had a significant economic effect on firms' financing constraints, reducing small firms' constraints by 80%.

25.6.2 Household-level approaches

While the availability of financial information for listed companies and survey data for non-listed companies has resulted in a rapid expansion of firm-level studies, the lack of comparable data for households has impeded similar research for the effect of access to finance on household welfare until recently. As in the case of aggregate and firm-level studies, the identification problem prevents inference from cross-sectional household surveys with data on welfare and access to finance variables. A final and very recent technique therefore uses controlled experiments with households and/or micro-entrepreneurs, whose financing constraints are randomly alleviated and who are then compared to a control group whose constraints were not alleviated. The challenges of these studies are less in estimation techniques than in the proper identification of treatment and control groups and of the experimental treatment itself. In the following, we will discuss three examples.

First, Pitt and Khandker (1998) use household survey data to assess the impact of micro-credit on household welfare across several programs in Bangladesh. However, as in the case of cross-country regressions, omitted variable bias and reverse causation would bias the result of simple OLS estimation, as illustrated by the following system:

$$y(i,j) = C(i,j)\alpha_1 + \beta f(i,j) + \eta(i) + \varepsilon(i,j) \tag{25.28}$$

$$f(i,j) = C(i,j)\alpha_2 + Z(i,j)\delta + \mu(i) + \nu(i,j), \tag{25.29}$$

where y is a measure of household welfare of household i in village j, f is the amount of credit obtained by a household, C is a vector of household characteristics, and Z is a set of household or village characteristics that serve as instruments for the endogenous credit variable. μ and η are unobservable village characteristics, that are correlated with household welfare and credit, respectively. Correlations

between μ and η and between ε and ν can result in a biased OLS estimate of β in (25.28). These correlations can arise because micro-credit program placement is non-random, often related with specific village characteristics, such as poverty levels. Further, unmeasured household and village characteristics can influence both the demand for micro-credit and household outcomes y. Pitt and Khandker (1998) therefore use the exogenously imposed restriction that only farmers with less than a half-acre of land are eligible to borrow from micro-finance institutions in Bangladesh as an exclusion condition to compare eligible and non-eligible farmers in program and non-program villages. Using survey data for 1,800 households and treating landownership as exogenous to welfare outcomes, they exploit the discontinuity in access to credit for households above and below the threshold and find a positive and significant effect of credit on household consumption expenditures. Morduch (1998), however, shows that mistargeting, that is, allowing farmers with landholdings above the threshold to access micro-credit, violates the exclusion condition, and that different econometric techniques exploiting the landholding restriction lead to different findings.

Coleman (1999) exploits the fact that future micro-credit borrowers are identified before the roll-out of the program in Northern Thailand and can thus exploit the differences between current and future borrowers and non-borrowers in both treated and to-be-treated villages.[35] His model is:

$$y(i,j) = C^{(1)}(i,j)\alpha + \beta p(i,j) + C^{(2)}(j)\gamma + \delta M(i,j) + \varepsilon(i,j) \tag{25.30}$$

where y is an array of measures of household welfare, $C^{(1)}$ is a set of observable household and $C^{(2)}$ a set of observable village characteristics, M is dummy that takes the value one for current and future borrowers and p is a dummy that takes the value one for villages that already have access to credit programs. M can be thought of as a proxy for unobservable household characteristics that determine whether a household decides to access credit or not, whereas β measures the impact of the credit program by comparing current and prospective borrowers. Coleman (1999) does not find any robustly significant estimate of β and therefore rejects the hypothesis that micro-credit helps households in this sample and this institutional setting.

A final example is Karlan and Zinman (2006), who use a sample of marginally rejected applicants of a South African consumer credit institution. They convinced the credit institution to provide loans to a randomly chosen sub-set of these borrowers. Surveying both treatment and control groups six and twelve months after providing credit to the treatment group, they find that borrowers were more likely to retain wage employment and less likely to experience hunger in their household and be impoverished:

$$y(i) = C(i)\alpha + \beta p(i) + \varepsilon(i), \tag{25.31}$$

where y is an indicator of household welfare, C is a vector of household characteristics and p is the treatment dummy that takes the value 1 if the individual surveyed has received a loan.

While controlled experiments can assess the effect of access to credit (or other financial services) on the growth of micro-enterprises or household welfare, there are shortcomings to this methodology. First, they are very costly to conduct. Second, they are environment-specific and it is not clear whether the results will hold in a different environment with a different sample population. Third, the controlled experiments, as they have been undertaken up to now, do not consider any spillover effects of access to credit by the treated individuals or enterprises to other individuals or enterprises in the economy.

25.7 Concluding remarks

The finance and growth literature has come a long way from simple correlation and OLS regressions to dynamic panel regressions and the use of firm- and household-level data. While each of the different methodologies and aggregation levels has its shortcomings, the body of evidence accumulated over the past 15 years provides a strong case for a relationship between financial development and economic growth that is not driven by omitted variables, measurement error or reverse causation.

While the profession has made great progress in measuring financial development, especially by moving towards micro-data, this chapter has focused on methodological advances to overcome the biases illustrated by a simple cross-country OLS regression. Most importantly, overcoming endogeneity and simultaneity biases with a proper identification strategy has been the main challenge for researchers. While the cross-country literature has focused on finding external and internal instruments, the time-series literature has exploited high-frequency data, a rich lag structure, and the forecast capacity of finance for GDP per capita. Differences-in-differences approaches address the identification challenge by assessing natural experiments, exploiting either exogenous policy reforms or inherent industry characteristics that result in a differential impact of financial development.

Using firm- and household-level data allows a deeper look into the mechanisms through which finance enhances firm growth and household welfare and thus provides additional evidence, but poses its own set of identification challenges. While many of the methodologies used at the cross-country-level, such as instrumental variables or differences-in-differences, can also be applied at the firm and household level, randomized controlled experiments with households and micro-entrepreneurs open new and exciting research opportunities, as they allow researchers to subject households and micro-enterprises to a specific treatment under the control of the researcher.

Different methodologies imply different aggregation levels. While assessing the finance and growth relationship on a more disaggregated level might allow better controlling for different biases – such as measurement error when considering a specific policy change on the sub-national level or simultaneity bias when using household data in a controlled randomized experiment – this has to be balanced with the limited extent to which we can draw policy conclusions from such a specification. Further, using firm- or household-level data does not properly control

for spillover effects, are often very costly exercises, and do not lend themselves easily to compute the aggregate growth effect of financial development. While randomized experiments have the advantage that they are the cleanest exercise possible, as they are controlled by researchers, they might not properly mimic the real world, and might not allow inferences outside the geographic and institutional experiment area.

While a wide array of cross-country techniques has been applied to the finance and growth field, some techniques have not been used yet, such as identification through heterogeneity in structural shocks (Rigobon, 2003). Further, it is easy to predict that there will be further advances in GMM techniques that control better for country heterogeneity and in techniques to assess the finance and growth relationship at different frequencies. As before, the finance and growth literature will benefit in the years to come from methodological advances in neighboring fields, especially in growth econometrics. Merging VAR and cross-country techniques – two literatures which have moved mostly parallel to each other up to now – also promises further methodological insights.

More important than these advances at the aggregate level, however, will be advances at the micro-level, and specifically on two fronts. First, randomized experiments involving both households and micro- and small enterprises will shed light on the effect of access to finance on household welfare and firm growth. One of the challenges to overcome will be to include spillover effects and thus move beyond partial equilibrium results to aggregate results. Second, further studies evaluating the effect of specific policy interventions can give insights into which policy reforms are most effective in enhancing financial development and positive real sector outcome.[36] Advances in both areas, however, will depend on the collection of micro-based data on access to and use of financial services.

Acknowledgments

I am grateful to George Clarke, Aart Kraay, Luc Laeven, Ross Levine, Kerry Patterson and Peter Rousseau for comments and useful discussions.

Notes

1. See Levine (1997, 2005) for surveys of the theoretical literature.
2. For a broader survey on the econometrics of growth regressions, see Durlauf, Johnson and Temple (2005).
3. See Beck, Demirgüç-Kunt and Levine (2000) for an overview of different cross-country indicators of financial development and Beck *et al.* (2008) for a discussion of the different dimensions of financial development, such as depth, efficiency and reach. See World Bank (2007) for a discussion of financial outreach indicators.
4. Other early finance and growth studies using cross-sectional OLS regressions include Atje and Jovanovic (1993) and De Gregorio and Guidotti (1995).
5. Most of the papers using this approach assume that only financial development is an endogenous variable and thus treat all control variables as exogenous.
6. The literature has developed several tests to resolve the issue of OLS versus IV, including the Hausman test.

7. The presence of heteroskedasticty can be examined with a test proposed by Pagan and Hall (1983).
8. See Beck and Levine (2005) for an overview.
9. An alternative test was developed by Basmann (1960) and does not impose the overidentifying restrictions.
10. In the case of several endogenous variables, the Stock and Yogo test also requires each instrument to predict primarily just one of the endogenous variables.
11. For further discussion on weak instruments and how to deal with them, see Murray (2006) and Baum, Schaffer and Stillman (2003).
12. Most papers in the literature, however, do not formally test whether the difference between the OLS and the IV estimate is significant, which could be done with a Hausman test.
13. Alternatively, one can use the forward orthogonal deviation transformation.
14. Formal unit root tests as discussed in section 25.4 are not feasible in this context, as there are too few observations.
15. Given that lagged levels are used as instruments in the difference regressions, only the most recent difference is used as an instrument in the level regressions, as using additional differences would result in redundant moment conditions (Arellano and Bover, 1995).
16. Rousseau and Wachtel (2000) was also the first paper to combine dynamic panel techniques with vector autoregression techniques discussed in the next section.
17. Other papers using dynamic panel techniques include Rioja and Valev (2004a, 2004b) and Benhabib and Spiegel (2000). The latter, however, assume exogeneity of financial development and weak exogeneity only for capital accumulation, but not the other control variables.
18. This negative short-run coefficient is consistent with the finding of the banking crisis literature. See, for example, Demirgüç-Kunt and Detragiache (1999).
19. It is important to note, however, that the power of such high-frequency tests depends on the span of the time series rather than the number of observations.
20. Specifically, the "trace" test can be used to test the hypothesis of r against zero cointegrating vectors, while the "λ-max" or maximum eigenvalue test can be used to test the hypothesis of $r + 1$ cointegrating vectors against r cointegrating vectors.
21. Specifically, Toda and Phillips (1993, 1994) and Sims, Stock and Watson (1990) show that in the case of cointegrated series the conventional Wald statistic converges to a χ^2 distribution.
22. Following this approach, Rousseau and Sylla (2005) use data for the US over the period 1850–1997, Bell and Rousseau (2001) use data for India, and Xu (2000) uses data for 43 countries over the period 1960–93; all find robust evidence for a leading role of finance.
23. While we treat such exogenous policy changes in the context of differences-in-differences estimations, one could also use them as instruments for financial development in the context of regular cross-sectional regressions (Guiso, Sapienza and Zingales, 2004).
24. Following the model of Jayartne and Strahan (1996), Dehejia and Lleras-Muney (2007) show that, over the period 1900–40 across states of the US, regulatory changes that allowed branching accelerated the mechanization of agriculture and spurred growth in manufacturing, while the introduction of deposit insurance had negative consequences.
25. On the other hand, focusing on one country reduces the policy relevance of its findings, as the relationship might vary across countries with different economic and institutional settings. Further, sub-national variation might not be independent from each other given the higher mobility of capital and labor within rather than across countries.
26. Bertrand, Duflo and Mullainathan (2004) find over-rejection of the null hypothesis using randomly assigned placebo treatments in Monte Carlo simulation.
27. Specifically, this would imply regressing growth on state and year fixed effects and other time-varying control variables, taking the residuals and averaging them for the period

before and after the treatment for each state. The estimate of the treatment can then be obtained from a regression of this two-period state panel on the treatment dummy.

28. This argument, however, is only valid if there is sufficient variation in growth across different counties within the state.
29. Given the lack of randomness of the sample relative to the population, Huang (2008) constructs critical values from a distribution of the effects of fictitious placebo treatments on county pairs on non-event borders, taking into account spatial correlation across counties along the same borders. Only if 95% of all placebo treatments result in a growth difference below a certain value can this value be considered a significant growth difference for a real world treatment at the 5% significance level.
30. Rajan and Zingales (1998) compute the industry-level dependence on external finance from data of listed firms in the US, that is, firms that should have the least problems in raising external finance and thus face a perfectly elastic supply curve, to get measures of industry-level demand for external finance. They conjecture that demand for external finance measured in this way proxies for the industry-inherent demand for external finance, rather than country- or firm-specific characteristics, in the US.
31. The differences-in-differences approach of Rajan and Zingales (1998) has subsequently been used by many other researchers interested in the linkage between financial development and growth and specific mechanisms and channels, including Beck and Levine (2002), Beck (2003), Beck *et al*. (2008), Braun and Larrain (2005), Claessens and Laeven (2003), Fisman and Love (2003), and Raddatz (2006).
32. Indirect effects of financial development can be very important, as shown by Beck, Levine and Levkov (2007), who find that the main channel through which branch deregulation across US states led to lower income inequality was through labor market effects rather than through providing increased access to finance.
33. The three simplifying assumptions are as follows. First, the ratio of assets used in production to sales is constant. Second, the firm's profits per unit of sales are constant. Finally, the economic deprecation rate equals the accounting depreciation rate.
34. Subsequently, this technique has been applied by Demirgüç-Kunt and Maksimovic (2002) and Guiso, Sapienza and Zingales (2004), among others.
35. This technique is also referred to as "pipeline matching" (Goldberg and Karlan, 2005).
36. One example assessing the effect of different legal reforms is Haselmann, Pistor and Vig (2005).

Spatial Hedonic Models

Luc Anselin and Nancy Lozano-Gracia

Abstract

In this chapter, we focus on some econometric aspects related to a sub-set of hedonic house price models, which we refer to as spatial hedonic models. In these, the locational aspects of the observations are treated explicitly, and the estimation of the models is an application of spatial econometrics. As defined in Anselin (2006), spatial econometrics "consists of a sub-set of econometric methods that is concerned with spatial aspects present in cross-sectional and space-time observations." These methods focus in particular on two forms of so-called spatial effects in econometric models, referred to as spatial dependence and spatial heterogeneity. In this chapter we provide a review of the principles underlying the hedonic house price model, and continue to extensively discuss spatial econometric aspects due to spatial models and spatial data specific to house price applications. We review and discuss the treatment of spatial dependence (including space-time dynamics) and spatial heterogeneity with selective illustrations from the empirical literature.

26.1 Introduction

Hedonic pricing models have become a common tool in applied microeconomics, going back to the classic contributions of Lancaster (1966) and Rosen (1974) (for a recent review, see, e.g., Malpezzi, 2002). The ability of hedonic models to relate the price of a product to the relative contributions of different characteristics has led to a wide range of applied econometric work using these specifications. An important class of applications pertains to house price models, in which characteristics of the property, the neighborhood and other amenities are included in an econometric specification for the sales price or assessed value of a housing unit. Such models are now routinely used in mass appraisal exercises as well as in the valuation of non-market amenities that contribute to the price of the house. The rationale for the latter is that, in an efficient market, superior amenities (such as clean air, access to parks or beaches, and views) should be capitalized into the value of the house. In other words, *ceteris paribus*, houses with superior amenities should be more expensive and the price differential constitutes a measure for the value of the amenity as expressed through market transactions.

In this chapter, we focus on some econometric aspects related to a sub-set of hedonic house price models, which we refer to as *spatial hedonic models*. In these, the locational aspects of the observations are treated explicitly, as an application of *spatial econometrics*. As defined in Anselin (2006), spatial econometrics "consists of a sub-set of econometric methods that is concerned with spatial aspects present in cross-sectional and space-time observations." These methods focus, in particular, on two forms of so-called *spatial effects* in econometric models, referred to as *spatial dependence* and *spatial heterogeneity* (Anselin, 1988).

As outlined in Anselin, spatial dependence or spatial autocorrelation is a special case of cross-sectional dependence in which the structure of the covariation between observations at different locations is subject to a spatial ordering. This ordering is related to the relative positioning, distance or spatial arrangement of the observations in geographic space, or, more generally, in (social) network space. This type of dependence differs from time series dependence in that it is both two-dimensional as well as multidirectional. This implies a simultaneous feedback between observations ("I am my neighbor's neighbor"), which requires the application of specialized techniques that are not simply an extension of time series methods to two dimensions.

Spatial heterogeneity is a special instance of structural instability, which can be observed or unobserved. The spatial aspect of this issue is that spatial structure provides the basis for the specification of the heterogeneity. This may inform models for spatial structural change (referred to as spatial regimes), heteroskedasticity, or spatially varying and random coefficients.

Spatial patterns in the housing market are expected to arise from a combination of spatial heterogeneity and spatial dependence (Anselin, 1998). For example, spatial heterogeneity may originate from spatially differentiated characteristics of demand, supply, institutional barriers, or racial discrimination. This systematic variation in the behavior of economic agents across space warrants special attention, since any model that imposes homogeneity will be misspecified.

Spatial autocorrelation may appear when either the prices or characteristics of houses that are closer together are more similar to each other than those from houses that are farther apart. Alternatively, it may also stem from measurement problems in explanatory variables, omitted variables, and other forms of model misspecification (Baumont, 2004). A major class of such misspecifications pertains to so-called neighborhood effects, which are typically unobserved and modeled as part of the error term. Importantly, spatial heterogeneity and spatial autocorrelation may be observationally equivalent (Anselin, 2001a), which may lead to difficulties in isolating the two effects in practice. Spatial autocorrelation may also result from spatial heterogeneity not being modeled correctly (Anselin and Griffith, 1988; Baumont, 2004).

The consequences of ignoring spatial autocorrelation and spatial heterogeneity when they are, in fact, present in the data-generating process have been widely discussed in the literature and has led to the separate field of spatial econometrics (Anselin, 1988; Anselin and Bera, 1998). A recent comprehensive review of the field can be found in Anselin (2006). Also, after some initial work by Dubin (1988) and Can (1990, 1992), among others, the explicit consideration of spatial effects through the application of spatial econometrics has become more commonplace in empirical studies of housing and real estate markets. Reviews of the basic specifications and estimation methods applied to these spatial hedonic models are provided in Anselin (1998), Basu and Thibodeau (1998), Pace *et al*. (1998), Dubin *et al*. (1999), Gillen *et al*. (2001), and Pace and LeSage (2004), among others.

The literature on hedonic models is vast, both theoretical as well as empirical. We do not attempt to review this in the current chapter, but instead focus on the methodological aspects related to the implementation of spatial hedonic house price models in empirical studies. We illustrate how different spatial econometric approaches have been applied and their implications for model specification, estimation and interpretation. We do not attempt to provide a comprehensive review of the empirical literature, but consider a wide range of articles, illustrative of the different perspectives taken in applied work.

We begin the remainder of the chapter by setting the stage with a brief review of the principles underlying the hedonic house price model, followed by an extensive discussion of spatial econometric aspects due to spatial models and spatial data, specific to house price applications (for a more comprehensive technical review, see Anselin, 2006). We then review in turn the treatment of spatial dependence (including space-time dynamics) and spatial heterogeneity, with selective illustrations from the empirical literature. We close with a discussion of policy implications and some conclusions.

26.2 Hedonic house price models

In this section, we first outline the main properties of the hedonic price model in the context of specifications for house prices. Next, we discuss some important features of the estimation and identification of such models. We postpone the discussion of specific spatial aspects to the next section.

26.2.1 General framework

In the second half of the 1960s, a new branch of utility theory evolved from the pioneering work of Lancaster (1966), in which utility was defined as a function of the characteristics of a good. Initially, the focus was primarily on consumer models, until Rosen (1974) generalized this to a model of market equilibrium that took into account both consumers and producers. In this, the individual's utility becomes a function of the characteristics of a commodity, and producer costs depend on the characteristics of the good.

The hedonic price equation defines a market equilibrium after all interactions between supply and demand have taken place. A considerable literature has built upon this basic model (for a review, see, e.g., Malpezzi, 2002), and active research pertaining to both theoretical and econometric aspects continues apace (e.g., Ekeland *et al.*, 2004).

In the specific context of house price models, the basic hedonic specification assumes that the utility of a household or an individual is a function of a composite good x, a vector of location specific environmental characteristics q, a vector of structural characteristics S, a vector of social and neighborhood characteristics N, and finally a vector of locational characteristics L (Freeman, 1999). One of the main assumptions of the hedonic model is that preferences are weakly separable in housing and its characteristics. This implies that the demand for housing characteristics can be written as a function of "expenditure and prices within the group alone" (Deaton and Muellbauer, 1980, p. 124). Specifically, this implies that housing demand can be written as a function of the house price, with the prices of all other goods represented by a composite good x as the numeraire. Also, perfect information is assumed, in the sense that a consumer perceives all relevant house characteristics and takes them into consideration when purchasing a house.

The decision problem involved in a house purchase then consists of maximizing utility subject to the usual income constraint. Formally, for house i:

$$\begin{aligned} Max \quad & U\left(x, q_i, S_i, N_i, L_i\right) \\ \text{s.t.} \quad & M = P_i + x, \end{aligned} \tag{26.1}$$

where M is the household income, P_i is the price of house i, and the composite good x is the numeraire.

For each characteristic of interest, the first-order condition defines the marginal willingness to pay (MWTP) for changes in the levels of such a characteristic. For

example, for environmental characteristic q_i, this would yield:

$$\frac{\partial U/\partial q_i}{\partial U/\partial x} = \partial P_i/\partial q_i. \tag{26.2}$$

The hedonic price function is an equilibrium price equation where the price of house i is defined as a function of the house characteristics:

$$P_i = P(q_i, S_i, N_i, L_i). \tag{26.3}$$

With estimates for the coefficients in this function to hand, it then becomes possible to estimate the individual's marginal willingness to pay for any characteristic that enters the utility function. As shown in equation (26.2), differentiating equation (26.3) with respect to the characteristic of interest yields the desired result.

The marginal willingness to pay can be interpreted as a "price" for the characteristic and exploited to construct an inverse demand function. To accomplish this, the MWTP is "observed" at different levels of the characteristic, say q_i, and combined with additonal demand shifter variables C in a demand function:

$$MWTP_i = f(q_i, C_i). \tag{26.4}$$

This allows for the analysis of non-marginal changes in the characteristic.

26.2.2 Estimation

The operational implementation of a hedonic analysis consists of two stages: the estimation of a hedonic price function and the construction of the inverse demand function for house characteristics. In most applied work, the second stage is not carried out.

In the first stage, a hedonic price function is specified in terms of the relevant characteristics of the house, typically a combination of individual house features (size, number of rooms, amenities such as air conditioning, etc.), environmental characteristics, neighborhood characteristics and location. Different functional forms can be used, either linear or nonlinear, the most commonly being linear, semi-log and log-log. Alternatively, a flexible Box–Cox approach can be taken. In a much cited study, Cropper *et al*. (1988) carried out a large number of simulations to assess the sensitivity of the results to functional specification. They found that when there are omitted variables or when proxies are used in the absence of a measure of the real variable, simpler functional forms such as linear or semi-log perform better than more complex forms. In most applied work, this is the path taken.

The estimates of the parameters in the price function yield the marginal price for each characteristic as the partial derivative of the function with respect to the characteristic. Depending on the functional form, this marginal price may change with the level of the characteristic. It is interpreted as the marginal willingness to pay for the characteristic.

The second stage of a hedonic analysis is to relate the marginal willingness to pay to different levels of the characteristic in order to yield an inverse demand function

for the characteristic. The general form of this expression is as in equation (26.4). This second stage is especially important when interest centers on the effect of non-marginal changes in the characteristic.

One important problem associated with this second stage is identification (Palmquist, 1991; Freeman, 1999). This is primarily a result of the fact that the prices used in the second-stage inverse demand function are not actually observed, but derived from the coefficient estimates in the first stage (the hedonic price function). Also, the MWTP is computed as a function of at least one of the explanatory variables used in the price specification. In order to be able to separately identify the inverse demand function, it is necessary that additional variables (demand shifters) be included in the second stage.

Furthermore, the attribute variable (amount of the characteristic) is an explanatory variable in both the first and second stage and is thus endogenous. This follows because the selection of a point on the hedonic price function simultaneously determines the level of the characteristic and the marginal price associated with it. This endogeneity must be taken into account in the second stage estimation, typically by using instrumental variables. The instruments should be truly exogenous to the model, which in practice may be difficult to establish.

One solution to the identification problem, suggested by Palmquist (1991), is to use information from spatially or temporally distinct sub-markets. The rationale behind this is that the heterogeneity between the sub-markets provides sufficient variability to identify a demand function for the characteristic. This is estimated by taking marginal prices from different sub-markets as well as demand shifters that vary sufficiently across the sub-markets (e.g., income).

Apart from the identification issue for the demand function (the second stage), sub-markets should also be explicitly considered when spatial heterogeneity invalidates the assumption of a single equilibrium. After defining meaningful spatially delineated sub-markets, a separate hedonic price function should be estimated for each.

In practice, interest has focused on the first stage of the hedonic model and on estimation of MWTP for various characteristics. An important body of applications pertains to the valuation of amenities, such as environmental quality, access to open space and views. Very few spatial econometric applications have carried out the second stage of estimating the inverse demand function. Recent exceptions are Beron *et al*. (2004) and Brasington and Hite (2005).

26.3 Spatial models

Increasingly, applied econometric work dealing with hedonic house price models has taken an explicit spatial econometric perspective. Some recent examples include Basu and Thibodeau (1998), Dubin *et al*. (1999), Bell and Bockstael (2000), Bowen *et al*. (2001), Bourassa *et al*. (2003), Kim *et al*. (2003), Beron *et al*. (2004), Pace and LeSage (2004), Brasington and Hite (2005), Anselin and Le Gallo (2006), Neill *et al*. (2007) and Anselin and Lozano-Gracia (2008). This work focuses, in particular, on the treatment of market interactions or unobserved neighborhood effects

through the incorporation of spatial dependence and on the use of model specifications that allow for spatial heterogeneity in the form of submarkets. Several different model formulations and estimation methods have been applied, reflecting the richness of the spatial methodology (Anselin, 2006).

The motivation for incorporating spatial effects into the specification of a hedonic house price model is based on two main concerns. One, which we refer to as *substantive*, is that the model form is intended to capture either interaction effects, market heterogeneity, or both. The other is more pragmatic and we refer to it as a *nuisance*, in that spatial autocorrelation in omitted variables, or unobserved externalities and heterogeneities, are relegated to the error term. In dealing with spatial dependence, these two perspectives are reflected in the *lag* and *error* models (Anselin, 1988). In addressing spatial heterogeneity, varying coefficient models and spatial regimes reflect substantive models, whereas various specifications for heteroskedasticity deal with nuisance effects.

The econometric treatment of these two types of effects differs considerably. Substantive models require a new class of estimation methods and specification tests, whereas nuisance models are simply special cases of a non-spherical error variance-covariance matrix. The consequences of ignoring these effects differ as well. Omitting substantive effects when they should be included results in model misspecification. Consequently, the estimates of the remaining parameters will be biased and inconsistent, and inference may be spurious. In a hedonic context, this implies that conclusions about the marginal price of specific characteristics (e.g., environmental improvements) may be wrong. On the other hand, nuisance effects are primarily a problem of efficiency. Ignoring those effects when present will yield biased estimates of standard errors in a traditional ordinary least squares (OLS) regression if the proper adjustments are not carried out. This will yield biased t-tests and misleading indications of precision. Since the coefficient estimates in hedonic models are used in further calculations (e.g., of marginal willingness to pay), it remains important to have correct measures of standard errors in order to properly address uncertainty in a policy decision making context.

One additional complexity with spatial models is that spatial dependence and spatial heterogeneity are often difficult to distinguish in a cross-sectional setting. The properties of specification tests and estimators developed for one type of effect are affected by the presence of the other type. In practice, one typically addresses one type of spatial effect first, carries out specification tests for remaining problems and subsequently addresses those if warranted.

In this section, we review the main model specifications and estimation methods that have been applied in hedonic studies. Here, we only focus on the basic properties and do not intend to duplicate the extensive methodological reviews provided in Anselin and Bera (1998) and Anselin (2006), among others. We also limit our discussion to the most commonly used specifications. For spatial (and space-time) dependence, these are the lag and error models, as well as some recently suggested semiparametric approaches. For spatial hetereogeneity, we cover the treatment of discrete (regimes) and continuous (varying coefficients) spatial heterogeneity.

26.3.1 Spatial dependence

26.3.1.1 Spatial lag model

The spatial lag specification is characterized by the inclusion of a new variable on the right-hand side of the equation. This variable, referred to as a spatially lagged dependent variable (Anselin, 1988) captures the spatial interaction effect as a weighted average of neighboring observations. This is most commonly applied in a linear form, as:

$$y = \rho Wy + X\beta + u, \tag{26.5}$$

where y is an $n \times 1$ vector of observations on the dependent variable, X is an $n \times k$ matrix of observations on explanatory variables, W is an $n \times n$ spatial weights matrix, u is an $n \times 1$ vector of independent and identically distributed (i.i.d.) error terms, ρ is the spatial autoregressive coefficient, and β is a $k \times 1$ vector of regression coefficients.

The $n \times n$ spatial weights matrix defines the neighbor set for each individual location. Its positive elements w_{ij} are non-zero when observations i and j are *neighbors*, and zero otherwise. By convention, self-neighbors are excluded, such that the diagonal elements of W are zero. In addition, in practice the weights matrix is typically row-standardized, such that $\sum_j w_{ij} = 1$. Many different definitions of the neighbor relation are possible, and there is little formal guidance on the choice of the "correct" spatial weights.[1] The term Wy in equation (26.5) is referred to as a spatially lagged dependent variable, or spatial lag. For a row-standardized weights matrix, it consists of a weighted average of the values of y in neighboring locations, with weights w_{ij}.

As stated in Anselin and Bera (1998), there are two main interpretations for a significant spatial autoregressive coefficient ρ. First, this may suggest a contagion process or the presence of spatial spillovers. However, this interpretation is valid only if the process takes place at the spatial unit used in the analysis, and is supported by a theoretical model. In the context of spatial hedonic models, this is often difficult to maintain, since it is unlikely that economic agents simultaneously take into account the prices of neighboring units. An alternative explanation for a significant spatial autocorrelation coefficient is the existence of a mismatch between the observed spatial unit and the true spatial scale of the process being studied.

The theoretical motivation for a spatial lag specification is based on the literature on interacting agents and social interaction. For example, a spatial lag follows as the equilibrium solution of a *spatial reaction function* (Brueckner, 2003) that includes the decision variable of other agents in the determination of the decision variable of an agent (see also Manski, 1993, 2000). In hedonic models, however, where a purely cross-sectional setting is more common, it is often difficult to maintain such a theoretical motivation, since it would imply that buyers and sellers simultaneously take into account prices obtained in other transactions.

An alternative interpretation is provided by focusing on the reduced form of the spatial lag model:

$$y = (I - \rho W)^{-1} X\beta + (I - \rho W)^{-1} u, \tag{26.6}$$

where, under standard regularity conditions, the inverse $(I - \rho W)^{-1}$ can be expressed as a power expansion:

$$(I - \rho W)^{-1} = I + \rho W + \rho^2 W^2 + \ldots. \tag{26.7}$$

The reduced form thus expresses the house price as a function of its own characteristics (X), but also of the characteristics of neighboring properties, (WX, W^2X), albeit subject to a distance decay operator (the combined effect of powering the spatial autoregressive parameter and the spatial weights matrix). In addition, omitted variables, both property-specific as well as related to neighboring properties, are encompassed in the error term. In essence, this reflects a scale mismatch between the property location and the spatial scale of the attributes that enter into the determination of the equilibrium price.

From a purely pragmatic perspective, one can also argue that the spatial lag specification allows for a *filtering* of a strong spatial trend (similar to detrending in the time domain), i.e., ensuring the proper inference for the β coefficients when there is insufficient variability across space. Formally, the spatial filter interpretation stresses the estimation of β in:

$$y - \rho Wy = X\beta + u. \tag{26.8}$$

In most spatial hedonic applications, the use of a spatial lag specification follows as the result of a specification search based on specialized Lagrange multiplier tests that indicate the preference of this alternative over an error specification (Anselin and Bera, 1998; Anselin, 2001a; Florax *et al*., 2003). In such instances, the selection of this model is mostly pragmatic, without necessarily implying a theoretical model of social interaction.

The most commonly applied estimation method for the parameters of the spatial lag model is maximum likelihood, following the principles outlined by Ord (1975) (for additional technical details, see, e.g., Anselin, 1988; Anselin and Bera, 1998; Anselin, 2006). More recently, an instrumental variables or spatial two stage least squares approach has gained greater popularity, because it lends itself more readily to application in the large datasets characteristic of hedonic studies. Early results were given in Anselin (1988) and Kelejian and Robinson (1993), but more recently interest has focused on formal proofs of asymptotic properties and the choice of optimal instruments, e.g., in Lee (2003, 2007), Das *et al*. (2003) and Kelejian *et al*. (2004). Bayesian estimation of spatial autoregressive models is covered in LeSage (1997).

We leave a more detailed discussion of specific applications of spatial hedonic models to section 26.5.

26.3.1.2 Spatial error model

From a theoretical viewpoint, a spatial error specification is the more natural way to include spatial effects in a hedonic model. Unobserved neighborhood effects will be shared by housing units in the same area and naturally lead to spatially correlated error terms. This results in a non-diagonal error variance-covariance matrix:

$$\text{Var}[uu'] = \text{E}[uu'] = \Sigma, \tag{26.9}$$

where $\Sigma \neq \mathbf{I}$, with $\mathbf{I}$ as the identity matrix. Typically, Σ contains "nuisance" parameters that need to be estimated consistently. This, in turn, yields consistent estimates for the regression coefficients by means of a feasible generalized least squares (FGLS) estimation. The interpretation of the nuisance parameters is very different from the spatial autoregressive coefficient in the spatial lag model, in that there is no particular relation to a substantive model of spatial interaction. These parameters are only included in order to obtain better estimates for the regression slope coefficients.

The particular structure of Σ follows from a spatial ordering of the observations (e.g., as argued in Kelejian and Robinson, 1992). In practice, the most commonly used specification assumes a spatial autoregressive process for the error terms:

$$y = X\beta + \varepsilon, \tag{26.10}$$

with:

$$\varepsilon = \lambda W\varepsilon + u, \tag{26.11}$$

with $u \sim i.i.d.$, and λ as the spatial autoregressive coefficient.

The resulting error variance-covariance matrix is as follows:

$$E[\varepsilon\varepsilon'] = \sigma^2[(I - \lambda W)(I - \lambda W')]^{-1}. \tag{26.12}$$

A commonly used alternative in hedonic analyses is to base the structure of the error variance-covariance matrix on principles from geostatistics. Early work by Dubin (1988) (see also Dubin, 1992; Basu and Thibodeau, 1998; Dubin *et al.*, 1999; Miltino *et al.*, 2004) suggested a so-called *direct representation* for the elements of the variance-covariance matrix.

In this approach, the covariance between each pair of error terms is specified as an inverse function of the distance between them. Formally:

$$\mathrm{E}[\varepsilon_i\varepsilon_j] = \sigma^2 f(d_{ij}, \phi), \tag{26.13}$$

with $\varepsilon_i, \varepsilon_j$ as the regression error terms, σ^2 the error variance, and d_{ij} the distance separating i and j. The function f should be a distance *decay* function that ensures a positive definite covariance matrix. This requires $\partial f/\partial d < 0$ and $|f(d_{ij}, \phi)| \leq 1$, with $\phi \in \Phi$ as a $p \times 1$ vector of parameters on an open sub-set Φ of $\mathbb{R}^p$. This approach is closely related to the variogram models used in geostatistics, and requires assumptions of stationarity and isotropy (see Cressie, 1993, for an extensive review). The complete variance-covariance is then:

$$\mathrm{E}[\varepsilon\varepsilon'] = \sigma^2\Omega(d_{ij}, \phi). \tag{26.14}$$

A commonly used specification is based on a negative exponential distance decay:

$$\mathrm{E}[\varepsilon\varepsilon'] = \sigma^2[I + \gamma\Psi], \tag{26.15}$$

with the off-diagonal elements of Ψ being $\Psi_{ij} = e^{-\phi d_{ij}}$, and γ as a non-negative scaling parameter. In order to facilitate interpretation and specification testing, the diagonal elements of Ψ are often set to zero (the variance is captured by the term $\sigma^2 I$). The distance metric and parameter space must be such that the elements of $e^{-\phi d_{ij}}$ yield a valid spatial correlation matrix (see Anselin, 2001a, for technical details).

Estimation in parametric spatial error models is most commonly based on the ML principle (see Anselin, 1988; Dubin, 1988). Due to computational limitations in very large datasets, recent attention has shifted to alternatives, such as the generalized moments (GM) and generalized method of moments (GMM) estimators suggested by Kelejian and Prucha (1998, 1999). An early application of this approach to a hedonic specification can be found in Bell and Bockstael (2000) (see also section 26.5 for further examples). Generalization of this approach to an error structure that contains both spatial autocorrelation and heteroskedasticity can be found in recent papers by Lin and Lee (2005) and Kelejian and Prucha (2006).

A different approach is to avoid the parametric specification of spatial covariance as a function of a distance metric and to use a nonparametric perspective. This is an extension to the spatial domain of the principle behind the heteroskedasticity and autocorrelation consistent covariance matrix estimation of Newey and West (1987) and Andrews (1991), among others.

As in the direct representation approach, the spatial covariance is a function of the distance separating two observations, but the functional form is left unspecified. For example, for the regression error terms:

$$\mathrm{E}[\varepsilon_i \varepsilon_j] = f(d_{ij}), \tag{26.16}$$

where d_{ij} is a "proper" positive and symmetric distance metric (for regularity conditions on the distance metric, see Conley, 1999; Kelejian and Prucha, 2007).

This estimator follows essentially the same principle as in the time series domain by adding up sample spatial autocovariances. In order to ensure positive definiteness of the estimator, a kernel is applied to the cross-products. For example, in the recent paper by Kelejian and Prucha (2007), a general covariance matrix estimator takes the form:

$$\hat{V} = n^{-1} \sum_i \sum_j x_i x_j' \hat{\varepsilon}_i \hat{\varepsilon}_j K(d_{ij}/d), \tag{26.17}$$

where $K()$ is a kernel function and d a suitable cutoff distance. This yields a so-called heteroskedastic and spatial autocorrelation consistent, or HAC, estimator. A recent application of this approach to spatial hedonic models can be found in Anselin and Lozano-Gracia (2008).

Arguably, the treatment of spatially structured omitted variables may be addressed without resorting to a spatial error. The most commonly used technique in the empirical literature is to address this by means of spatial fixed-effects, e.g., by including a dummy variable for a larger spatial area that individual housing

units belong to, such as a census tract or block group. This rests on the assumption that the spatial range of the unobserved heterogeneity/dependence is specific to each spatially delineated unit. In practice, there may indeed be spatial units (such as school districts) where such a spatial fixed effects approach is sufficient to correct the problem. However, the nature of omitted neighborhood variables tends to be complex, as is the definition of the correct "neighborhood," and in many instances the fixed-effects approach will be insufficient to remove all residual spatial autocorrelation.

26.3.1.3 Other models of spatial dependence

In addition to the familiar spatial lag and spatial error models just outlined, a number of other techniques have been adopted to deal with spatial effects in hedonic house price functions. We briefly review here semiparametric approaches.

An alternative way to account for space in a hedonic regression is to incorporate it directly in the hedonic price function in the form of a trend surface, while maintaining the assumption of constant marginal prices across space. In a parametric approach, this would consist of including a polynomial in the X, Y coordinates of the observations as explanatory variables in the hedonic equilibrium equation. This could also be combined with a fixed-effects approach in the form of dummy variables for administrative units, such as zip code or census tracts.

A semiparametric alternative, first discussed by Clapp *et al*. (2002), includes, in addition to the usual hedonic variables, a nonparametric function $f(X_c, Y_c)$ of the location of the observations. This is to model the omitted spatial variables in the mean function, rather than relegating them to the error term. Formally, this yields:

$$P = X\beta + f(X_c, Y_c) + \varepsilon. \tag{26.18}$$

This function may be estimated using standard nonparametric techniques such as local polynomial regression. The Nadaraya–Watson estimator is the method most frequently used in the literature.

Clapp *et al.* suggest estimating this model in an iterative fashion consisting of two main steps. First, the parameters of all house characteristics are estimated using OLS. In a second step, the residuals from this regression are fitted using Bayesian or local polynomial regression techniques. The first step thus yields OLS residuals $\hat{\eta}^0$ as:

$$\hat{\eta}^0 = P - X\hat{\beta}^0. \tag{26.19}$$

In a first iteration, these residuals are then smoothed using a Nadaraya–Watson estimator, as:

$$\bar{\eta}^0 = \sum_{i=1}^{q} \frac{K_h(X_{c_i} - X_0)K_h(Y_{c_i} - Y_0)(\hat{\eta}^0)}{\sum_{i=1}^{q} K_h(X_{c_i} - X_0)K_h(Y_{c_i} - Y_0)}. \tag{26.20}$$

Then, the estimated residuals from a first iteration are obtained as:

$$\hat{\epsilon^0} = \hat{\eta^0} - \bar{\eta^0}. \tag{26.21}$$

In the next iteration, the linear part of the model is estimated again using OLS, but now using $\hat{Y}^1$ as the dependent variable, where:

$$\hat{Y}^1 \equiv X\hat{\beta}^0 + \hat{\varepsilon}^0. \tag{26.22}$$

Iterations between the parametric and nonparametric portions of the model continue until the $\hat{\beta}$s change by no more than 5%.

A different estimation approach for this model is described in Gibbons (2003) and Day *et al*. (2007), who use *spatially filtered* variables to consistently estimate the β coefficients, following the steps first outlined in Robinson (1988). To implement this, the model in equation (26.18) is rewritten as:

$$P - E[P|X_c, Y_c] = (X - E[X|X_c, Y_c])\beta + \varepsilon. \tag{26.23}$$

Estimates for the marginal prices are obtained by using the spatially weighted means of the explanatory variables. First, the conditional means $E[P|X_c, Y_c]$ and $E[X|X_c, Y_c]$ are estimated using nonparametric regression. Estimates of these functions are then substituted into equation (26.23) and, following Robinson (1988), consistent estimates for the β coefficients are obtained from OLS on equation (26.23).

Day *et al*. (2007) consider an additional complication and allow for the presence of spatial error autocorrelation in the form of a spatial autoregressive process (as in equation 26.11). Rather than applying OLS, estimates for the β in equation (26.23) are obtained using the Kelejian and Prucha (1999) GM approach.

Alternatively, Clapp *et al*. (2002) utilize Bayesian methods to remove any remaining spatial autocorrelation from the model. In standard Bayesian fashion, the error terms are specified as consisting of two components; one being spatial, the other a white-noise process. Formally:

$$\hat{\varepsilon}(c_i) = \delta(c_i) + \psi(c_i), \tag{26.24}$$

in which $\delta(c_i)$ is assumed to come from a stationary Gaussian spatial process with mean 0 and spatial covariance function $cov(\delta(c), \delta(c')) = \sigma^2 exp(-\psi\|c - c'\|)$ and ψ is assumed $i.i.d \sim N(0, \tau)$. Bayesian fitting is then applied to the first stage residuals using Gibbs sampling combined with a Metropolis–Hasting procedure to account for remaining spatial autocorrelation in the residuals.

26.3.1.4 Models for space-time dependence

The temporal dimension has not received much attention in spatial hedonic models. There are both theoretical as well as practical reasons for this omission. First, using data for several time periods would require the assumption that the marginal prices stay constant through time. While this assumption may seem appropriate for a short period of time, it is unlikely to hold when several years are considered. As a result, hedonic analyses have tended to favor pure cross-sectional approaches.

Furthermore, explicitly including both the temporal and spatial dimension requires complex estimation methods. Most applications have used Bayesian methods to tackle this complexity. Some examples of spatio-temporal hedonic analyses

include Pace *et al*. (1998), Pace *et al*. (2000), Gelfand *et al*. (2004), Sun *et al*. (2005) and Huang *et al*. (2006).

As an example, consider Pace *et al*. (1998) and Pace *et al*. (2000). They propose a spatio-temporal specification in which a filtering approach is carried out across both dimensions. The model is:

$$(I - W)Y = (I - W)X\beta + u, \tag{26.25}$$

where W is a row-standardized $N \times N$ lower triangular spatio-temporal weights matrix. The weight matrix W is used to filter out the spatio-temporal correlation and the model is then estimated for the uncorrelated variables $(I - W)X$ and $(I - W)Y$.

Data are ordered by time period, so that the first row in the data refers to the earliest observation. Therefore, only previous sales are allowed to influence current house prices. This explicit relation between time periods contrasts with the approach taken in cross-sectional studies, where all sales are assumed to have taken place during the same period. As a result, in a cross-sectional set-up, there is a simultaneous feedback between all house prices in the sample, even though technically the sales may have taken place at different times during the period (so, conceivably, a later sale could affect an earlier sale). The explicit inclusion of space-time correlation allows for a more realistic model of the actual timing of real estate transactions.

In this approach, W is not assumed *a priori* but rather defined through a flexible form, where $(I - W) = (I - \phi_S S - \phi_T T - \phi_{TS} TS - \phi_{ST} ST)$, with T and S respectively defined as temporal and spatial weight matrices. The expanded definition of $(I - W)$ is then plugged back into equation (26.25) and the model is estimated using Bayesian methods for the unfiltered variable Y.

Gelfand *et al*. (2004) introduce time and space in the model by allowing the coefficients to change over time. They define three possible forms for the error term in a separable form, which avoids explicit specification of space-time interactions:

$$U(s,t) = \alpha(t) + W(s) + \varepsilon(s,t), \tag{26.26}$$

$$U(s,t) = \alpha_s(t) + \varepsilon(s,t), \tag{26.27}$$

$$U(s,t) = W_t(s) + \varepsilon(s,t), \tag{26.28}$$

with $\varepsilon(s,t)$ as *i.i.d.*$N(0, \sigma_\varepsilon^2)$ error terms, $\alpha_s(t)$ as the temporal effect and $W(s)$ as the spatial effect.

Equation (26.26) provides a structure that is additive in spatial and temporal effects. In contrast, equation (26.27) suggests that the temporal effects are local, changing from one site to the other. Finally, the form for the error term suggested in equation (26.28) pertains to the case where the spatial effects are specific to the time period. Gelfand *et al*. (2004) then outline a fully Bayesian approach and specify the associated likelihoods together with the prior distributions for all parameters in the model.

A simpler spatio-temporal approach is introduced in Huang *et al.* (2006). Here, an expanded version of a spatial lag model is estimated using ML, under the assumption that spatial correlation remains constant through time. Furthermore, after the inclusion of the spatially lagged dependent variable, the error terms are assumed to be correlated only in time. This spatio-temporal version of the spatial lag model takes the following form:

$$y^* = \rho(W \otimes I_T)y^* + X^*\beta + u^*, u^* \sim N(0, \sigma_u^2), \tag{26.29}$$

with $y^* = (I_N \otimes Q)y$, $X^* = (I_N \otimes Q)X$, and $u^* = (I_N \otimes Q)u$. Q is a transformation matrix that "removes the effect" of the $AR(1)$ process in the residuals following a method suggested in Judge *et al.* (1988) and Hsieh *et al.* (2001). If the $AR(1)$ correlated residuals are defined as:

$$u_{it} = \lambda u_{i,t-1} + \upsilon_{it}, \tag{26.30}$$

with $\upsilon_{it} \sim N(0, \sigma_\upsilon^2)$, $E[u_{it}u'_{is}] = \sigma_\upsilon^2\Omega(\lambda)$, and $t \neq s$, then:

$$\Omega(\lambda) = I_n \otimes \frac{1}{1-\lambda^2}\begin{bmatrix} 1 & \lambda & \lambda^2 & \cdots & \lambda^{T-1} \\ \lambda & 1 & \lambda & \cdots & \lambda^{T-2} \\ \lambda^2 & \lambda & 1 & \cdots & \lambda^{T-3} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \lambda^{T-1} & \lambda^{T-2} & \lambda^{T-3} & \cdots & 1 \end{bmatrix}, \tag{26.31}$$

and Q is the transformation matrix such that $\Omega^{-1} = I \otimes (Q(\lambda)'Q(\lambda))$. In particular, Q takes the following form:

$$Q(\lambda) = \begin{bmatrix} \sqrt{1-\lambda^2} & 0 & 0 & \cdots & 0 & 0 \\ -\lambda & 1 & 0 & \cdots & 0 & 0 \\ 0 & -\lambda & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & -\lambda & 1 \end{bmatrix}. \tag{26.32}$$

This Q is used to define the transformed model in equation (26.29), which can then be estimated using ML. Huang *et al.* (2006) conclude that introducing these spatial and temporal correlations improves the goodness-of-fit of the model.

26.3.2 Spatial heterogeneity

26.3.2.1 Discrete spatial heterogeneity

Discrete spatial heterogeneity is a special case of structural instability in the model specification (functional form and/or parameters), where the form of the instability follows a spatial structure, referred to as *spatial regimes* (Anselin, 1988, 1990). In practice, this often occurs when structural breaks can be observed between different sub-regions, such as core and peripheral regions or urban and rural areas. In

hedonic models, discrete spatial heterogeneity is taken into account in the form of separate models for *sub-markets*. For example, inelasticities in supply and demand may lead to market segmentation that results in spatial heterogeneity in the form of varying marginal prices (Goodman and Thibodeau, 1998). Sub-markets can be defined spatially or non-spatially but, in practice, preference goes to delineations that follow clearly observed spatial boundaries (for examples, see section 26.6.1).

More formally, discrete spatial heterogeneity can be expressed as:

$$y_i = f_i(X_i, \beta_i, \epsilon_i), \tag{26.33}$$

with i as an index corresponding to a given discrete sub-set of the data. This general formulation includes as special cases functional instability, $f_i \neq f_j$ (e.g., linear model for one region, log-linear in another), parameter variation, $\beta_i \neq \beta_j$ (e.g., different parameter values for house characteristics in different sub-markets), as well as heteroskedasticity, $Var[\epsilon_i] \neq Var[\epsilon_j]$.

These examples represent fairly standard methodological issues that can readily be addressed and do not require an explicit spatial econometric treatment. However, in practice, in many instances heterogeneity and spatial dependence occur together, or, are difficult to identify separately (Anselin and Griffith, 1988). For example, spatial spillover may not be constrained to each specific spatial sub-set of the data, but may reach across the boundaries. In those cases, the treatment of the heterogeneity becomes complicated by the presence of spatial dependence, and extensions of the standard spatial lag and error models and associated specification tests are in order. One example of such tests is the so-called spatial Chow test of coefficient stability, which is an extension of the standard case that incorporates spatial dependence (Anselin, 1990).

In spatial hedonic models, attention has focused primarily on the delineation of sub-markets, and the acknowledgment of spatial dependence between sub-markets has only received limited attention. We provide specific examples in section 26.6.1.

26.3.2.2 Continuous spatial heterogeneity

As an alternative to considering discrete spatial sub-sets of the data, heterogeneity can be viewed as a smooth continuous process of varying parameters. One of the earliest applications of this perspective to spatial analysis was in the so-called *spatial expansion method* proposed by Casetti in the early 1970s (see, e.g., Casetti, 1972, 1997).

Spatial expansion is a special case of a varying coefficients model and also shows great similarity to the approach taken in multi-level modeling (e.g., Goldstein, 1995). Using Casetti's terminology, the first step is a so-called initial equation, which is a simple linear regression specification for each observation i:

$$y_i = \sum_k x_{ki}\beta_{ki} + \epsilon_i, \tag{26.34}$$

for k explanatory variables, including a constant term. Next, an expansion equation expresses the variability of the regression coefficient over i as a function

of additional explanatory variables z_{hi} (again, including a constant term):

$$\beta_{ki} = \sum_h z_{hi}\gamma_h, \tag{26.35}$$

where the γ_h are an additional set of parameters. Note that, unlike the standard multilevel model, the observational unit for the x and z variables is the same (i). The combination of the initial model with the expansion equation yields the so-called final equation, which contains the original explanatory variables, as well as interaction variables, the product of each x_{ki} with all the z_{hi}:

$$y_i = \sum_k x_{ki}\left(\sum_h z_{hi}\gamma_h\right) + \epsilon_i. \tag{26.36}$$

A slight generalization is obtained when the expansion equation includes an error term, which yields a heteroskedastic model (Anselin, 1992). A common problem in the implementation of this approach is a high degree of multicollinearity.

In spatial hedonic specifications, the expansion method is used to model heterogeneity in the form of so-called neighborhood drift (Can, 1992). This may also account for some omitted variables at the neighborhood level and therefore reduce the intensity of the spatial autocorrelation problem. However, it is important to note that, even if a parametric drift is introduced, spatial autocorrelation and heterogeneity may remain as a problem.

An alternative to the parametric specification of the expansion equation is a nonparametric approach, in which the variability of the model parameters is determined by the data. The best known among these approaches is arguably the geographically weighted regression (GWR), popularized in the work of Fotheringham and collaborators (for an overview, see Fotheringham *et al.*, 2002).

GWR is essentially a special case of a local regression model (LRM) (e.g., as proposed in Cleveland and Devlin, 1988), in which the weighting scheme that determines the variability in the parameters is based on the spatial closeness of observations (for examples of spatial hedonic applications, see Pavlov, 2000; Gelfand *et al.*, 2003; Cho *et al.*, 2006; Kestens *et al.*, 2006, among others). In this approach, a model parameter is defined as a function of the location of individual observations. In addition, a weighting scheme is designed such that greater weight is given to locations that are closer in space. To illustrate this approach, consider a hedonic model specified as:

$$P = \beta_0(c) + \sum_k X_k\beta_k(c) + \varepsilon, \tag{26.37}$$

where c is a vector of X_c, Y_c coordinates that define the location of the data points. The parameters are estimated by minimizing a weighted residual sum of squares:

$$\min_{p,q} \sum_i \left\{ W_i(c)\left[P - \beta_0(c) - \sum_k X_k\beta_k(c)\right]^2 \right\}, \tag{26.38}$$

where $W_i(c)$ are the weights that depend on the location (c). The solution to the minimization problem in equation (26.38) yields the standard weighted least squares expression, in matrix notation:

$$\hat{\beta} = (X'WX)^{-1}(X'Wy). \tag{26.39}$$

In this expression, W is not a spatial weights matrix, but a matrix that extracts the observations used in the estimation of the parameter for each location i. Several approaches have been suggested, such as a straightforward k-nearest neighbors weighting scheme (Pavlov, 2000), or a kernel smoother. The latter is the common approach taken in GWR, where a Nadaraya–Watson-type kernel smoother ensures that those observations near the point where the parameters are being estimated have more influence than those observations further away. Using such a kernel function in GWR then yields the function to be minimized as:

$$\min_{p,q} \sum_i \left\{ K_h(d_{0i}) \left[P - \beta_0(c) - \sum_k X_k \beta_k(c) \right]^2 \right\}, \tag{26.40}$$

where $K_h(\cdot) = K(\cdot/h)$, K is a given kernel function and h a bandwidth parameter.

Common choices for the kernel are the bi-square function:

$$K(t) = \begin{cases} (1-t^2)^2, & \text{if } |t| \leq 1, \\ 0, & \text{otherwise,} \end{cases} \tag{26.41}$$

and the Gaussian kernel:

$$K(t) = exp\left(-\frac{1}{2}t^2\right). \tag{26.42}$$

Since the term "GWR" was first introduced in Brunsdon *et al*. (1996), an extensive set of papers has been published treating various theoretical issues related to model estimation, specification testing and cross-validation (see, among others, Fotheringham *et al*., 1998, 2002; Paez *et al*., 2002a, 2002b). Specific empirical applications to spatial hedonic specifications are reviewed in section 26.6.2.

26.4 Methodological challenges

Spatial hedonic analysis not only considers the specification of spatial relationships in the model, but also the estimation of relevant parameters on the basis of *spatial data*. In this section, we briefly point out some important methodological issues that need to be accounted for, especially the problem of spatial scale and the treatment of endogeneity.

26.4.1 Spatial scale

Spatial scale is important in the empirical implementation of hedonic models in a number of ways. The standard assumption is that the spatial units of observation match the process under consideration. However, with spatial data, this is not necessarily the case, and errors due to aggregation or interpolation need to be

accounted for. In addition, it is not always obvious how the sample of observations relates to a population (or super-population), which has repercussions for the type of asymptotics that can be applied.

26.4.1.1 Spatial observations

The theoretical framework outlined in section 26.2 implies that the proper estimation of the model parameters should be based on observations for individual transactions. In practice, this is not always possible and many studies instead rely on spatially aggregated data for units such as block groups, census tracts, and even counties (e.g., Brasington and Hite, 2005; Capozza *et al.*, 2005; Chay and Greenstone, 2005; Huang *et al.*, 2006). This leads to the problem of *ecological inference*, also known in geography as the modifiable areal unit problem, or in the statistical literature as the change of support problem (Gotway and Young, 2002). As shown in Anselin (2002), the parameters of spatial models estimated at an aggregate level (in particular the spatial autoregressive coefficient) do not correspond to those at the individual level. Consequently, estimates of hedonic specifications based on such aggregate units have only a tenuous basis in micro-theory and rely on a notion of representative agents (representative housing units) that may be highly unrealistic. The crucial aspect determining the extent of the problem is the intra-unit heterogeneity. If housing units, their characteristics, or the profiles of the household units that occupy them, vary considerably within a spatial unit, then an aggregate analysis based on a mean or median characteristic will not be very meaningful.

A second issue related to the change of support problem occurs when observations on some housing characteristics are not available for each individual unit. For example, in many instances, data on socioeconomic variables related to the households, such as income and education, cannot be obtained at the micro-level, but instead are proxied by spatial aggregates, such as the median income or percentage high school graduates at the census tract. All individual observations in the same census tract thus share the same value for these explanatory variables. At the very least, this leads to heteroskedastic error terms, but it may also result in more serious specification problems, as pointed out in Moulton (1990).

In other instances, the change in support problem manifests itself in a mismatch between the location and scale at which observations are collected for specific explanatory variables and the location of the housing units. A common example is the use of interpolated values for environmental variables related to air quality (e.g., ozone), which are typically collected at a small number of monitoring stations. In Anselin and Le Gallo (2006), the effect of applying different interpolation methods on the resulting estimates of MWTP for air quality is assessed. In a comparison of Thiessen polygons, inverse distance weighting, kriging and splines, the geostatistical kriging method yielded the best results in terms of model fit. More importantly, the differences in both coefficient estimates as well as in the calculations of MWTP were significant between the various interpolation methods, suggesting that greater attention to this aspect of the data is warranted.

26.4.1.2 Spatial sampling

The statistical foundations for the analysis of spatial hedonic models derive from two very different paradigms, related to the way in which the sampling of

observations is conceptualized (for details, see Anselin, 2002). The most widely used framework is referred to as lattice analysis, due to the fact that considerable early work in this area pertained to regularly spaced or gridded observations (e.g., Besag, 1974). In lattice analysis, the observations are discrete spatial units that exhaust the space, such as contiguous census tracts or counties. The main distinction is that the notion of interpolation is not supported, since observations are available on all spatial units in the "population." Asymptotics are based on a notion of expanding domain, i.e., growing the sample by adding additional units at the edge. In contrast, in so-called geostatistical analysis (Cressie, 1993), observations are a sample from a continuous surface. The main objective is to extract the characteristics of the continuous surface, so that interpolation (spatial prediction) can be carried out. The proper asymptotics are referred to as infill asymptotics and can be conceived of as increasing the density of sampling. Importantly, the two forms of asymptotics are different and properties that hold under one do not necessarily hold under the other (see, e.g., the discussion in Lahiri, 1996).

Hedonic house price studies are typically based on a sample of individual sales transactions or appraisals, and seldom include the full population. This is only the case in analyses for aggregate spatial units, such as census tracts or counties. Because of the nature of the sales sample, a geostatistical perspective should be the preferred approach. However, in practice, most empirical work is couched in a lattice perspective, using the standard spatial lag and spatial error specifications with spatial weights derived from contiguity or nearest neighbor criteria. This aspect is seldom highlighted, but it does raise potential problems in terms of the asymptotics necessary to obtain the consistency of estimators. For example, when a simple contiguity weights matrix is used between the locations of sales transactions (e.g., by using Thiessen polygons to define neighboring sales), a lattice approach assumes that the observed houses are the only houses in the population. In other words, the effect of the *neighbors* should be interpreted as the effect of neighboring *sales*, but not of neighboring properties. When the sales only constitute a sample of all transactions, the underlying assumption becomes that the effect of sampled neighbors is the same as that of the unobserved true neighbors. The validity of this assumption rests on the degree of spatial homogeneity of the housing market, in terms of both house and household characteristics. Without further information, this is very difficult to verify in practice.

26.4.2 Endogeneity

The issue of endogeneity in the estimation of demand equations that arise from a nonlinear hedonic price schedule is a familiar problem (see, e.g., Palmquist, 2005). Much less common is the focus on endogeneity in the estimation of the hedonic price equation itself. In the context of spatial hedonic models, this has received some attention, specifically in the study of the valuation of the contribution of air quality (and, to a lesser extent, of school quality).

There are two different perspectives on the endogeneity problem. In one, attention focuses on a specific house characteristic and the degree to which this is truly exogenous. For example, this would not be the case if air quality is correlated with

other unobserved characteristics of the house. Alternatively, if the house purchase decision is taken jointly with the assessment of environmental quality, endogeneity would also result. Similarly, sorting by house purchasers when there is heterogeneity in their preference functions associated with different pollution levels would result in endogeneity of the air quality variable. This aspect was treated extensively in a recent paper by Chay and Greenstone (2005), in the context of an application where air quality is measured by total suspended particles. They suggest the use of instrumental variables to obtain consistent estimates. While considerable care is taken in addressing these specification problems, the model itself is estimated at a fairly aggregate spatial scale of US counties.

Bayer *et al*. (2006) follow Chay and Greenstone (2005) by considering the possibility that local air pollution is correlated with unobserved local characteristics. They address this form of endogeneity by using the contribution of distant sources to local air pollution as an instrument. However, this study is also carried out at the spatially aggregate county level, and could therefore suffer from ecological fallacy.

The potential correlation of specific house or household characteristics with unobserved errors is considered by Gibbons (2003). Using a semiparametric model, the potential endogeneity of educational composition is accounted for by using the postcode-sector proportion of households in social housing as an instrument for educational composition.

In the second perspective, endogeneity follows as a consequence of an "errors in variables" problem. This is a special case of the change in support problem due to the limited number of sample points for air pollution. As a result, the "observations" of air quality at individual house locations are actually the result of a statistical spatial interpolation process with its own prediction error. In Anselin (2001b), it was pointed out that the spatial structure of the prediction error is likely to lead to correlation with the overall model disturbance term and thus to the familiar simultaneity bias. Anselin and Lozano-Gracia (2008) elaborate on this idea and estimate a spatial lag hedonic price equation using spatial two-stage least squares (2SLS), including additional instrumental variables to address the endogeneity of the air quality variable. Specifically, they use the components of a polynomial in the coordinates of the house locations as instruments.

Irrespective of the actual source of the endogeneity, the use of instrumental variables for some of the characteristic variables will yield consistent estimates. However, in the absence of optimal instruments, the precision of these estimates (and of the resulting computations of MWTP and other related measures) may be improved upon. This remains a subject of future investigation.

26.5 Empirical evidence: spatial dependence

The first attempts to incorporate spatial considerations into empirical hedonic house price studies consisted of including distance from the central business district as an explanatory variable in the model specification. While appropriate for monocentric cities, this is less suitable for polycentric areas, such as the Los Angeles metropolitan area. This resulted in several empirical studies reporting either

insignificant or positive signs for distance decay, a finding not compatible with theory (Dubin, 1992).

Dubin (1988) introduced the concept of spatial autocorrelation into the treatment of hedonic house price models. Her approach was based on geostatistical principles, in which the structure of spatial autocorrelation follows from an estimated theoretical semi-variogram.[2] As argued in section 26.4.1.2, the geostatistical approach is conceptually most suited to the analysis of a sample of house sales transactions. In spite of this, it has seen relatively few applications in applied spatial hedonic work. Other than the work of Dubin and co-authors (e.g., Dubin, 1992, 1998; Case *et al*., 2004), some notable examples include articles by Thibodeau (Basu and Thibodeau, 1998; Gillen *et al*., 2001), Miltino *et al*. (2004), and Bourassa *et al*. (2007), as listed in in Table 26.1. An overview of the major methodological issues is given in Dubin *et al*. (1999).

The bulk of applied work in spatial hedonic house price analysis takes a lattice data perspective and employs the standard spatial lag and spatial error models. An overview of several illustrative studies is given in Tables 26.2 and 26.3, for cases where, respectively, the spatial lag and spatial error specifications were the primary focus of attention. Topics covered range from the simple definition of the hedonic equilibrium and explanation of price differentials to the valuation of environmental benefits, accessibility to transportation systems, wildfire risk, and the impact of preservation policies.

Around the same time as Dubin's article appeared, Can (1990) was one of the first to consider the implications of spatially autocorrelated errors in the estimation of spatial regression models using the lattice perspective. Specifically, she allowed coefficients of the structural characteristics to vary across observations in a spatial lag specification. Using a sample of 577 house sales for 1980 in Columbus, Ohio, she concluded that a linear neighborhood quality drift expansion model is the most appropriate hedonic price specification. Later on, Can (1992) used data from 563 single-family house sales in 1980 for Franklin County to obtain heteroskedastic consistent estimators for a spatial autoregressive model based on bootstrapping techniques.

In recent years, the application of spatial econometric techniques in empirical hedonic studies has become more widespread. Most analyses still rely on ML

estimation (e.g., Kim *et al*., 2003; Brasington, 2004; Capozza *et al*., 2005; Hunt *et al*., 2005; Armstrong and Rodríguez, 2006; Hui *et al*., 2007), although alternative methods are being increasingly considered as well. For example, general method of moments estimators were applied in Bell and Bockstael (2000), Legget and Bockstael (2000), Anselin and Le Gallo (2006), Munroe (2007), Anselin *et al*.

(2008) and Anselin and Lozano-Gracia (2008), among others. A comparative perspective is offered in Bell and Bockstael (2000), using about 1,000 observations on parcel data for Anne Arundel County, Maryland. Overall, the average difference between estimates for the characteristics based on ML and GM methods is less than 5%. However, the estimates for the (error) spatial autoregressive coefficient differ between 10% and 29%.

In general, studies using a spatial econometric approach show significant differences in the estimates of marginal prices, in particular when employing a spatial lag specification. For example, Pace and Gilley (1997) find that the simultaneous spatial autoregressive (SAR) model ML estimator obtains a much better fit than the OLS estimator using data from 506 sales in Boston SMSA (Standard Metropolitan Statistical Area). Pace and Gilley (1998) also compare a SAR with OLS and a grid adjustment model and conclude that, by going from the OLS to the SAR specification, the estimated residuals fall by 44%.

For a spatial error model, the issue is not consistency of the estimates, but precision. Here again, a spatial approach seems to pay off. For example, Legget and Bockstael (2000), using data on coastal properties from Ann Arundel County in Maryland, suggest that the significance of the coefficients improves considerably. This allows them to confirm the relationship between residential prices and water quality with more confidence relative to the estimates obtained from OLS.

An important sub-set of empirical studies focuses on the way in which environmental quality, and air quality in particular, becomes capitalized into the house price. Considerable differences between the results of spatial and non-spatial estimates are observed in these studies as well. For example, Kim *et al*. (2003) found that the marginal price for air quality estimated using spatial 2SLS for a spatial lag model was half the size of the estimate obtained through OLS. Using a survey of 609 owner-occupied households in Seoul, Korea, they estimated a hedonic price equation in which air pollution is introduced as NO_x and SO_2, obtained from readings from 20 monitoring stations. The air pollution measures were interpolated to allocate a value to each of 78 residential sub-districts. An important contribution made in Kim *et al*. (2003) is to spell out the estimation of the marginal benefit in a spatial lag model. They note that it does not only include the direct effect seen in traditional OLS applications, but also a so-called *spatial multiplier* effect that captures the "induced effects of a neighborhood's housing characteristics change."

Beron *et al*. (2004) go one step further and consider the welfare effects of non-marginal changes in air pollution by estimating the second stage of the hedonic model. They compare the welfare estimates from a 10% reduction in air pollution between a standard regression using OLS and SAR-based models. Using single-family home sales records for four counties in the South Coast Air Basin (Los Angeles, Orange, San Bernardino and Riverside Counties), they estimate a semi-log form of the hedonic price equation for six different years (1980, 1983, 1986, 1989, 1992 and 1995). Air quality is measured as the annual average of PM10 (airborne particulate matter resulting from the burning of fossil fuels, such as petrol in cars) at each of 40 monitoring stations, and interpolated using the geostatistical kriging technique. Interestingly, an additional random resampling is carried

out to eliminate the effects of spatial autocorrelation, which reduces the ultimate sample size to 51,110 observations. The WTP estimates obtained from the different models ranged between $15,719 and $34,154 for the SAR model and between $15,639 and $30,489 for the OLS-based models. Beron *et al.* (2004) suggest that, even though a spatial model for the first stage of the hedonic model provides a statistically superior specification, it does not reduce the variability seen in estimated benefits derived from different model specifications. While it is clear that both spatial heterogeneity and spatial dependence violate the assumption of spherical error terms, the implications for the empirical results of the hedonic model of taking these misspecifications into account may vary from one case to the other.

The wide range seen in the estimated WTP for reductions in air quality calls for further research in this area. Additional insight remains to be gained into the sensitivity of the WTP to different specifications. In addition, many studies do not obtain standard errors for the calculated welfare effects, which makes meaningful comparisons difficult.

Further attention to non-marginal changes in environmental quality is given in Brasington and Hite (2005), who found that the demand for environmental quality is considerably more inelastic in spatial models than non-spatial models suggest. They use house sales data in Ohio for 1991, aggregated to the census block group (CBG) level, to estimate a hedonic specification that considers the presence of spatial autocorrelation in both first and second stages of the model.[3] The original number of house transactions considered is 44,255. However, since the study is carried out at the CBG level, the effective sample size consists of the number of CBG in the study, 5,051. Brasington and Hite estimate a model that includes both a spatial lag and a spatially correlated error term, with the environmental variable measured as the distance to the nearest hazard.[3]

They show that the explanatory power of the spatial model is higher and, most importantly, this model suggests a more inelastic demand function than the other specifications. For example, using the non-spatial model, the estimated consumer surplus loss from a decrease of half a mile in the median distance to a hazard is $2,276 per household. In contrast, the spatial model gives an estimate of $3,278. These results suggest that ignoring spatial characteristics may lead to underestimating the consumer surplus loss of a reduction in environmental quality. However, since no standard errors are reported, it is difficult to assess the significance of the difference in estimates.

Other recent examples of spatial econometric hedonic applications include Anselin and Le Gallo (2006), Donovan *et al.* (2007), Hui *et al.*, (2007), Munroe (2007), Anselin and Lozano-Gracia (2008) and Anselin *et al.* (2008), among others.

Anselin and Le Gallo (2006) point out that the spatial interpolation method used to create some of the explanatory variables included in hedonic models determines to a great extent the estimates of marginal prices. They recommend the kriging interpolator as the preferred method. Donovan *et al.* (2007) use a spatial lag model to estimate the effect of wildfire risk on house prices. This study follows an interesting approach to define the weights matrix, in which a correlogram is used to determine the extent of spatial correlation. They conclude that ignoring spatial

autocorrelation leads to biases for the estimated risk measures that range between 37% and 167%.

Munroe (2007) combines geovisualization of single-family residential site prices, exploration of univariate and bivariate measures of spatial autocorrelation, and spatial econometric estimation of a hedonic model, to identify factors that are likely to affect the land value in Mecklenburg County, North Carolina.

Finally, Anselin and Lozano-Gracia (2008) consider the endogeneity from an errors in variable problem of the interpolated air pollution variable. Furthermore, they provide the first empirical application of the HAC estimator suggested in Kelejian and Prucha (2007). By reporting standard errors and 95% confidence intervals, they compare the estimates from spatial and non-spatial models. Although statistical differences are mainly seen between estimates that ignore (or not) endogeneity, they point out that the spatial models allow for a distinction between direct and multiplier effects in the estimation of benefits associated with marginal changes in house characteristics, which is not possible in the standard non-spatial specification.

An interesting set of studies has focused on comparing the performance of geostatistical and lattice spatial econometric models, with particular attention given to the estimates in the hedonic price equation and out of sample prediction. For example, Miltino *et al*. (2004) compare a conditional autoregressive model (CAR) and a SAR model with a geostatistical model and a linear mixed effects model. The parameters of these four specifications are estimated using a relatively small sample, consisting of 293 dwelling sales in Pamplona, Spain. Coefficient estimates are very similar across models. Using AIC and BIC information criteria, the CAR model seems to be a better alternative than the SAR model, but differences do not appear to be significant. Miltino *et al*. (2004) suggest that using a linear mixed effect model may be a better alternative, because this type of model avoids the problems associated with the selection of an appropriate weights matrix. A similar comparison for a larger dataset remains to be carried out.

Case *et al*. (2004) find superior out of sample prediction performance for three spatial models relative to OLS using 50,000 house sales observations for Fairfax County, Virginia. Bourassa *et al*. (2007) extend this work by also including an OLS model that includes dummy variables for different sub-markets. This is assessed for 4,880 house sales from Auckland, New Zealand. Specifically, they compare the performance of a geostatistical model, lattice spatial models, and a standard model with dummy variables (spatial fixed effects) for mass appraisal purposes. The addition of sub-market dummy variables seems to outperfom both geostatistical as well as lattice models in terms of out of sample predictions. However, these conclusions may need to be put into perspective, since the sub-market models considered did not include spatial effects (see also section 26.6). To some extent then, the spatial and dummy variable specifications are not directly comparable. Also, for lattice models, the notion of out-of-sample prediction is complicated when some observations are removed from the original dataset. Since this alters the specification of the weights matrix, additional uncertainty is introduced, which needs to be taken into account (see also section 26.4.1.2).

Overall, there is ample empirical evidence that properly accounting for spatial dependence by means of spatial econometric methods pays off in terms of superior estimates of marginal price coefficients as well as welfare effects. However, several methodological issues still require further investigation.

26.6 Empirical evidence: spatial heterogeneity

Following the same organization as the methodological discussion, spatial heterogeneity can be classified as either discrete or continuous. In this review of some of the empirical literature, we follow the same distinction. An overview of the empirical applications considered is given in Table 26.4.

26.6.1 Discrete heterogeneity: sub-markets

Heterogeneity in the determination of house prices across spatial sub-units of the market is commonly approached by considering this as a special case of market segmentation (see Stevenson, 2004, for a review). This segmentation may result from the existence of market barriers or other types of market imperfections across space.

The main methodological problem is then how to delineate the submarkets. In the literature, this has been approached in a number of different ways. Examples include the use of political boundaries, such as census tract, zip code zone or county boundaries (see, e.g. Goodman, 1981; Goetzmann and Spiegel, 1997; Brasington and Hite, 2005), or subjectively determined areas defined by real estate agents or appraisers (e.g., Bourassa *et al*., 2003, 2007). Alternatives rely on the application of statistical techniques, such as principal component and cluster analysis (Bourassa *et al*., 1999, 2003, 2008), including model-based clustering (Day *et al*., 2004), hierarchical models (Goodman and Thibodeau, 1998, 2003), and mixtures of linear models (Ugarte *et al*., 2004). In addition to geographical boundaries, physical characteristics of a property, such as the number of rooms, the lot and floor area, and the type of property, have also been used to define sub-markets.

In practice, most attempts to account for this type of spatial heterogeneity include dummy variables for each sub-market in the hedonic specification, rather than estimating a separate hedonic equilibrium for each sub-market (e.g., Bourassa *et al*., 2007). The inclusion of sub-market dummies may improve the predictive power of the model, which is usually the stated objective. However, it does not fully account for parameter heterogeneity, which may be important for identification purposes.

Representative examples of the prior selection of sub-markets are the work of Bourassa and co-authors. For example, in Bourassa *et al*. (2003), sub-markets defined by real estate agents are compared to those derived from the application of principal components and cluster analysis for 8,421 house sales transactions in Auckland, New Zealand, in 1996. Specifically, factor scores obtained using principal components are used in *k*-means cluster analysis, which results in sub-markets that do not impose contiguity. In terms of out of sample prediction, the geographically defined sub-markets used by appraisers outperform those based on statistical criteria. Also, for mass appraisal purposes, urban boundaries seem to be better as definitions of spatial sub-markets.

Further comparative evidence is provided in Bourassa *et al*. (2008), where alternative specifications of sub-markets are evaluated using a sample of 13,000 housing transactions for Louisville, Kentucky. Districts defined by local property tax assessment, as well as a classification of census tracts generated by principal components and cluster analysis, are used to derive sub-markets. For the purposes of mass appraisal, both the use of sub-market dummy variables as well as geostatistical methods increase the predictive accuracy of hedonic models.

In contrast to this spatial fixed effects approach, Allen *et al*. (1995) suggest that the differences between the sub-markets identified may be treated as random effects. The specific application is a study of an aggregate residential rental market. Through this approach, the authors allow for the possibility of individuals considering more than one property type in their choice set, while still considering an aggregated rental market, instead of modeling each sub-market independently.

Goodman and Thibodeau (1998), on the other hand, suggest that submarkets should not be imposed but specified explicitly using a hierarchical approach. For example, they use 28,939 single-family property transactions in Dallas, Texas,

between 1995 and 1997 and derive aggregates of school zones as sub-markets. The procedure starts by estimating a hierarchical model for two adjacent school zones. Then, if the coefficient associated with the sub-market is significant, those school zones are considered to pertain to different sub-markets. If, on the other hand, the coefficients are not significant, the two zones are merged. One by one, each school zone is added until all zones have been included. To avoid sub-market definitions that are path dependent, sensitivity checks are included of how the final sub-market definition depends on the starting point.

Comparative evidence is provided in the evaluation of the hierarchical approach to a sub-market definition using zip codes and census tracts in Goodman and Thibodeau (2003). In terms of prediction accuracy, the Goodman and Thibodeau (1998) hierarchical approach outperforms the other two methods.

In more recent work, Ugarte *et al*. (2004) propose the use of a mixture of linear models. This first provides a classification of the observations into groups (sub-markets), and then estimates the parameters for the hedonic price equilibrium in each group. The data are allowed to determine the group structure and coefficients are estimated jointly. A linear mixed model with random effects is estimated by means of nonparametric ML. However, due to the small number of properties considered (293 in Pamplona, Spain), the degree of generality of this approach remains a topic for further research.

In the empirical literature, the discussion of sub-market definition and evaluation of the performance of different methods has tended to focus primarily on the out-of-sample predictive precision. The effect of different sub-market definitions on the substantive interpretation of the value and MWTP of specific house (and environmental) characteristics largely remains to be investigated.

26.6.2 Continuous spatial heterogeneity: spatially varying coefficients

Early efforts to allow for continuous variation of the parameters in a hedonic specification were based on applications of Casetti's expansion method. This was first implemented by Can (1990) as a way to address spatial heterogeneity in house prices at the neighborhood level. In her specification, the marginal price of housing attributes are assumed to vary as a function of neighborhood characteristics. Specifically, Can defined a composite neighborhood quality (NQ) index and introduced linear and quadratic functions of NQ as the expansion equation. The hedonic price equilibrium is then specified as:

$$P = \alpha + \sum_k \beta_k S_k + \varepsilon, \tag{26.43}$$

where the S_k are the structural characteristics of the house and β_k is a function of a neighborhood variable NQ. For example, for the linear case:

$$\beta_k = \beta_{k0} + \beta_{k1} NQ + u. \tag{26.44}$$

Other examples of applications of the expansion method to hedonic specifications can be found in Can (1992), Theriault *et al*. (2003), Fik *et al*. (2003) and

Kestens *et al*. (2006). However, their feasibility in practice is typically limited due to the severe problems of multicollinearity that follow from the interaction terms.

Continuous spatial heterogeneity as implemented in GWR has seen several applications to hedonic specifications. Fotheringham's text contains multiple examples of hedonic price models (Fotheringham *et al*., 2002), but others have applied this methodology as well, such as Cho *et al*. (2006), Kestens *et al*. (2006), Farber and Yeates (2006), Long *et al*. (2007), Bitter *et al*. (2007) and Wang *et al*. (2008). Related applications to repeat house sales models include McMillen (2003, 2004).

Pavlov (2000) suggests that the spatial varying coefficient model forms an alternative approach to dealing with sub-markets that outperforms several competing specifications in terms of cross-validation residuals. The models evaluated include a standard linear regression and a linear regression that includes dummy variables for zip codes, as well as a parametric model including a quadratic polynomial of the X, Y coordinates of the points in the data.

Other applications focus more on the parameter instability related to specific characteristics in the hedonic specification, such as environmental quality. For example, Cho *et al*. (2006) investigate whether public open space is capitalized into nearby residential property values. They use an original dataset that includes over 22,000 single-family housing sales transactions between 1998 and 2002 in Knox County, Tennessee. Of this total sample, 15,500 transactions were randomly selected for analysis. GWR estimation of a hedonic specification that includes proximity to water bodies and parks suggests considerable variation in the marginal prices of both amenities along different regions of the county. The resulting local marginal prices would be obscured in a global model that assumes a constant marginal price across the whole region.

A number of studies have compared the performance of the parametric expansion method to the nonparametric GWR. For example, using data on 761 single-family properties sold between 1993 and 2001 in Quebec City, Canada, as well as information on the profiles of buyers, Kestens *et al*. (2006) compare the results from a spatial expansion method and GWR. They also suggest that introducing detailed household-profile data into the hedonic specification helps in explaining spatial heterogeneity while at the same time reducing spatial dependence. Household income, previous tenure status and age of the buyer show a significant effect on house prices.

A similar comparison is carried out by Farber and Yeates (2006), who consider global specifications, such as a standard linear and a SAR model (both estimated using OLS) relative to local models such as GWR. Using an adjusted version of R^2 as the criterion, they conclude that GWR obtains the best fit. Similarly, Bitter *et al*. (2007), using data for over 10,000 single-family house sales in Tucson, Arizona, find that GWR outperforms the expansion method in terms of both explanatory power and predictive accuracy.[4] On the other hand, Kestens *et al*. (2006) suggest that, in their application, GWR and the expansion method have similar explanatory power.

Long *et al*. (2007) assess the difference in predictive accuracy between moving windows regression (MWR), GWR, kriging, and moving windows kriging (MWK)

using data on 33,494 transactions of single-family detached houses sold between January 2001 and December 2003 in the City of Toronto; 10% of this sample is taken out for out-of-sample validation. The MWR is an alternative to the locally weighted regression (LWR) (and therefore GWR) in which a window (neighborhood) is defined at every location. All points inside the window, and only those points, are used to estimate the parameters for each observation. Therefore, in contrast to LWR/GWR, a constant weight is given to all observations within the window, ignoring observations outside the window. Similarly, MWK uses a local spatial covariance structure that varies at every point in the sample (Haas, 1990). In this example, MWR and GWR provide the most accurate results in terms of prediction, while MWK produces very poor results in terms of out-of-sample prediction.

Overall, the explicit incorporation of spatial heterogeneity in hedonic specifications illustrates the need to better understand the nature of market segmentation and the complex interactions between location and the value of individual house characteristics.

26.7 Concluding remarks

The contribution of spatial econometrics to hedonic analysis is not limited to improving the quality and precision of the estimates obtained, as reviewed in the previous sections. Spatial econometric methods also provide additional insight for policy analysis. In this concluding section, we focus on two aspects in particular, the notion of the spatial multiplier and its implications for the interpretation of welfare effects, and the use of spatially explicit simulations to assess the impact of non-marginal changes in characteristics.

As outlined in detail in section 26.2.1, the marginal implicit price derived from the hedonic price equilibrium may be interpreted as a measure of a household's marginal utility. Therefore, the derivative of the hedonic price equilibrium equation with respect to the characteristic of interest forms the basis for the estimation of MWTP.

In a non-spatial log-linear model, this MWTP equals the estimated coefficient for the characteristic of interest z_k times the price (P), or:

$$\widehat{MWTP}_{z_k} = \frac{\partial P}{\partial z_k} = \hat{\beta}_{z_k} P. \tag{26.45}$$

As shown in Kim *et al*. (2003), in a spatial lag model this is no longer the case. Instead, a spatial multiplier effect needs to be accounted for to accurately compute the MWTP. Specifically, in the case of a uniform change in the amenity across all observations, the MWTP can be shown to be:

$$\widehat{MWTP} = \hat{\beta}_{z_k} P \left(\frac{1}{1 - \widehat{\rho}} \right), \tag{26.46}$$

with $\widehat{\rho}$ as the estimate of the spatial autoregressive coefficient.

The distinction between equations (26.45) and (26.46) is important in light of the points recently raised by Small and Steimetz (2006). They considered a different interpretation of welfare effects between the *direct* valuation in equation (26.45) and the multiplier effect included in (26.46). In their view, the multiplier effect should only be considered as part of the welfare calculation in the case of a technological externality associated with a change in amenities. In the case of a purely pecuniary externality, the direct effect is the only correct measure of welfare change. Only in a spatial lag specification is it possible to distinguish between these two effects.

The use of an analytical approach to deriving MWTP in impact analysis is limited in a number of ways. It is constrained by the functional specification of the hedonic model. Specifically, if nonlinearities are introduced in the hedonic model, such nonlinearities will be transfered to possible dependencies and/or nonlinearities in the MWTP itself. Also, the analytical derivation of MWTP is limited to marginal changes in the characteristics. For non-marginal changes, the inverse demand function needs to be estimated, which is often difficult in practice. Moreover, nonlinear specifications require a value for the price and/or characteristics in the calculation, which is typically simplified by using a mean or median value.

An alternative to the analytical derivation is to use a simulation approach, as outlined in Anselin and Le Gallo (2006). The essence of the approach is that valuation is based on the computation of predicted values for individual observations given their actual household characteristics. In essence this boils down to a discrete approximation to the notion of marginal willingness to pay. A major advantage of the simulation approach is that it allows greater flexibility, both in the specification of the type of policy experiment as well as in the valuation. Since the valuation is computed for individual house observations, the results can be obtained for any desired level of spatial aggregation, such as by county or zip code (for an extensive application, see Anselin *et al.*, 2008).

In a non-spatial linear model, the change in predicted values can be expressed as follows:

$$\hat{p}_0 - \hat{p}_{-k} = (z_0 - z_{-k})\beta_k, \tag{26.47}$$

where $\hat{p}_0 - \hat{p}_{-k}$ is the change in valuation and $(z_0 - z_{-k})$ is the change in characteristic k. If a spatially lagged dependent variable is included in the hedonic price equilibrium, the change in valuation resulting from a change in characteristic k would turn out to be $(I - \hat{\rho}W)^{-1}(z_0 - z_{-k})\beta_k$. Any nonlinearities of the hedonic price function would also be reflected in this approximation to the change in valuation.

By ignoring this multiplier effect and looking at individual or private benefits only, underestimation of the overall social welfare from changes in house characteristics may result, such as reductions in air pollution, greater access to public facilities, and public services. In decision making under strict efficiency rules, this may lead to an underinvestment in such characteristics.

In sum, a spatial econometric approach yields more efficient estimates of policy effects of interest, allows for a distinction between direct and indirect welfare effects

and forms the basis for flexible policy simulation experiments. While the field has made significant progress to date, several important methodological issues remain to be addressed satisfactorily. Foremost among these are the treatment of spatial scale, endogeneity and sub-market heterogeneity. It is hoped that the current chapter has raised awareness of these issues and will stimulate further progress.

Notes

1. For a more extensive discussion, see Anselin (2002, pp. 256–60) and Anselin (2006, pp. 909–10).
2. Commonly used theoretical specifications include the negative exponential, spherical and Gaussian semi-variograms. A detailed discussion of specific functional forms is given in Dubin *et al*. (1999).
3. Note that, rather than estimating the more traditional inverse demand function, Brasington and Hite (2005) estimate a direct demand function in the second stage of the hedonic model.
4. Bitter *et al*. (2007) also introduce a spatially lagged variable into the GWR specification, but it is doubtful that the OLS estimation procedure used would yield consistent estimates of this lag term.

Spatial Analysis of Economic Convergence

Sergio J. Rey and Julie Le Gallo

Abstract

This chapter reviews some of the major econometric models, approaches and issues related to the spatial dimensions of economic convergence and inequality. Key themes concern the implications of spatial dependence (autocorrelation) and heterogeneity for the specification, estimation, and interpretation of convergence models on the one hand and, on the other, the treatment of these spatial effects in the analysis of distributional dynamics and the application of related exploratory data analysis methods. We draw linkages between recent contributions in the mainstream econometric literature and developments in spatial econometrics and regional science We identify a number of areas where cross-fertilization between these fields would be beneficial.

27.1 Introduction

The last two decades have witnessed a renaissance in the field of growth econometrics. Defined as the set of statistical tools for the study of growth (Durlauf *et al.*, 2005), growth econometrics can be organized along two dimensions. In the first, which we refer to as the regression approach, predictions from formal neoclassical (and other) growth theories have been tested using cross-sectional, time series and panel data econometric specifications. The second group of methods departs from the representative economy assumption underlying most of the regression approaches and instead examines the entire distribution of incomes. Here the focus shifts to how different parts of the distribution may behave over time, and to questions of whether there are changes in modality and shape of the distribution and concerns with the intradistributional dynamics and mixing. These methods are distinct not only in their focus, but also in the specific statistical techniques that are employed.

A prominent trend in the growth literature has been a decidedly regional turn, where the focus has shifted from cross-country analyses to examine the nature of convergence as it may operate at the sub-national scale (cf. Barro and Sala-i-Martin, 1992; Carlino and Mills, 1993; Neven and Gouyette, 1995; Sala-i-Martin, 1996; Rey and Montouri, 1999; Fingleton, 2004). Early in this regional turn, there was some appreciation for the challenges that regional data posed for the application of standard growth models. Given that regions typically display a greater deal of openness than is the case for national economies, various forms of regional interdependencies, such as labor and capital flows along with trade, take on increased importance at the finer spatial scale. Yet there was also a perception that there was a lack of econometric methods for modeling regional interdependencies. When confronted with evidence of spatial dependence and heterogeneity in regional growth sets, the strategy adopted by many researchers has been to remain in the closed-economy model but to adjust the closed model for these spatial effects.

Paradoxically, during this period of renewal and resurgence of interest in growth econometrics, there was a similar burst of activity in the fields of spatial econometrics and spatial statistics (for example, Anselin, 1988; Cressie, 1993; Anselin *et al.*, 2004). Indeed, as Arbia (2006, p. 3) has noted: "until a few years ago, spatial econometric methods were well developed in the literature but the drama was that no one used them in the mainstream applied economic analysis!"

Towards the close of the century this began to change, with a number of studies adopting methods and tools of spatial analysis to the question of regional, or sub-national, economic convergence beginning to appear in the literature. The intersection of these two literatures has generated a large, and growing, body of empirical studies, as well as the identification of a number of challenging methodological issues and some advances in the modeling and analysis of spatial growth and convergence. The growing recognition of the unique characteristics of spatial data is reflected by Durlauf *et al.* (2005), who note: "The problem of spatial correlation has been much studied in the regional science literature, and statisticians in this field have developed spatial analogues of many time series concepts ..."

While this recognition is promising, it is also indicative of the need for further interaction between the growth econometric and spatial analysis literatures. As we develop more fully in what follows, spatial correlation is not a simple spatial analogue to temporal correlation, nor are the methods that have been developed in the spatial literature simple extensions of time series methods. Moreover, spatial correlation/dependence is but one of several types of spatial effects encountered in the analysis of geographically referenced data.

This chapter explores the intersection of the growth empirics and spatial analysis literature. Our objectives for doing so are threefold. First, while there have been some efforts at providing overviews of regional convergence research, these have tended to appear in the regional science and economic geography literature (e.g., Magrini, 2004; Abreu *et al*., 2005; Rey and Janikas, 2005) and not the wider growth literature. Because of this the amount of cross-fertilization between the traditional growth econometrics literature and the spatial analysis is not as advanced as it could be. Thus we hope that by updating previous reviews we can bring this work to a wider audience.

At the same time, existing reviews have divided the literature into those studies adopting a confirmatory approach to formal growth modeling on the one hand and, on the other, the "atheoretical" exploratory literature. In our view this is an artificial distinction as we see both literatures as complementary, and thus our second objective is to explore the potential synergies between these two fields. Finally, there are a number of outstanding methodological issues that require further attention in order for the field of regional convergence analysis to move forward. We identify these and suggest an agenda for future research.

The chapter is organized as follows. Section 27.2 provides a selective survey of the treatment of space in empirical econometric work on convergence. Section 27.3 examines methods for distributional dynamics and related exploratory data analysis and their application to spatially referenced data. Section 27.4 concludes with a summary evaluation of progress to date and the identification of possible directions for future research.

27.2 Space and econometric modeling of convergence

27.2.1 Models of economic growth

The primary basis for the analysis of spatial effects in empirical convergence studies has been cross-country growth regressions, based on the seminal studies by Barro and Sala-i-Martin (1992) and Mankiw *et al*. (1992). The main prediction of the neoclassical growth models is that the growth rate of an economy is positively related to the distance that separates it from its own steady-state. Let us take as a starting point the canonical form for such regressions:

$$\frac{1}{T}\log(y_{i,t_0+T}/y_{i,t_0}) = \alpha + \beta \log(y_{i,t_0}) + X_{1,i}\delta_1 + X_{2,i}\delta_2 + \varepsilon_i, \qquad (27.1)$$

where $y_{i,t}$ is the per capita income of country or region i at time t, and $X_{1,i}$ is a set of additional structural regressors suggested by the Solow growth model (population growth, technological change and physical and human capital savings rates).

They are transformed in ways implied by the model (see Durlauf and Quah, 1999, for additional insights into this specification). $X_{2,i}$ is a set of additional control variables capturing differences in aggregate production functions and ε_i is an error term with the following properties: $\varepsilon_i \sim i.i.d.(0, \sigma_\varepsilon^2)$.

In this specification, the average growth rate in per capita income over the period t_0 to $t_0 + T$ is related to the initial level for income y_{i,t_0} and a set of steady-state determinants ($X_{1,i}$ and $X_{2,i}$). There is conditional convergence if the estimate of β is significantly negative, with a convergence speed equal to $b = -\log(1 + T\beta)/T$ and a half-life equal to $\tau = -\log(2)/\log(1+\beta)$. The concept of unconditional convergence is defined when all the economies are assumed to be structurally similar, that is, that they are characterized by the same steady-state, and differ only by their initial conditions. This assumption is tested with the cross-sectional model, including only the initial per capita income as an explanatory variable.

As frequently pointed out in the growth econometrics literature, the tests of conditional convergence face several problems, such as robustness with respect to choice of control variables, multicollinearity, heterogeneity, endogeneity, and measurement problems (Durlauf and Quah, 1999; Temple, 1999; Durlauf *et al.*, 2005). Durlauf *et al.* question the assumption usually made on the error terms. Indeed, by assuming that they are independent and identically distributed (i.i.d.), the researcher thinks of them as interchangeable across observations. This is the concept of exchangeability: "different patterns of realized errors are equally likely to occur if the realizations are permuted across countries. In other words, the information available to a researcher about the countries is not informative about the error terms" (2005, p. 36). They show that many econometric problems highlighted in growth regressions can be interpreted as violations of exchangeability. Parameter heterogeneity (discussed below) or omitted regressors induce non-exchangeability.

The assumption of constant returns to scale, on which neoclassical theory is based, has been challenged by new economic growth and new economic geography theories. Consequently, Fingleton and McCombie (1998) suggest alternative theoretical frameworks that allow increasing returns to scale, especially when one deals with regions. At the heart of this approach is Verdoorn's law, based on Kaldor's second law, which has been traditionally estimated as a linear relationship between the exponential growth rate of labor productivity (p) and output (q):

$$p = b_0 + b_1 q + \varepsilon, \tag{27.2}$$

where $\varepsilon \sim i.i.d.(0, \sigma_\varepsilon^2)$. In equation (27.2), the coefficient b_0 is the autonomous rate of productivity and the coefficient b_1 is called the Verdoorn coefficient. Its estimated value is consistently about one-half when the model is fitted to various data on manufacturing productivity growth and output growth. This implies that a one-percentage-point increase in output growth induces an increase in the growth of employment of one-half of a percentage point and an equivalent increase in the growth of productivity. The increasing returns implied by Verdoorn's law have been illustrated by Fingleton (2000) using a static Cobb–Douglas production

function model. While exchangeability problems have not been discussed in this specific context, it is also relevant given the type of assumption made on the errors terms.

27.2.2 The cross-sectional approach to growth and convergence

We focus in this section on another possible violation of the exchangeability assumption: spatial dependence in the error terms (Ertur and Koch, 2007). Indeed, in the cross-sectional context, the observational units are spatially organized and the i.i.d. assumption may therefore be overly restrictive. Various alternative specifications are appropriate to deal with different forms of spatial dependence (Rey and Montouri, 1999). They are best described if we rewrite equations (27.1) and (27.2) in matrix form:

$$y = X\gamma + \varepsilon, \tag{27.3}$$

where y is the $(N \times 1)$ vector containing the observations on the dependent variable, X is the matrix containing the observations on all explanatory variables including the constant term, ε is the $(N \times 1)$ vector of error terms, the properties of which we describe below, and α and γ are the unknown parameters to be estimated. In the convergence case, y contains the vector of average growth rates of per capita income between date t_0 and $t_0 + T$ and X contains the initial log per capita income and all the other control variables. In the Verdoorn case, y contains the labor productivity growth rate. Several spatial econometric specifications have been used to control for spatial dependence in growth econometrics models: the spatial lag model, the spatial error model and the spatial Durbin model.[1] In the spatial lag model, or mixed regressive spatial autoregressive (AR) model, a spatially lagged dependent variable Wy is added to the right-hand side of the regression specification:

$$y = \rho Wy + X\gamma + \varepsilon, \tag{27.4}$$

where W is an $(N \times N)$ spatial weights matrix, usually row-standardized, and ρ is the spatial autoregressive parameter. In a convergence context, for instance, this specification allows measuring how the growth rate in a region may relate to the ones in its surrounding regions (as defined in W) after conditioning on the starting levels of per capita income and the other variables. Unlike the time series case, the spatial lag term is endogenous, since it is always correlated with ε (Anselin, 1988). Therefore, this specification must be estimated using instrumental variables (IVs) or, assuming that ε follows a multivariate normal distribution with zero mean and a constant scalar diagonal variance-covariance matrix $\sigma^2 I_N$, by maximum likelihood (ML). In the former case, Kelejian and Prucha (1999) show that the low-order spatial lags of the exogenous variables can be used as instruments for Wy. Of course, if additional endogenous variables are present in the specification, this approach can easily be extended by adding additional instruments.[2]

The spatial error model is a special case of a non-spherical error covariance matrix in which the spatial error process is based on a parametric relation between a location and its neighbors. Two specifications have commonly been used in spatial

econometrics: the autoregressive and the moving average specifications. It is interesting to note that only the former has been extensively used for the modeling of spatial error dependence in convergence or Verdoorn's law models. A spatial autoregressive specification for the $(N \times 1)$ error vector can be expressed as:

$$\varepsilon = \lambda W \varepsilon + u, \tag{27.5}$$

where λ is the spatial autoregressive parameter and $u \sim i.i.d.(0, \sigma_u^2 I_N)$. Note that this model can be rewritten in another form, called the spatial Durbin model: if (27.3) is premultiplied by $(I - \lambda W)$, we get $(I - \lambda W)y = (I - \lambda W)X\gamma + u$. Hence:

$$y = \lambda W y + X\gamma + \delta WX + u, \tag{27.6}$$

with $\delta = -\lambda\gamma$. These restrictions can be tested by the common factor test (Burridge, 1981). If it cannot be rejected, then model (27.6) reduces to model (27.5). In this model, the average growth rate of a region i is influenced by the average growth rate of neighboring regions, by the initial per capita income of neighboring regions and the spatial lags of the other explanatory variables.

Conversely, the spatial moving average specification can be expressed as:

$$\varepsilon = \widetilde{\lambda} W u + u, \tag{27.7}$$

where $\widetilde{\lambda}$ is the spatial autoregressive parameter and $u \sim i.i.d.(0, \sigma_u^2 I_N)$. Both models can be estimated by ML, under the normality assumption, or generalized methods of moments (GMM) (see Kelejian and Prucha, 1999, for the AR case and Fingleton, 2008, for the moving average (MA) case). These two specifications differ in the terms of the range of spatial dependence in the variance-covariance matrix and of the diffusion process they imply. More precisely, in the first case, the variance-covariance matrix for ε is $\Omega = \sigma_u^2 (A'A)^{-1}$ with $A = I_N - \lambda W$. While W may be sparse, the inverse term $(A'A)^{-1}$ is not. As a consequence, a random shock at one location i is transmitted to all other locations of the sample: the spillovers are global. Rey and Montouri (1999) and Le Gallo *et al*. (2005) illustrate this property in the context of a β-convergence model and show how a random shock in one US state or in one European region impacts upon the per capita income growth rates of all the regions in the sample. Conversely, in the MA case, the variance-covariance matrix does not involve a matrix inverse: $\widetilde{\Omega} = \sigma_u^2 \widetilde{A}'\widetilde{A}$. Therefore, the spillovers remain local: a shock at location i will only affect the directly interacting locations as given by the non-zero elements in W. Finally, higher-order spatial models have been investigated by Kosfeld *et al*. (2006).

This basic framework has been extensively used to analyze the convergence patterns among several sets of countries and regions: convergence among US states (Rey and Montouri, 1999; Lee, 2004; Garrett *et al*., 2007), European regions (Fingleton, 1999; Maurseth, 2001; Carrington, 2003; Le Gallo *et al*., 2003; Arbia, 2006; Le Gallo and Dall'erba, 2006), Brazilian states (Lall and Shalizi, 2003; Magalhães *et al*., 2005; Azzoni and Silveira-Neto, 2006), Spanish regions (Villaverde, 2005, 2006) and Turkish regions (Gezici and Hewings, 2004; Yildirim and Öcal, 2006). Similarly,

these spatial econometric models have been fitted to Verdoorn's law specifications by Bernat (1996), Fingleton and McCombie (1998), Pons-Novell and Viladecans-Marsal (1999) and Dall'erba *et al*. (2008).[3] Several methodological issues should be kept in mind when dealing with these models.

First, in the absence of sound theoretical foundations for the specific form taken by spatial autocorrelation in these models, most of these papers apply a classical "specific to general" specification search approach outlined in Anselin and Rey (1991) and Anselin and Florax (1995) to discriminate between the two forms of spatial dependence – spatial error autocorrelation or spatial lag. Several Lagrange multiplier (LM) tests are used for that purpose. Florax *et al*. (2003) show by means of Monte Carlo simulation that this classical approach outperforms Hendry's "general to specific" approach. Note that this classical approach has several drawbacks, including the problem of multiple comparisons highlighted by Savin (1984): the significance levels of the sequence of tests conducted in this section are unknown.

Second, particular attention should be given to the interpretation of the coefficients in the spatial lag model, as compared to those of the spatial error model or the simple model estimated by ordinary least squares (OLS). Indeed, in these latter models, the marginal effect of one explanatory variable x_k corresponds to the associated parameter β_k. Conversely, the spatial lag model (27.4) can be rewritten as $y = (I - \rho W)^{-1}(\rho W y + X\gamma + \varepsilon)$. Since (in most cases) the elements of the row-standardized weights matrix W are less than one, a Leontief expansion of the matrix inverse follows as: $(I - \rho W)^{-1} = I + \rho W + \rho^2 W^2 + ...$ Consequently, the growth rate of per capita income (in the convergence context) or of labor productivity (in the Verdoorn context) of one region i is not only affected by a marginal change of the explanatory variables of region i but is also affected by marginal changes of the explanatory variables in the other regions, more importantly so for closer regions. As a consequence, the estimated coefficients in a spatial lag model include only the direct marginal effect of an increase in the explanatory variables, excluding all indirect induced effects, while in the standard model estimated by OLS, they represent the total marginal effect. It is therefore not relevant to compare OLS and ML or two-stage least squares (2SLS) estimates for a spatial lag. This aspect has so far been overlooked in the spatial econometrics literature in general (Pace and LeSage, 2007) and in the spatial growth empirics literature in particular (Abreu *et al*., 2005) and should be kept in mind when drawing inference on determinants of the economic growth process using, for instance, the computationally feasible means of summarizing the output into direct and indirect impacts of each variable of interest suggested by Pace and LeSage (2007).

Third, endogeneity in cross-country regression models is a problem that is commonly encountered as output growth, investment rates, and so on, in a particular period are likely to be jointly determined. Caselli *et al*. (1996) note that "At a more abstract level, we wonder whether the very notion of exogenous variables is at all useful in a growth framework (the only exception is perhaps the morphological structure of a country's geography)." In a non-spatial context, they deal with this issue using the Arellano and Bond (1991) GMM procedure. Similarly, while Verdoorn's law is usually treated as a single equation and estimated via OLS,

there is a debate on the assumed endogeneity and exogeneity of this specification (Kaldor, 1975; Rowthorn, 1975a, 1975b).

In a spatial context, as mentioned previously, the case of a spatial lag model with additional endogenous variables is straightforward since it can be estimated by 2SLS. However, the estimation of a model with a spatial error process and endogenous variables is not possible with the usual ML approach. In this case, Fingleton and Le Gallo (2008) have extended the Kelejian and Prucha (1998) feasible generalized spatial two-stage least squares (FGS2SLS) estimator to account for endogenous variables due to system feedback, given an AR or a MA error process. Angeriz *et al*. (2008) use this strategy in the Verdoorn context. Alternatively, rather than modeling the error process, Kelejian and Prucha (2007) have suggested a nonparametric heteroskedastic and autocorrelation consistent (HAC) estimator of the variance-covariance matrix in a spatial context (SHAC), which can be computed for general regression models allowing for endogenous regressors, their spatial lags and exogenous regressors. This methodology may also prove useful in spatial econometric growth studies. Coupled with this is an extensive taxonomy of simultaneous equation frameworks for spatial process models, recently suggested by Rey and Boarnet (2004), that appears well-suited to convergence research.

Finally, the problem of model uncertainty has been raised by Brock and Durlauf (2001), Fernandez *et al*. (2001), Doppelhofer *et al*. (2004) and Sala-i-Martin (1997). This problem can arise from several sources. First, the selection of appropriate conditioning variables is a difficult issue in convergence models and involves a trade-off between the arbitrary selection of a small number of variables, which may imply some omitted variables bias, and the introduction of a larger set of variables with a number of econometric problems such as endogeneity or multicollinearity. Second, as is typical in all regression models, we also face parameter uncertainty. Fernandez *et al*. (2001) and Doppelhofer *et al*. (2004) employ Bayesian model averaging techniques that can accommodate both model and parameter uncertainty. In a convergence framework, they find that the posterior distribution of β computed across alternative specifications assigns all probability mass to the negative half interval. This results in strong support to the convergence hypothesis. However, LeSage and Fischer (2007) point out that in a spatial setting an additional source of model uncertainty arises: one also has to specify the appropriate weights matrix W that defines connectivity between regions. In other words, the estimates and associated inferences in spatial growth regressions are not only conditional on the set of explanatory variables employed but also on the chosen spatial weights matrix. Extending the approach of LeSage and Parent (2007), LeSage and Fischer (2007) derive a Bayesian model comparison approach that simultaneously specifies the spatial weights structure and the explanatory variables in spatial Durbin models, with an application to the convergence process among European regions.

27.2.3 Dealing with heterogeneity

In this section, we deal with heterogeneity problems and how the literature has considered them in conjunction with spatial autocorrelation. We consider the

convergence literature here as these problems have been mainly encountered in this context. First, unobserved heterogeneity is one of the most common problems related with conditional convergence models, in particular due to technological differences between economies. Given the difficulty in accounting for technological differences in a cross-sectional framework (Islam, 2003), an alternative tactic is to resort to the panel data approach to eliminate unobservable economy-level heterogeneity. For that purpose, a dynamic panel data model with individual fixed effects has been suggested by Islam (1995). Panel data techniques have several advantages. They allow controlling for unobserved heterogeneity in the initial level of technology and omitted variables that are persistent over time. Moreover, endogeneity bias, common in convergence equations as stated above, may also be rectified by estimating the panel data convergence model using Arrelano and Bond's (1991) GMM procedure.

Inclusion of spatial autocorrelation in this context has investigated been by few authors to date. One possibility is to get rid of spatial autocorrelation in order to apply the usual estimators. This strategy has been adopted by Badinger *et al*. (2004), who propose a two-step estimation procedure. First, they apply the filtering technique suggested by Getis and Griffith (2002) that separates the spatially correlated component from the data. Second, standard GMM estimators are used to provide inference on convergence. However, the properties of the estimators obtained in this two-step procedure are unknown. Moreover, this approach assumes that spatial autocorrelation is only a nuisance, whereas the following section shows how spatial autocorrelation can be considered as a component of the growth process in its own right. In their suggestion to deal with spatial autocorrelation directly, Arbia and Piras (2005) analyze the European growth process by including a spatial lag variable or a spatial error term in a convergence model with region fixed effects. The spatial parameters are assumed to be fixed over time and the model is estimated using ML. One drawback of this method is that consistent estimation of the individual fixed effects is not possible as $N \to \infty$, due to the incidental parameter problem (Anselin *et al*., 2008).

Heterogeneity may also concern the regression parameters. While absolute β-convergence is frequently rejected for large samples of countries and regions, it is usually accepted for more restricted samples of economies belonging to the same geographical area. This observation can be linked to the presence of convergence clubs: there is not only one steady-state to which all economies converge. Rather, there may be multiple, locally stable, steady-state equilibria. Therefore, a convergence club is a group of economies whose initial conditions are near enough to converge toward the same long-term equilibrium. It is noteworthy that the hypothesis $\beta < 0$ can be consistent with non-converging alternatives, such as a threshold growth model with multiple steady-states (Azariadis and Drazen, 1990). The determination of those clubs, when they exist, is then a critical issue. In this respect, some select *a priori* criteria, such as initial per capita gross domestic product (GDP) cut-offs (Durlauf and Johnson, 1995). On the contrary, endogenous methods of club detection are quite diverse and include regression trees (*ibid*.), projection pursuit methods (Desdoigts, 1999), Bayesian methods that identify a

mixture distribution for the predictive density of per capita output (Canova, 2004), among others.

It is noteworthy that Durlauf and Johnson (1995), by endogenizing the splitting using the regression tree method, point out the geographic homogeneity within each group. This is even more bound to happen in a regional context, as regional economies are often characterized by strong geographic patterns. In Europe, the core–periphery pattern has frequently been underlined as representative of a form of *spatial heterogeneity*. In a regression context, spatial heterogeneity can be reflected by spatially varying coefficients, that is, structural instability, and/or by spatially varying variances across observations. With this observation in mind, several attempts aimed at analyzing spatial convergence clubs have been suggested. A first strand of papers just use *a priori* spatial regimes. For example, Neven and Gouyette (1995) define two regimes: Northern and Southern European regions. Ramajo *et al*. (2008) split their sample of European regions between the EU cohesion-fund countries (Ireland, Greece, Portugal and Spain) and all the others. Using a model with groupwise heteroskedasticity, two spatial regimes and spatial dependence, they show that, over 1981–96, there was a faster conditional convergence speed in regions belonging to cohesion countries than in the rest of the regions. A similar strategy has been adopted by Roberts (2004) on a sample of British counties, by distinguishing between northern and southern counties.

Others explicitly take into account the spatial dimension of the data and use exploratory spatial data analysis to detect spatial regimes. These techniques are described in more detail in the following section. We note here that Ertur *et al*. (2006) use Moran scatterplots (Anselin, 2006), based on the initial per capita GDP of a sample of European regions, to determine spatial clubs. Two clubs are constructed this way: HH (High–High) regions and LL (Low–Low) regions, corresponding respectively to regions with High (Low) initial per capita GDP surrounded by regions with High (Low) initial per capita GDP. Atypical regions (that is, regions classified as High–Low or Low–High) are eliminated from the sample as they are not numerous enough to constitute a club. Alternatively, Le Gallo and Dall'erba (2006), Dall'erba and Le Gallo (2008) and Fischer and Stirböck (2006) prefer the use of Getis–Ord statistics (Ord and Getis, 1995), applied to initial per capita GDP, that lead to a two-way partitioning of the sample: spatial clusters of high values of per capita GDP (corresponding to positive values of the statistic) and spatial clusters of low values of per capita GDP (corresponding to negative values of the statistics). We can think of these methods as being "semi-endogenous," as the number of clubs is fixed (four in the case of Moran scatterplots and two in the case of Getis–Ord statistics) but the economies are endogenously allocated to the clubs.

The endogenous detection of convergence clubs in data characterized by spatial autocorrelation remains a serious problem, as the properties of the methods already suggested (regression trees, and so on) remain unknown in the presence of spatial autocorrelation. A first step in this direction is described in the paper by Basile and Gress (2005), who suggest a semiparametric spatial autocovariance specification that simultaneously takes into account the problems of nonlinearities and spatial dependence. To that end, Liu and Stengos' (1999) nonparametric specification is

extended by allowing a spatial lag term or a spatial error process. Another methodological problem is the fact that spatial heterogeneity (representative of spatial convergence clubs) and spatial dependence may be observationally equivalent in a cross-section (Abreu *et al.*, 2005). Indeed, a cluster of high-growth regions may be the result of spillovers from one region to another or it could be due to similarities in the variables affecting the regions' growth. Moreover, standard tests of structural instability and heteroskedasticity are not reliable in the presence of spatial autocorrelation. Therefore, as Rey and Janikas (2005) note, the existing specification search procedures should be extended to be able to distinguish between spatial dependence and spatial heterogeneity, while formal specification search strategies for spatial heterogeneity have yet to be suggested.

Rather than partitioning the cross-sectional sample into regimes based on structural characteristics, parameter heterogeneity might also be country- or region-specific. For example, Durlauf *et al.* (2001) allow the Solow growth model to vary according to a country's initial income by using the varying coefficient model suggested by Hastie and Tibshirani (1993). In a spatial context, Ertur *et al.* (2007) argue that similarities in legal and social institutions, as well as culture and language, might create spatially local uniformity in economic structures, which lead to situations where rates of convergence are similar for observations located nearby in space. One possibility is to use geographically weighted regression (GWR) (Fotheringham *et al.*, 2004), which is a locally linear, nonparametric estimation method aimed at capturing, for each observation, the spatial variations of the regression coefficients. For that purpose, a different set of parameters is estimated for each observation by using the values of the characteristics taken by the neighboring observations. For the conditional β-conditional convergence model (equation 27.1), this procedure allows estimation of the set of unknown parameters (β and coefficients associated with the other structural characteristics) for each economy of the sample:

$$\frac{1}{T}\log(y_{i,t_0+T}/y_{i,t_0}) = \alpha_i + \beta_i \log(y_{i,t_0}) + X_{1,i}\delta_{1i} + X_{2,i}\delta_{2i} + \varepsilon_i. \tag{27.8}$$

This model is estimated using weighted least squares with the weights being specific to each observation: for an observation i, the weights are a continuous and monotone decreasing function of the distance between observation i and all other observations. This method is useful for identifying the nature and patterns of spatial heterogeneity over the observations and the results of a GWR (local estimated coefficients, local t-statistics and measures of quality of fit) can be mapped. In a convergence context, this method has been used by Bivand and Brunstad (2003) for a sample of European regions and by Eckey *et al.* (2007) for 180 labor market regions in Germany. Eckey *et al.* show that the German labor market regions are moving at different speeds towards their steady-states, with the value of the half-life increasing from North to South.

While useful for capturing heterogeneity in growth experiences in a sample of economies, inference in this context is problematic. Indeed, Wheeler and Tiefelsdorf (2005) show that the local regression estimates are potentially collinear even if

the underlying exogenous variables in the data-generating process are uncorrelated. This collinearity can degrade coefficient precision in GWR and lead to counter-intuitive signs for some regression coefficients. Another methodological problem has been pointed out by Paez *et al*. (2002) and Pace and LeSage (2004). Indeed, one of the motivations of this approach is that, if spatial autocorrelation only arises due to inadequately modeled spatial heterogeneity, GWR can potentially eliminate this problem. However, this is not necessarily the case as substantive spatial interactions may coexist with parameter heterogeneity, as we will show in the next section. Therefore, Pace and LeSage (2004) have generalized GWR to allow simultaneously for spatial parameter heterogeneity and spatial autocorrelation: the spatial autoregressive local estimation (SALE). Formally, estimates are produced using n-models, where n represents the number of cross-sectional sample observations, using the locally linear spatial autoregressive model:

$$U(i)y = \rho_i U(i)Wy + U(i)X\gamma_i + U(i)\varepsilon, \tag{27.9}$$

where $U(i)$ represents an $(N \times N)$ diagonal matrix containing distance-based weights for observation i that assign the weight of one to the m nearest neighbors to observation i and weights of zero to all other observations. The product $U(i)y$ then represents an $(m \times 1)$ sub-sample of observed per capita income rates associated with the m observations nearest in location to observation i. The other products are interpreted in a similar fashion. As $m \to N$, $U(i) \to I_n$, and the local estimates approach the global estimates from (27.4) as the sub-sample size increases. This model is estimated by recursive ML for $\varepsilon_i \to N(0, \sigma_i^2 U(i)I_N)$. This approach has been implemented by Ertur *et al*. (2007) for a sample of 138 European regions for the period 1980–95. Moreover, they also control for non-constant variances with a Bayesian spatial autoregressive local estimation. They show that, while the mean of the estimates for ρ is near zero, there are still a number of regressions for which spatial dependence estimates take on large and significant values. Country-level differences are also obvious for the different estimates of the convergence parameter β, with negative and significant values across EU regions in Spain, Portugal and some French regions.

27.2.4 Theoretical foundations of spatial effects

As pointed out by Islam (2003), the specifications of growth regressions used in initial studies of β-convergence were not derived from theoretical growth models. Only at a subsequent stage were the regression specifications formally derived from the neoclassical growth models by Barro and Sala-i-Martin (1992) and Mankiw *et al*. (1992). The literature focusing on the relationships between space and growth has evolved quite similarly. All the studies surveyed above included spatial effects in an *ad hoc* way, allowing for spatial autocorrelation and/or spatial heterogeneity in conditional β-convergence models or Verdoorn models in order to obtain a better fit and consistent estimates. Spatial autocorrelation in this context may reflect spatial spillovers arising between economies but can also be the result of some model misspecification or omitted variables. Recently, some authors have tried to

provide sound theoretical foundations for the inclusion of spatial dependence in β-convergence or Verdoorn models. We review some of this recent work here.

Ertur and Koch (2007) show how a spatial Durbin version of the β-convergence model (equation 27.6) can be obtained from a theoretical growth model with Arrow–Romer externalities and spatial externalities that imply inter-economy technology interdependence. They start with an aggregate Cobb–Douglas production function for economy i at time t that exhibits constant returns to scale in labor and reproducible physical capital:

$$Y_i(t) = A_i(t)K_i^{\alpha}(t)L_i^{1-\alpha}(t) \tag{27.10}$$

$$\text{where } A_i(t) = \Omega(t)k_i^{\Phi}(t)\prod_{j\neq i}^{N}A_j^{\gamma w_{ij}}(t),$$

where $Y_i(t)$ is output, $K_i(t)$ is the level of reproducible physical capital, $L_i(t)$ is the level of labor, N is the number of economies and $A_i(t)$ is the aggregate level of technology of economy i at time t. This level depends on three terms. First, as in the standard Solow growth model, Ertur and Koch (2007) assume that some proportion of technological progress is exogenous and identical in all countries: $\Omega(t) = \Omega(0)e^{\mu t}$, where μ is the constant growth rate. Second, each economy's aggregate level of technology increases with the aggregate level of physical capital per worker $k_i(t) = K_i(t)/L_i(t)$, and the parameter Φ (with $0 \leq \Phi < 1$) describing the strength of home externalities generated by physical capital accumulation. Finally, as these externalities may spill over to neighboring economies, it is also assumed that there is technological interdependence generated by the level of spatial externalities γ (with $0 \leq \gamma < 1$). The w_{ij} are the usual terms of the spatial weights matrix.

This specification yields a spatially augmented β-convergence model, similar to a non-constrained spatial Durbin model, where the growth rate of real income per worker not only depends on its own saving rate and population growth rate, but also depends on the same variables in the neighboring economies and on the growth rate of its neighboring economies weighted by their speed of convergence. Interestingly, complete parameter heterogeneity can be allowed for when the speed of convergence is not assumed to be identical across economies. Ertur and Koch (2007) estimate this heterogeneous model on a set of countries using the SALE model as in equation (27.9). Other such attempts to motivate theoretically the presence of spatial dependence have been suggested. For instance, López-Bazo *et al*. (2004) assume that the spatial externalities originate from physical and human capital accumulation rather than knowledge, yielding a β-convergence model with a spatial lag term as in (27.4). Egger and Pfaffermayr (2006) decompose the speed of convergence term into three components: one measuring the speed of convergence net of spillovers, and the other two accounting for the importance of spatial spillovers.

A similar path has recently been followed to provide theoretical foundations for the spatial versions of Verdoorn's law. In particular, Fingleton (2000) shows how Verdoorn's law including a spatial lag term can be motivated by inter-regional

technology diffusion. Indeed, take as a point of departure a static Cobb–Douglas production function given by:

$$Q = A_0 \exp(\lambda t) K^{\alpha} E^{\beta}, \tag{27.11}$$

in which A_0 is the level of technology at time 0, λ is the growth of total factor productivity or exogenous technical change, Q, K and E are the levels of output, capital, and employment at time t; α and β are elasticities. Fingleton (2000) assumes that the technical progress made by firms as a result of the growth of capital per worker (p) is not fully internalized but spills over to benefit other firms and individuals. Two forms of technology spillovers are envisaged: one occurs as a result of intraregional technical change and one occurs as a result of extraregional technical change in neighboring regions:

$$\lambda = \lambda^{*} + \phi p + \kappa W p. \tag{27.12}$$

λ in one region is then proportional to p in the same region and, through the matrix product Wp, is also a function of capital accumulation occurring within the neighbors for each region, as specified by W. Taking equation (27.11) in logs, differentiating with respect to time and assuming that capital stock growth and output growth are approximately the same,[4] he shows that the reduced equation can be written as:

$$p = \rho W p + b_0 + b_1 q + Xb + \varepsilon, \tag{27.13}$$

where X contains other determinants of labor productivity growth, such as the initial level of technology gap between each region and the leading technology region, and measures of peripherality and urbanization. In subsequent papers, Fingleton (2001a, 2001b) shows that the spatial lag version of Verdoorn's law is, in fact, also consistent with assumptions that underpin new economic geography with, as a starting point, a Cobb–Douglas production function for the level of output produced by manufacturers that depends on the input of manufacturing labor efficiency units, on composite intermediate services and on the input of land. Increasing returns are modeled via the product variety theory emphasized by Dixit and Stiglitz (1977) and the rate of technical progress is assumed to be as in equation (27.11).

27.3 Exploratory spatial data analysis of convergence

While a great deal of work has been done on confirmatory econometric analysis of growth and convergence, a number of criticisms have been pointed at the relatively restrictive nature of the underlying theoretical frameworks, their inability to account for empirical regularities in growth datasets and the general problem of using cross-section regressions to explain time-averaged growth rates with which to make inferences about growth dynamics (Quah, 1993b). In response to some of the criticisms, a number of researchers have adopted novel methods of exploratory

data analysis (EDA) to examine growth datasets. EDA has its roots in the work of John Tukey (Tukey, 1977), who defined the field as a set of statistical methods designed to detect and describe patterns, trends, and relationships in data. EDA methods often rely on interactive statistical graphics to support different types of interrogation of the data.

In this section we provide an overview of the main branches of EDA methods that have appeared in the convergence literature. These follow from some of the particular challenges posed by the study of growth and convergence in a spatial context. On the one hand, traditional EDA techniques often rest on the same restrictive assumptions regarding random sampling that we encountered in early econometric work on regional convergence. There has been much recent work developing spatially explicit methods of EDA designed to take the spatial characteristics of the data into account. These methods fall under the heading of *exploratory spatial data analysis* (ESDA) (Anselin, 1996).

At the same time, the dynamic characteristics of growth datasets pose interesting challenges for the use of ESDA methods, since the latter have primarily been designed for cross-sectional datasets. The second branch of the exploratory literature we review consists of efforts designed to extend ESDA methods to the dynamic context. We refer to this branch of the literature as *exploratory space-time data analysis* (ESTDA).

The use of ESDA and ESTDA methods for convergence and growth analysis relies on a number of computational tools as well as interactive statistical graphics and maps for data exploration. In what follows, we draw on examples using the statistical package STARS: Space-Time Analysis of Regional Systems (Rey and Janikas, 2006), which has implemented a number of these methods for spatial convergence analysis.[5]

27.3.1 Exploratory spatial data analysis

27.3.1.1 Spatial σ-convergence

The point of departure in the EDA branch of the convergence literature has been the entire distribution of regional incomes itself, with a focus on a number of characteristics of this distribution. The earliest studies examined the level of dispersion in the distribution and its evolution over time. Labeled as σ-convergence, the typical approach is to consider the cross-sectional variance (or standard deviation) of the incomes:

$$\hat{\sigma}_t^2 = \frac{1}{(n-1)} \sum_{i=1}^{n} (y_{i,t} - \bar{y}_t)^2, \tag{27.14}$$

where $y_{i,t}$ is the per capita income or product of economy i in time period t and $\bar{y}_t = \frac{1}{n} \sum_{i=1}^{n} y_{i,t}$. Implicit in the application of this measure is its theoretical relationship to β-convergence:

$$\sigma_t^2 = (1-\beta)^2 \sigma_{t-1}^2 + \sigma_\epsilon^2, \tag{27.15}$$

where α, β, and σ_ϵ^2 are as defined in equation (27.1). If $0 < \beta < 1$ the difference equation is stable and β-convergence gives rise to the steady-state variance:

$$\sigma_*^2 = \frac{\sigma_\epsilon^2}{1-(1-\beta)^2}. \tag{27.16}$$

The cross-sectional variance in incomes will fall with increases in β (in the stable range) but rise with the initial σ_ϵ^2.

There are a number of limitations of σ-convergence for studying the dynamics of the distribution. First, it focuses on only the second moment of the distribution and is thus silent on other moments, such as skewness and kurtosis, which can be important from a substantive perspective. Second, the sample variance would also mask any multimodality or twin-peakedness in the distribution, which tends to be a common finding at the international scale. In addition to being silent on the morphology of the distribution, measures of σ-convergence provide no insight on the degree of intradistributional mixing and mobility.

While these criticisms are generally well known, there are also several lesser known problems with the application of σ-convergence to spatially referenced data. The first is a spatial identification problem. This arises from the sample variance being what is known as a "whole map" statistic. More specifically, given a map (spatial distribution) of n incomes $y_{i,t} : i = 1, 2, \ldots, n$, with sample variance $\hat{\sigma}_t^2$, there are $n!$ spatial permutations of the map that would have the same sample variance.

The second difficulty with σ-convergence in a spatial context relates to the i.i.d. assumption on ϵ. As is the case for the confirmatory econometric modeling of convergence, the presence of spatial dependence in the error term of the model complicates the analysis. The impact of spatial dependence on the interpretation of σ-convergence has been examined by Egger and Pfaffermayr (2006) and Rey and Dev (2006), who show that, in addition to the β coefficient and the initial variance level, the value of the sample variance will also reflect the level and structure of the spatial dependence. More specifically, if the underlying data generating process is the spatial lag specification, then the sample variance for the income levels will be sensitive to the value of the spatial lag parameter and the specific structure of the spatial weights matrix. These additional sources of dynamics complicate the interpretation of the sample variance as a measure of σ-convergence.

27.3.1.2 Markov chain models

Quah (1993a, 1996a) has adopted a discrete Markov chain approach to study the evolution of income distributions. Using international data for 1962–84, Quah discretizes the income distribution in each period into k classes, and the probability of an economy transitioning between each pair of classes is estimated from the income series for the country economies. An application of this approach to the lower 48 state incomes for the US over the period 1929–2000 is reported in Table 27.1. The income values are standardized to the national value each year and the class cut-offs are taken from the quintiles of the relative distribution for the first year in the sample. Thus, for a state that had an income level below 66% of

Table 27.1 Markov transitions: US state incomes 1929–2000

	$t+1$				
t	0.661	0.884	1.031	1.309	1.934
0.661	0.893	0.107	0.000	0.000	0.000
0.884	0.013	0.913	0.073	0.001	0.000
1.031	0.000	0.054	0.872	0.074	0.000
1.309	0.000	0.001	0.065	0.913	0.021
1.934	0.000	0.000	0.000	0.112	0.888

Note: The row (column) headings are the upper bounds for the quintiles of relative incomes normalized by the national average. The values in the body of the table are the empirical transition probabilities of moving from class i in period t to class j in period $t+1$.

Table 27.2 Ergodic US state income distribution

x	0.661	0.884	1.031	1.309	1.934
$P(x)$	0.029	0.233	0.314	0.358	0.067

Note: Column headings are the upper bounds for the quintiles of relative incomes normalized by the national average.

the national average, the probability of moving up into the next higher income class during one year was 0.107. At the other end of the distribution, states with incomes greater than 193% of the national level moved down one income class with a probability of 0.112.

Based on an estimate of the transition probability matrix, one can in turn generate an estimate of the ergodic distribution for the regional incomes. For the US case, the long-run distribution implied by these transitional dynamics is reported in Table 27.2. The tendency towards convergence is clearly evident in this distribution, as the extreme classes lose mass over what they had in the quintile distribution at the beginning of the period (1929).

While the Markov chain is an innovative approach to the exploration of distributional dynamics, the estimates of the transition probabilities rest on several assumptions, such as order, time-homogeneity and independent transitions. Independent transitions mean that the spatial context facing a given economy is not taken into account when estimating the probability of movement out of a particular income class.

27.3.1.3 Spatial Markov

Rey (2001) extends the discrete Markov approach to consider this context by estimating transition matrices subject to the spatial lag of the income values for an economy. This is done for the US example in Table 27.3, where the same five income

	1.934	0.000	0.000	0.000	0.048	0.952

classes are used to estimate transition matrices for subsets of the states at different points in time. The sub-setting is based on the spatial lag of the incomes. For example, focusing on the first matrix, we see that poor states that were surrounded by poor states (i.e., those with incomes less than 66% of the national average) moved out of the bottom class with a probability of 0.015. However, if this is contrasted with other states in the lower class, but those who had neighbors that were slightly better off (i.e., in the second class), the probability of moving out of the bottom class now jumps to 0.158. The impact of the spatial context can also be seen for the higher-income states, as the wealthiest states, when surrounded by similarly wealthy states, have a probability of remaining in the upper class of 0.952. However, when a wealthy state is surrounded by states with average incomes in the next lower class, the probability of remaining in the upper class of the distribution drops to 0.863.

The spatial Markov approach has been applied by Le Gallo (2004) to a sample of European regions and by Hammond (2004) to US labor markets. This approach has

also been adopted to explore the question of regional heterogeneity. Bickenbach and Bode (2003) do this by estimating transition matrices for the groups of states in each of the Bureau of Economic Analysis (BEA) regions of the US. They also suggest formal tests of regional homogeneity and find strong evidence that the transitional dynamics are not homogeneous across the US space economy.

While the spatial Markov approach offers an interesting extension of the classic Markov chain to the geographical context, there are a number of methodological issues associated with the approach that require further investigation. The first issue surrounds the data-intensive requirements needed to estimate a spatial Markov matrix. Rather than having to estimate k^2 transition probabilities as in the classic approach, when one is conditioning on k classes for the spatial lag, the number of probabilities to estimate grows to k^3. This can lead to many zero, or small count, observations for specific types of transitions, which in turn means a loss of precision in the estimation of those probabilities.

One solution to this degrees of freedom problem is to combine the thin count cells with other cells and estimate the transition probabilities for the new aggregated cells. This could be done in several ways. One approach would be to keep the number of classes for the spatial lag fixed, and then collapse the same group of cells within each of the k conditional transition matrices. This would result in k conditional matrices of order $r \times c$, with $r \leq k$ and $c \leq k$. An alternative approach would be to keep the number of income classes fixed at k but reduce the number of classes for the spatial lag, essentially aggregating together cells across the conditional transition matrices. In this case one would have $l \leq k$ conditional transition matrices of order $k \times k$. Of course, a third option would be to aggregate both the number of classes for the income variable as well as the spatial lag. The choice between these alternatives is not inconsequential, as the first approach would trade a loss in resolution of the income class transitions for maintaining detail in the effect of spatial context (that is, the spatial lag). In the second approach, more detail on the class transitions is gained at the expense of a coarser view of spatial context effects. To date, however, the relative merits of these different approaches remain unexplored.

A final issue with the spatial Markov approach is that it focuses only on the transitions of individual economies within the income distribution subject to the level of income in the surrounding economies in the initial period. It does not also treat the transition of the spatial lag, but uses that as the conditioning variable. Joint consideration of the transitions of the spatial lag and the income of an economy would require estimating k^4 transition probabilities (assuming k classes for incomes and the spatial lag). Clearly this would exacerbate the degrees-of-freedom problem.

27.3.1.4 Spatial rank mobility

Rank mobility measures attempt to address the problems with discretization to provide a more comprehensive picture of regional income mobility (Boyle and McCarthy, 1997; Webber *et al.*, 2005). One classic measure is Kendall's rank

correlation statistic:

$$\tau = \frac{n_c - n_d}{(n^2 - n)/2}, \tag{27.17}$$

where n_c is the number of concordant pairs of economies over a given interval. Concordant pairs are those that maintain the same relative pair-wise ranking in two periods. n_d is the number of discordant pairs, where a discordant pair are two economies whose relative ranks are reversed over the period. If all pairs are concordant in a given period then $n_c = (n^2 - n)/2,\ n_d = 0$ and $\tau = 1$. Conversely, if all pairs are discordant, then $\tau = -1$.

To introduce a geographical dimension to this rank mobility measure, Rey (2004b) suggested a decomposition of the concordance measure as:

$$n_c = n_{c,r} + n_{c,o}, \tag{27.18}$$

where $n_{c,r}$ is the number of concordant pairs in which the economies involved were geographical neighbors, while $n_{c,o}$ includes those discordant pairs that involve non-neighboring economies. Together with a similar spatial decomposition of the discordant pairs, spatial versions of the rank correlation statistic can be defined as:

$$\tau_r = \frac{n_{c,r} - n_{d,r}}{(n_r^2 - n_r)/2}, \tag{27.19}$$

for the neighboring pairs, and:

$$\tau_o = \frac{n_{c,o} - n_{d,o}}{(n_o^2 - n_o)/2}, \tag{27.20}$$

for the non-neighboring pairs of economies. The traditional measure of rank mobility can be related to these spatial versions:

$$\tau = \psi\tau_r + (1 - \psi)\tau_o, \tag{27.21}$$

where:

$$\psi = \frac{\omega_r}{\omega}, \tag{27.22}$$

with ω_r being the number of neighboring pairs of economies, and $\omega = (n^2 - n)/2$ being the number of all pairs.

Figure 27.1 summarizes the results of a spatial rank mobility analysis of state incomes. The right-hand figure shows the definition of the neighborhood sets, here based on BEA regions. The left-hand figure shows the z-value for the τ test statistic standardized against its expected value based on spatial permutations of the income values. The statistic is significantly negative in the earlier periods, indicating that the amount of intraregional concordance was below what would be expected if there was no spatial structure to income growth. In other words, the differences in

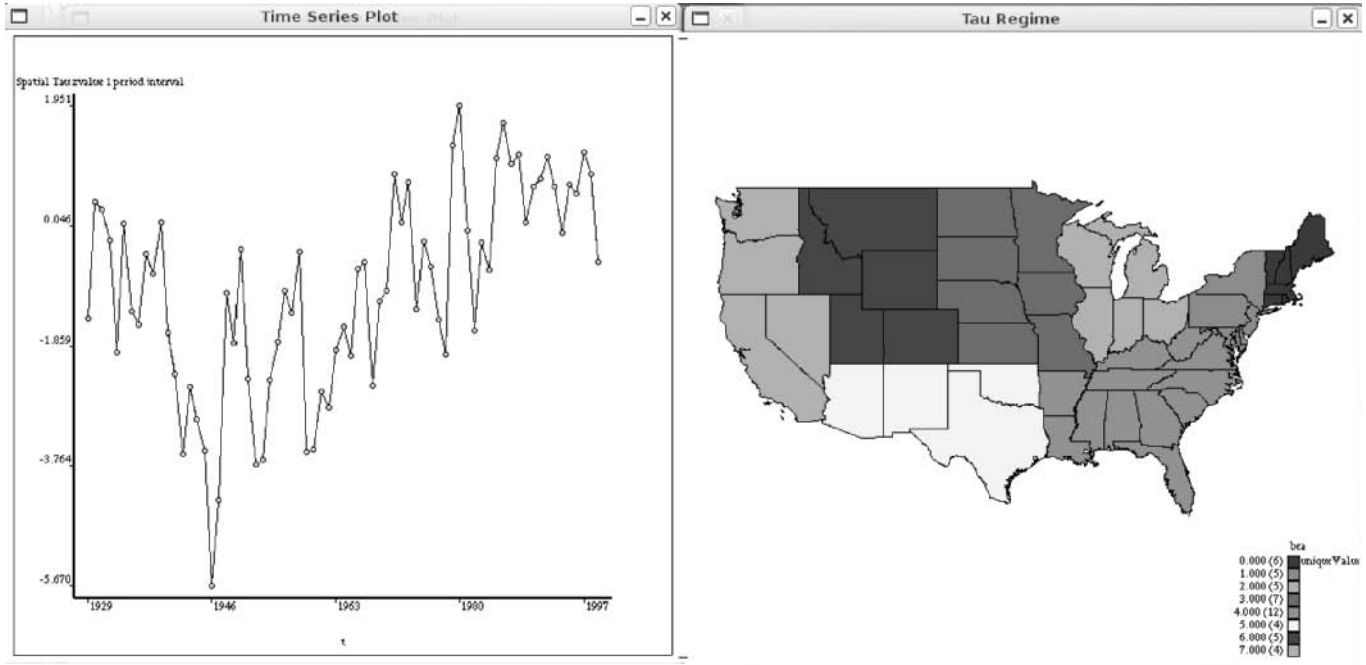

Figure 27.1 Spatial rank mobility

income levels between states from the same region are smaller (and the discordance in rank changes over time greater) than is the case for states from different regions. This form of spatial dependence weakens over time as the spatial rank mobility statistic lessens in absolute value.

27.3.2 Exploratory space-time data analysis

The previous sets of ESDA methods can be seen as attempts to extend a-spatial methods of exploratory convergence analysis to include a spatial component. A second set of methods have been developed that extend exploratory spatial data methods to the dynamic context.

27.3.2.1 Spatial transitions

Since full estimation of a square spatial Markov transition matrix is likely to be infeasible in most data contexts, alternative approaches towards analyzing the movements of the income level of an economy and that of its neighbors have been suggested. These are based on the notion of a local indicator of spatial association (LISA) statistic originally developed by Anselin (1995).

The LISA statistics can be visualized in a Moran scatterplot (Anselin, 1996), depicted in the right-hand panel of Figure 27.2. In the first quadrant are located relatively high-income economies that are neighbored by high-income economies reflected in the spatial lag (HH). Quadrant two contains lower-income (L) economies with wealthier neighbors (LH), while quadrant three might be considered spatial poverty zones since it contains poor economies with poor neighbors. Finally, quadrant four has the "diamonds in the rough" economies – those with high incomes and poor neighbors. These statistics have been extensively used to analyze spatial distributions in several samples of European regions (López-Bazo *et al.*, 1999; Le Gallo and Ertur, 2003; Ertur and Koch, 2007) or other sub-sets of regions (Ying, 2000; Mossi *et al.*, 2004; Patacchini and Rice, 2007).

The spatial concentration of the low values is seen in the map on the left where the user has selected a sub-set of the Southern states. In response, the positions of those states in the scatterplot are indicated by solid black circles. The degree of spatial association for this local cluster (dashed line) is contrasted against the global pattern (solid line). The user can move the lasso around on the map to explore the stability of the spatial clustering over regions of the map. Alternatively, the scatterplot could serve as the origin view and the lasso moved over regions of the plot to reveal the location of selected observations in geographical space, as shown in Figure 27.3.

A number of summary measures of distributional mobility have appeared in the literature. One such measure, due to Shorrocks (1978), is based on the estimates of the classic Markov transition matrix:

$$SI = \frac{k - \sum_i p_{ii}}{k - 1}, \tag{27.23}$$

which is bounded on the interval $[0, k/(k-1)]$, with the lower bound indicating a complete lack of mobility and the upper bound maximum mobility.[6] This captures

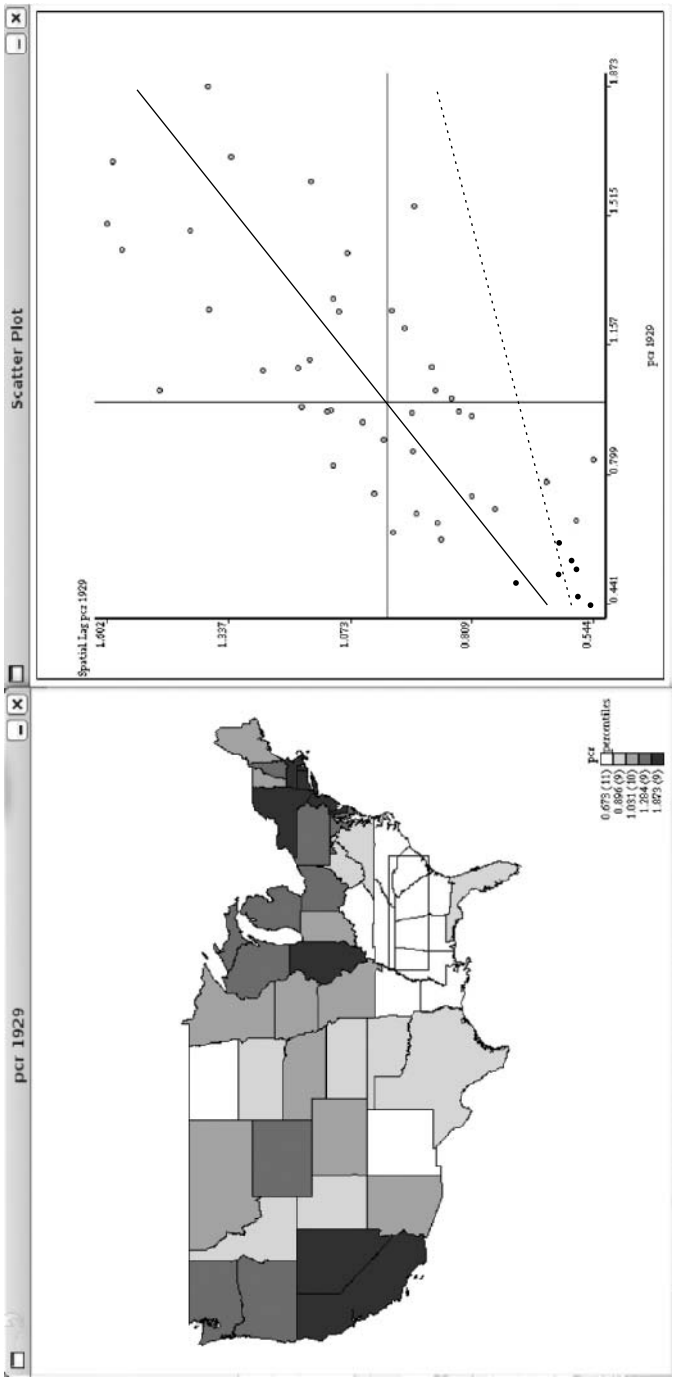

Figure 27.2 Moran scatterplot

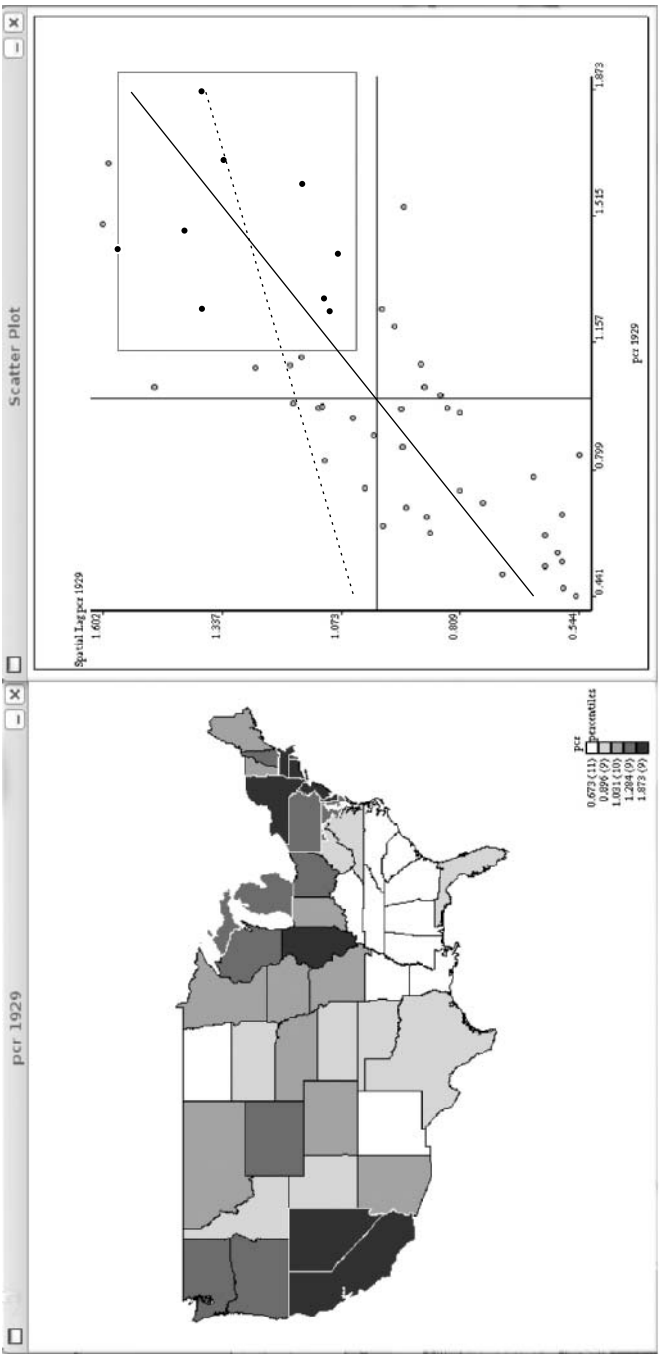

Figure 27.3 Moran scatterplot as origin

class mobility within the distribution and, as such, it is subject to the criticisms associated with the discretization of the income distribution to define the classes. Chief among these is that moves that cross a class boundary are the only kind recorded, while other moves of the same magnitude but remaining within the class are not recorded. Since it is based on the classic Markov approach, the measure also ignores any spatial dependence. However, one could construct a test statistic based on values for this index taken from the specific conditional matrices of the spatial Markov approach to explore whether mobility was affected by spatial context.

To incorporate a spatial dimension to the mobility analysis, Rey (2001) has suggested analyzing the movement of a LISA statistic over a given time interval and noting whether a particular LISA statistic remains in the same quadrant or transitions to a different quadrant. In any period there are four possible states for a LISA – HH, LH, LL, HL, so between any two periods there are 16 different spatial transitions that are possible. These can be summarized in a LISA Markov transition matrix, as is done for the US case in Figure 27.4.

Applying the summary mobility index (27.23) to the traditional Markov transition matrix generates a value of 0.130, which is also found for the case of the LISA Markov transitions, suggesting similar rates of mobility for the spatial versus a-spatial transitions. However, a closer inspection of the two tables reveals some subtle but important differences. In the classic Markov model, the probability of remaining in an extreme (poorest or richest) class is lower than the probability of remaining in the intermediate (2nd or 4th quintile) classes, reflecting a tendency away from polarization in the extreme tails of the distribution. By contrast, for the

	$t+1$		
t	HH	LH	LL
HH	0.929	0.037	0.004
LH	0.079	0.859	0.060
LL	0.005	0.020	0.947
HL	0.053	0.002	0.070

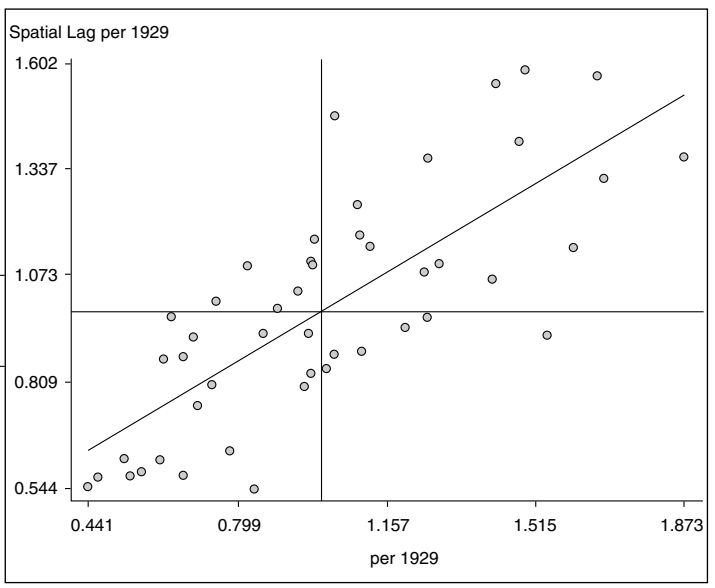

Figure 27.4 LISA Markov transitions

LISA Markov transitions there is evidence of spatial polarization in the transitions, as the "extreme" classes are the HH and LL cells, which have higher retention probabilities than is the case for the HL and LH cells.

27.3.2.2 Space-time paths

In addition to characterizing the global spatial dynamics, a more meso-level scale of analysis is possible. Figure 27.5 contains the *space-time* paths for Virginia (left) and New Jersey (right). The paths are generated interactively by selecting the states in the Moran scatterplot (lower left) and clicking. The time paths trace out the local statistic for each state, showing how its income and that of its neighbors co-evolve over the sample period. At first glance, a comparative view of the two states suggests that the same general trend is evident, reflecting strong spatial cohesion between each state and its neighbors. Closer inspection reveals, however, that

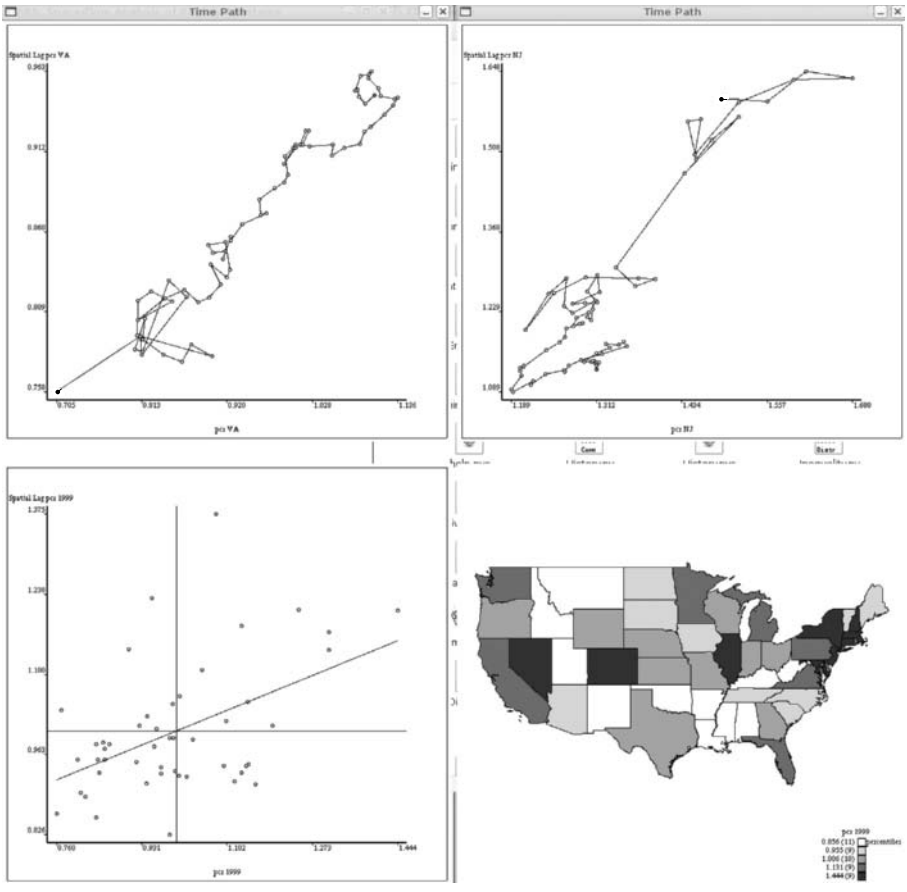

Figure 27.5 Space-time paths

the directionality between the two paths is distinct, with New Jersey's evolution moving downwards towards the mean of the distribution, while for Virginia the dynamics are upward.[7] Rey and Ye (2008) develop approaches for summarizing the properties of these time paths and their use in comparative analysis.

27.3.3 Stochastic kernels

A very active area of exploratory analysis has been the application of stochastic kernels to regional growth series (Magrini, 1999; López-Bazo *et al.*, 1999; Bulli, 2001; Basile, 2006). Here the focus is on the evolution of the distribution itself and a number of novel approaches towards the estimation of densities and their interpretation have been suggested.

27.3.3.1 Estimation

Letting $f_{x(t)}$ represent the regional income density for n economies in period t, the evolution of the cross-sectional distributions is modeled through the use of a stochastic kernel:

$$f_{x(t+s)} = \int_{-\infty}^{\infty} M_{t,s} f_{x(t)} dx, \tag{27.24}$$

where $M_{t,s}$ is the stochastic kernel which traces where points in $f_{x(t)}$ move to in $f_{x(t+s)}$. The kernel can be viewed as a continuous analog of the Markov transition matrix that we examined in the previous section. As such, the stochastic kernel contains important information regarding the distributional dynamics and thus the question of its estimation becomes important. One approach relies on an estimate of the conditional distribution:

$$\hat{M}_{t,s} = \hat{f}_{x(t+s)|x(t)} = \frac{\hat{f}_{x(t+s),x(t)}}{\hat{f}_{x(t)}}. \tag{27.25}$$

Estimates of the joint or marginal densities themselves rely on, somewhat confusingly, kernel density estimates. For example:

$$\hat{f}_x(t) = \hat{f}(x, t; h) = (nh)^{-1} \sum_{i=1}^{n} K\{(x - X_{i,t})/h\}, \tag{27.26}$$

where K is a function such that $\int K(x)dx = 1$, referred to as the kernel, h is the bandwidth and $X_{i,t}$ is the income for economy i for a given time period.

Based on the estimate of the stochastic kernel, alternative visualizations can be generated to explore the implied transitional dynamics. These include three-dimensional representations and the analogous two-dimensional contour plot. Evidence of polarization in the income distributions would be reflected in peaks in the 3D kernel or concentrated values in the contour. The sphericality of either of the graphs would be indicative of heightened income mobility and leap-frogging, while elongated ellipses along the 45-degree line would suggest a lack of mobility and convergence.

Other types of kernel visualizations are shown in Figure 27.6. The conditional densities (Figure 27.6(a)) have been estimated for a 71-year transition period from 1929 to 2000 for the US. By stacking the conditional densities, the figure shows how the regional income distribution from 1929 evolves into that in 2000. The highest-density region (HDR) plot in Figure 27.6(b) identifies the smallest region in the sample space that covers a given probability. For each conditional distribution, the darker shaded area is the 50% HDR, while the lighter shade represents the 99% HDR. The HDR plot reflects strong convergence over the 71-year period, as each of the conditional modes (dots) falls away from the diagonal, indicating that states tend to move towards the overall mean of the distribution.[8]

Alternatively, estimates of the marginal densities for the two periods could be examined. Bianchi (1997) has suggested that the multimodality of a density could serve as an indication of polarization. In this way, movement to a single mode would be reflective of convergence. It should be noted that this marginal approach risks loss of information on the transitions and can mask internal mixing.

While kernels provide novel visualizations of growth dynamics, their use with spatially referenced data is not without problems. To gain some understanding of the potential implications for spatial dependence in the estimation, rewrite the kernel density estimator for a given time period as:

$$\hat{f}(x;h) = n^{-1} \sum_{i=1}^{n} K_h(x - X_i), \tag{27.27}$$

where the incomes $X_1, \ldots, X_n$ are no longer independent but are identically distributed with a common density, so that $Cov(X_j, X_{j+k})$ depends only on k. In such a setting the bias of $\hat{f}(x;h)$ is robust to the dependence, but the variance becomes:

$$\begin{aligned} V\left[\hat{f}(x;h)\right] =& n^{-1} V\left[K_h(x - X_1)\right] \\ &+ 2n^{-1} \sum_{j=1}^{n-1} (1 - j/n) COV\left[K_h(x - X_j), K_h(x - X_{j+1})\right]. \end{aligned} \tag{27.28}$$

Applications of kernel density estimators to regional income datasets have implicitly assumed that the observations were pairwise independent. With spatially referenced data, however, such an assumption can be questionable. The implications for the properties of kernel density estimators and the related methods of stochastic dominance (Carrington, 2006) and relative distribution approaches (Janikas, 2007) have been largely ignored to date in the growth literature.

27.3.3.2 Regional conditioning and spatial filtering

Canova and Marcet (1995) suggest that income cross-correlations among countries need to be treated prior to constructing kernels. Their approach is to base the kernel on:

$$x^*_{i,t} = x_{i,t} / \sum_i x_{i,t}, \tag{27.29}$$

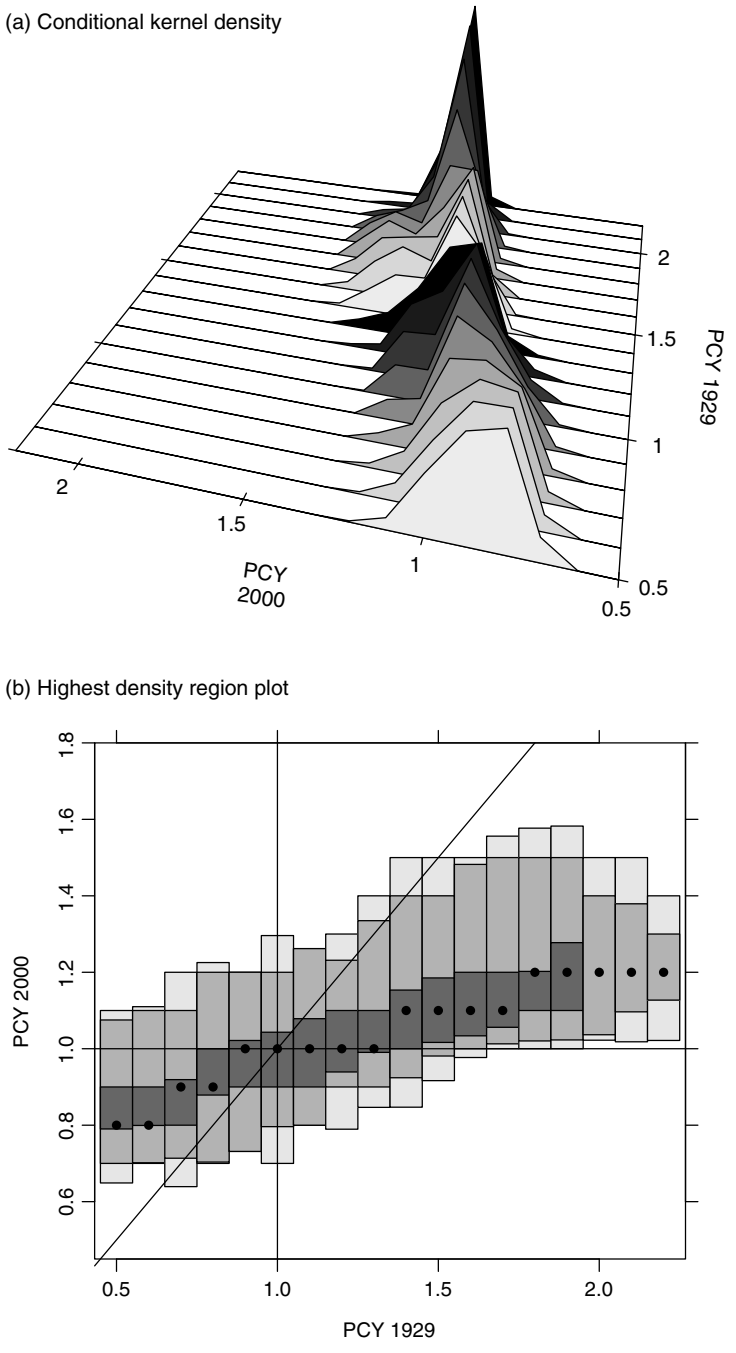

Figure 27.6 Kernel density visualization

where $x_{i,t}$ is per capita income for a given country. Canova and Marcet (1995, p. 9) argue that this alleviates potential problems of income cross-correlations among countries since recessions and expansions which affect the whole aggregate of regions would be factored out. This is not spatial autocorrelation, however, but rather a shift in the mean of the series over time.

In the same spirit, a number of approaches to regional conditioning have been suggested as ways to mitigate the impact of spatial autocorrelation in income series. Quah (1996b) and Arbia *et al*. (2003) rely on the following transformation:

$$\tilde{x}_{i,t} = \frac{x_{i,t}}{\sum_j w_{i,j} x_{j,t}}, \tag{27.30}$$

where a region's income is now expressed relative to its geographical neighbors rather than the national average. Applying this transformation to European data results in the removal of the bimodal characteristic of the income distribution.

Fischer and Stumpner (2008) apply the spatial filtering approach of Getis and Ord (1992) to European data using the following filter:

$$\tilde{x}_{i,t} = \frac{x_{i,t}\left[\frac{1}{n-1} W_i\right]}{G_i(\delta)}, \tag{27.31}$$

where $W_i = \sum_j w_{i,j}(\delta)$ and $w_{i,j}(\delta)$ is the (i, j)th element of the binary spatial weights matrix such that $w_{i,j}(\delta) = 1$ if a region's i and j are separated by a distance of less than the critical distance band δ, and $w_{i,j}(\delta) = 0$ otherwise. $G_i(\delta)$ is the local statistic defined as:

$$G_i(\delta) = \frac{\sum_j w_{i,j}(\delta) x_{j,t}}{\sum_j x_{j,t}}. \tag{27.32}$$

Comparing the unfiltered, $f(x)$, and the spatially filtered, $f(\tilde{x})$, distributions, Fischer and Stumpner (2008) find that the latter displays much less dispersion than the former, yet over the 1995–2003 period, the level of dispersion in the filtered series increases by 15%, while the unfiltered series experiences an actual decline in dispersion of 3.3%. Because the unfiltered series is highly spatially autocorrelated, the overall finding of σ-convergence is attributed to the role of the spatial dependence.

While the spatial filtering and regional conditioning approaches provide avenues to explore the impact of spatial dependence on the evolution of regional income densities, several questions remain. First, as Fischer and Stumpner (2008) note, there is currently a lack of a formal inferential framework to test hypotheses about distribution dynamics in the presence of spatial effects. Second, the filters applied in (27.30) and (27.32) keep $w_{i,j}$ fixed over time. In other words, the spatial structure is specified as time-invariant. Finally, the interpretation of just what the identified spatial components represent is not at all clear.

27.3.4 Space-time kernels

Rather than filtering out the spatial component, kernels that explicitly incorporate space can be developed. Figure 27.7 contains examples of how this can be done.

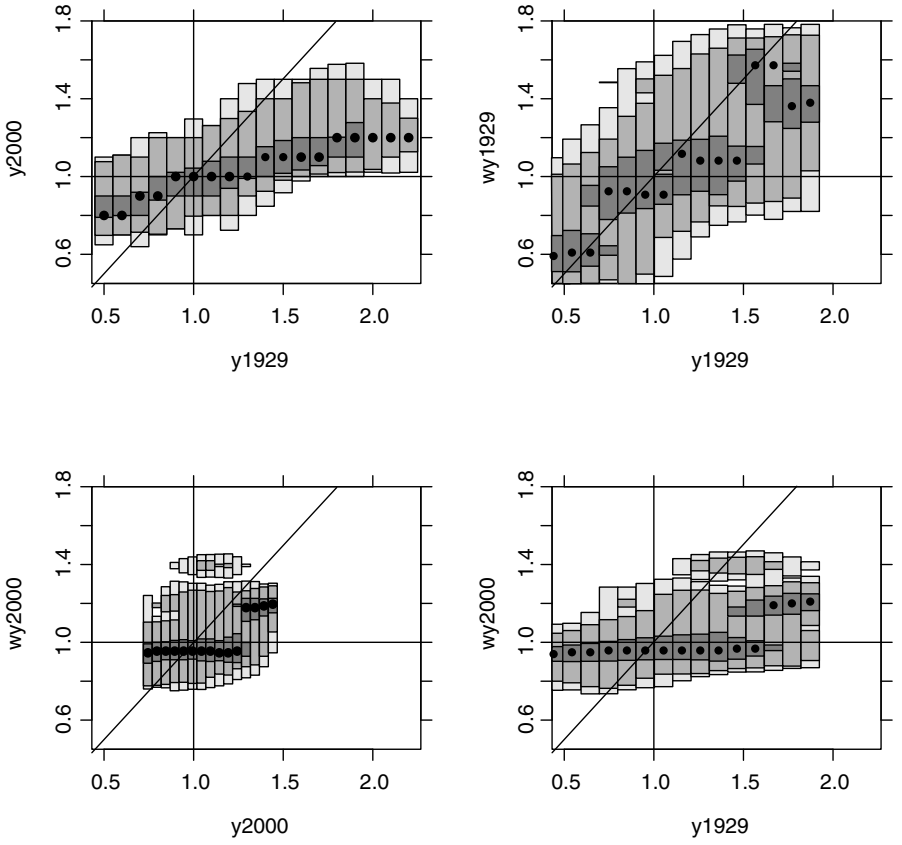

Figure 27.7 Space-time kernels US
Note: y1929 is relative income in 1929 (per capita income for a state relative to national per capita income), wy 1929 is the spatial lag of relative income for 1929 (see section 27.2.2).

The conventional HDR plot for US incomes from 1929 and 2000 is contained in the upper left figure. Next to it is the Moran HDR plot, which extends the Moran scatterplot to a conditional kernel density for the year 1929. The strong spatial autocorrelation is clearly evident as the modes for the conditional distributions for the spatial lag of high-income states in 1929 are all above the average, while for lower-income states, the mode of the conditional distributions are all below average.

The Moran HDR for 2000 in the lower left of the figure is radically different from the HDR for 1929. First, all the conditional spatial lag distributions display much less dispersion in 2000 than in 1929, while the range of the marginal distribution for relative incomes in 2000 is also much narrower than in 1929. Second, the strength of the spatial autocorrelation has weakened over the period, as reflected in the number of conditional modes located in the HH or LL quadrants of the HDR scatter dropping to 10 in 2000 from 15 in 1929.

The space-time Moran HDR in the lower right panel of Figure 27.7 provides a composite view of the spatial dynamics over this period. Here the spatial lag for incomes in 2000 is conditioned on state income in 1929. In contrast to the Moran HDR for 1929, the mode of the conditional lag distributions in 2000 display linear independence for low and moderate values of income in 1929. Moreover, in all cases, the respective modes of the conditional lag distributions have moved towards the overall average income value, with the convergence being upward for the conditional distributions below one, and downward for conditional distributions for $y_{1929} > 1.0$.

27.4 Conclusion

The previous two sections have reviewed a rapidly evolving body of literature concerned with spatial analysis of economic convergence. In both the formal confirmatory work and more recent exploratory data analysis, the unique challenges that spatially organized data pose continue to attract much attention. In this section we offer some final thoughts and identify some remaining outstanding issues for future research.

In the study of regional economic convergence it has become abundantly clear that spatial dependence tends to be the rule rather than the exception in regional income and product series. As a result, there is a growing recognition of the importance of treating this form of dependence in both formal confirmatory econometric models as well as in newer exploratory methods of data analysis.

While spatial autocorrelation and spatial dependence have attracted the majority of the attention in the literature, spatial heterogeneity has also been recognized as an important dimension of many regional series. In general terms, however, the treatment of spatial heterogeneity is more easily done using traditional (that is, a-spatial) econometric methods, while spatial dependence has necessitated a new body of models and methods.

Despite the growing awareness of spatial dependence and heterogeneity in empirical work, most studies tend to focus on only one type of spatial effect. Work on developing specification strategies within spatial econometrics (Anselin and Rey, 1991; Anselin and Florax, 1995; Florax *et al.*, 2003) has provided guidance to practitioners on how to detect and discriminate between different forms of spatial dependence, yet similar approaches to deal with alternative forms of geographical heterogeneity are lacking. Durlauf and Johnson (1995) use regression trees to examine whether international growth data obey a single Solow-type growth model or if there are specific sub-groups or regimes with distinct parameter values. They find evidence of substantial geographic homogeneity within the subgroups. That is, model parameters are found to vary across the regional regimes but are assumed to hold for all economies within a given regime. As acknowledged by Durlauf and Johnson, there is no asymptotic theory available to access the statistical significance of the identified regimes. An additional qualification offered is that there is the possibility that the parameter heterogeneity could hold within each regime as well as across the regimes. Moreover, the question of how to deal with the joint presence of spatial dependence and spatial heterogeneity remains unanswered.

Spatial dependence and heterogeneity do not exhaust the class of spatial effects that confront the regional convergence literature. The issue of the appropriate spatial scale has largely been ignored as the specification of the geographical unit of analysis has tended to be based on data availability rather than theoretical concerns. In the context of convergence research, the geographical unit has varied from countries, to regions, states and metropolitan areas (Drennan, 2005). As a vast literature in spatial analysis has demonstrated (cf. Wong and Amrhein, 1996), the modifiable area unit problem can give rise to inferences that are not robust to changes in the spatial scale and aggregation of the data.

The aggregation issue can also be confounded with the regional heterogeneity question. As work by Miller and Genc (2005) demonstrates, alternative definitions of regional groupings can lead to different inferences regarding the speed of convergence. Similarly, Rey (2004a) shows that changes in regional definitions can have similar impacts on measuring regional inequality dynamics. In these studies the groups are taken exogenously with regard to administrative boundaries, yet the possibility of endogenously determining these groupings was touched on in section 27.2.3. Regionally constrained clustering algorithms (Rey and Anselin, 2007) could be used to determine spatially explicit convergence clubs.

In existing studies of regional convergence, the underlying spatial structure has been assumed time invariant. Over the short run, the assumptions that the boundaries of economies, spatial weights matrices, and the composition of convergence clubs are unchanging, are likely to be plausible. However, as the period under consideration lengthens, such assumptions become increasingly untenable. A critical area for future research will be the integration of evolving spatial structure into formal growth models and distribution dynamics approaches.

Closely related to the issue of spatial scale is the relationship between regional inequality dynamics and personal income distribution dynamics. In the case of the US we have witnessed an apparent paradox of convergence over the last 150 years at the state and regional scales, yet strong evidence of growing polarization in personal and household income distributions (Jones and Weinberg, 2000). Regional patterns in personal income inequality, that is, the spatial distribution of personal income distributions, has attracted some attention (Bishop *et al.*, 1994; Levernier *et al.*, 1995; Partridge *et al.*, 1996; Morrill, 2000). However, the link between convergence in the mean of these distributions (that is, regional convergence) and the evolution of increasing inequality between individuals within these distributions remains largely unexplored and is an important avenue for future research. In particular, the relationship between spatial clustering at one scale and the pace of convergence at a higher spatial scale has received only limited attention (Janikas and Rey, 2008).

Finally, although we organized our review along the dimensions of confirmatory and exploratory analysis, we see these approaches as complements rather than substitutes. We can identify several areas where cross-fertilization between these literatures is likely to lead to new advances. The first is the use of ESDA methods applied to regional data series to identify interesting new patterns from which suggestions for new types of theories and hypotheses about the spatial nature of economic convergence may emerge. Rather than seeing ESDA as a case of

"measurement without theory," such applications may actually lead to theoretical advances.

The gap between the restrictive nature of most growth theory on the one hand and empirical complexity of regional datasets on the other has clearly been a motivating factor in the turn to EDA methods in convergence analysis. But rather than abandoning the classical regression based approach, we suggest that using ESDA and EDA methods to refine model specifications could work to relax some of the restrictions. In this regard, there is a rich conceptual literature on spatial poverty traps (cf. Bowles *et al*., 2006) that could, in our view, be tied to recent work in ESDA to develop operational measures for these theoretical constructs. A final area is the use of ESDA methods in enhanced diagnostic methods for spatial econometric modeling (Ord, 2008).

Notes

1. We focus here on the essential properties of these models, as they have been applied in the growth econometrics literature. For extensive technical discussion on these models, see Anselin and Bera (1998), Anselin (2003, 2006).
2. In assessing the effect of structural funds on the European regional convergence process, Dall'erba and Le Gallo (2008) use a spatial lag model and estimate it with IV by considering that both the spatial lag variable and the structural funds variable are endogenous.
3. See Fingleton and López-Bazo (2006) for a more complete description of papers including spatial effects in growth and Verdoorn regressions.
4. This assumption corresponds to one of Kaldor's stylized facts.
5. For a recent overview of software for ESDA, see Rey and Anselin (2006).
6. Since the probability of moving out of the current income class is 1 in each period and class.
7. The solid black circle indicates the first year in the time path for each state.
8. The conditional kernel and HDR plot were generated using the HDRCDE package (Hyndman, 1996; Hyndman *et al*., 1996).

Testing Econometric Software

B.D. McCullough

Abstract

The first part of this chapter is a non-technical survey of the relatively sparse literature on testing the accuracy of econometric software. Accuracy is primarily assessed by taking a test problem, with known inputs and outputs, giving it to the software, and comparing the software's output with the output of the test problem. We discuss the various types of tests (introductory, intermediate, and advanced) and the types of errors that these tests have uncovered. The reader is directed to specific resources for further information. The second part, which is technical, constructs a test problem (i.e., benchmark) for autoregressive moving average (ARMA) estimation. In 1994 it was reported in the literature that different packages give different answers to the same ARMA estimation problem. To date, this open problem has been unresolved. We provide benchmarks for conditional least squares and unconditional least squares ARMA estimation.

28.1 Introduction

McCullough (2000a) rhetorically entitled an article, "Is it safe to assume that software is accurate?" The answer, of course, is "No." Testing econometric software

is important because econometric software does not always produce accurate answers. Sometimes the inaccuracy can be traced to a bug, an incorrectly written line of code; at other times the algorithm is simply not up to the task of calculating the correct answer (e.g., as will be discussed in section 28.2, do not use the "calculator formula" to compute the sample variance, and, as will be discussed in section 28.3, do not invert the $(X'X)$ matrix when calculating the least squares regression coefficients $\hat{\beta}$; neither of these approaches is numerically sound for economic data). Unless the software is tested, the user has nothing more than mere hope or the software developer's blandishments on which to base his or her confidence that the computer program's output is correct. As we shall see, such blind confidence is misplaced.

Forty years ago, back when mainframe computers took their input from lines of code on punchcards, and a program consisted of a stack of punchcards, Longley (1967) worked out by hand the solution to a linear regression problem with a constant and six independent variables, for 16 observations, and he did so to several digits of accuracy. The dependent variable was "total employment" and the independent variables were: implicit price deflator, gross national product, unemployment, size of armed forces, population, and time. When he compared his hand-calculated results to those from the computer programs, he found wildly disparate results. As he put it (*ibid.*, p. 822):

> Test problems were run on available programs for use on the following electronic computers: IBM 1401, 7070/7074/ 360 model 50, 7090/7094, and General Electric 235. With identical inputs, all except four programs produced outputs which differed from each other in every digit.

To convey the essence of what Longley found, below we reproduce (to only three decimals) some of the regression coefficients produced by four computers/software packages from his Table 10 in our Table 28.1.

Within several years, most (if not all) linear regression programs could meet the so-called "Longley benchmark." In the present day, it is almost unheard of for any program not to meet the Longley benchmark. One may think that several different packages giving several different answers to the same problem is a relic of the "old" days, but it is very much a problem that still persists. In 1999, McCullough and Vinod (1999, p. 534) published three widely divergent sets of full information

Table 28.1 Some of Longley's regression results

	Defl.	*GNP*	*Unem.*	*Mil.*	*Pop.*	*Time*	*Constant*
Correct	15.026	−0.036	−2.020	−1.033	−0.051	1829	−3482258

maximum likelihood (FIML) estimates for Klein's Model I. Clearly, not all three sets of answers can be correct. McCullough and Renfro (1999) published seven different estimates for the parameters of the same generalized autoregressive conditional heteroskedasticity (GARCH) model. What does this make one think of the GARCH results published in the literature? As far as GARCH estimation is concerned, recall that any nonlinear estimation procedure requires starting values which need to be carefully chosen if the solver is to have much of a chance to find an extremum. Some GARCH procedures in some packages do not allow the user to set the starting values! What does one think of the developers of such packages? (What do the developers of such packages think of their users?) Brooks, Burke and Persand (2003) did the same thing for multivariate GARCH models, and it is instructive to present the model they estimated; the results from their Table II are given in our Table 28.2.

The multivariate GARCH model estimated by Brooks, Burke and Persand was:

$$
\begin{aligned}
s_t &= \mu_s + \epsilon_{s,t} \\
f_t &= \mu_f + \epsilon_{f,t} \\
h_{s,t} &= c_1 + a_1 \epsilon^2_{s,t-1} + b_1 h_{s,t-1} \\
h_{f,t} &= c_2 + a_2 \epsilon^2_{f,t-1} + b_2 h_{f,t-1} \\
h_{s,f,t} &= c_3 + a_3 \epsilon_{s,t-1} \epsilon_{f,t-1} + b_3 h_{s,f,t-1}.
\end{aligned}
$$

Study the coefficients in Table 28.2. Each package estimates completely different parameters for the same model. What does this say about multivariate GARCH results published in the literature? Perhaps the multivariate GARCH likelihood is complicated and difficult to optimize, and may have multiple optima. Not that these numerical difficulties are an excuse for inaccuracy, but maybe a user could have more faith in a simple nonlinear estimation problem for a convex likelihood like the probit model? Surely nothing could go wrong with that? Stokes (2004) gave the same probit problem to six packages and got six different answers. What is particularly interesting is that, for this particular probit problem, no solution exists. The problem, as posed, exhibited what is called "complete separability" and so there is no set of parameters that maximizes the likelihood. This phenomenon is ignored by most econometrics texts that present the probit model (but see Davidson and Mackinnon, 2004, pp. 458–9, for an exception). This minor impediment did not stop the six packages from reporting that they had found solutions. A seventh

package correctly reported that the problem has no solution. If you were to estimate a probit model, which package would you prefer to use?

Do not think that in the present day this lack of accuracy affects only nonlinear problems. McCullough (2004a) reported on econometrics packages that produced correlation coefficients larger than unity. Further evidence of inaccuracy of statistical and econometric software will be presented in subsequent sections. For the present, what is of interest is this: "How can a user protect him/herself against inaccurate econometric software?" The answer is, "Test the software." The natural follow-up question, "How?," is the subject of this chapter.

In its purest form, to test a software package is to give it some input for which the correct output is known. In the aforementioned case of the Longley benchmark, the input is the dependent and independent variables, and the correct output is the coefficients that he calculated by hand. For some problems it is too difficult to work out the correct answer, and an alternative is to have two (or more) independent programming efforts reach the same conclusion. This is the method used by Drukker and Guan (2003) to produce a benchmark for a particular panel data estimator. This chapter will concern itself with the former method – known inputs and known outputs. There are three classes of tests: introductory, intermediate, and advanced. We provide an overview of each class, including a description of inaccuracies uncovered, with directions to further reading for those who wish to read up on the subject. Section 28.2 briefly introduces a few necessary ideas about the numerical limitations of computational software. Section 28.3 discusses a set of introductory tests, known as "Wilkinson tests." Section 28.4 discusses a set of intermediate tests. Section 28.5 discusses a pair of advanced tests, one for FIML estimation and one for GARCH estimation. To illuminate the numerical issues involved, Section 28.6 creates a benchmark for ARMA estimation. Section 28.7 offers some conclusions.

In what follows we typically do not mention specific software packages, even when they were identified in the article or review that is cited. The reason for this is that many of the errors we recount have long since been corrected. A notable exception is Microsoft Excel, because Microsoft has a track record of not fixing errors in Excel. Should Excel even be mentioned in this chapter? Yes. One need only surf the web to find that many professors teach introductory econometrics with Excel.

28.2 Computer arithmetic

Generally, computers do not store numbers that are perfectly accurate, nor are the calculations performed on those numbers carried out with perfect accuracy. A computer stores numbers in bits (a bit is simply a single binary digit that holds either a zero or a one) and bytes (eight bits to a byte). Currently, most desktop computers have a 32-bit word length, but there do exist 64-bit computers, and soon there will be 256-bit computers.

To make ideas concrete, suppose that we have a 4-bit word, with each bit being a zero or a one. All counting must be in base-2 with up to four places. Zero is

represented as 0000, one is represented as 0001, two is represented as 0010, and three is represented as 0011. The biggest number that can be represented is 15, which is represented as 1111 = 1000 (8) + 0100 (4) + 0010 (2) + 0001 (1).

With a 32-bit word, rather than devote all 32 bits to representing powers of two, we use some for a *mantissa* and others for an exponent (which can be either positive or negative) to which the number two can be raised. This two raised to the exponent is then multiplied by the mantissa. Such a scheme provides for a wider range of representable numbers. This single-precision scheme has one sign bit, eight bits for the exponent (which can range from −126 to 127) and 23 bits for the mantissa. The smallest mantissa is 22 zeros followed by a one, which equals one, and the smallest exponent is −126, so the smallest number that can be represented is $1 \times 2^{-126} \approx 1.2 \times 10^{-38}$. Similarly, the largest number that can be represented is $(2 - 2^{-23}) \times 2^{127} \approx 3.4 \times 10^{38}$. If two words are chained together to permit a larger exponent and larger mantissa, then this is called "double precision."

Because a computer represents numbers in base-2, it cannot accurately represent all the real numbers. For example, the number 0.5 can be represented exactly, since it equals 1/2, which is 2^{-1}. The number 0.1 cannot be represented exactly. The binary representation of the real number 0.1 is given by 0.0001100110011... where the 0011 repeats infinitely. With a finite word length, this infinite sequence must be truncated, and when it is truncated and converted back to base-10, we get 0.099999994. For a quick overview of this topic, see McCullough and Vinod (1999, sec. 2.1). For a much more detailed, yet still very accessible discussion of computer arithmetic, see Goldberg (1991).

This small difference between 0.1 and 0.099999994 is an example of rounding error. A similar type of inaccuracy is called *truncation error*, an example of which is the calculation of $\sin(x)$ by infinite series. In a computer, the series cannot be cumulated infinitely, and must be terminated at some point. The difference between termininating and continuing forever is truncation error. Like a rounding error, it can be very small. Some calculations, e.g., matrix inversion, can require millions of operations, and these small rounding and/or truncation errors can add up. Eventually, they can swamp all the accurate digits, producing a final answer that is completely inaccurate. This is very probably what happened in Longley's paper.

28.3 Introductory tests

In 1985, Leland Wilkinson, developer of the SYSTAT statistical software package, produced a pamphlet describing some simple tests of software accuracy. The primary documents for understanding and applying Wilkinson tests are Wilkinson (1985) and McCullough (2004a). The tests are all based on a dataset that he called the "Nasty" dataset, which is reproduced in Table 28.3.

The Wilkinson tests are fully described in Wilkinson (1985). They have been applied by Sawitzki (1994a, 1994b), Bankhofer and Hilbert (1997a, 1997b), McCullough (2004a) and Choi and Kiefer (2005). These papers usually report errors in packages. For example, some packages could not accurately compute the sample standard deviation for either BIG or LITTLE. What this reveals is that the packages

Table 28.3 Dataset NASTY.DAT

LABEL$	*X*	*ZERO*	*MISS*	*BIG*	*LITTLE*	*HUGE*	*TINY*	*ROUND*
ONE	1	0	.	99999991	0.99999991	1.0E12	1.0E-12	0.5
TWO	2	0	.	99999992	0.99999992	2.0E12	2.0E-12	1.5

SEVEN	7	0	.	99999997	0.99999997	7.0E12	7.0E-12	6.5
EIGHT	8	0	.	99999998	0.99999998	8.0E12	8.0E-12	7.5
NINE	9	0	.	99999999	0.99999999	9.0E12	9.0E-12	8.5

in question employed the "calculator formula":

$$s^2 = \frac{\sum_{i=1}^{n} x_i^2 - (\sum_{i=1}^{n} x_i)^2/n}{n-1}. \tag{28.1}$$

This formula makes one pass through the data and squares the observations. Consider squaring the first two observations on the variable BIG: $99999991^2 = 9999998200000081$ and $99999992^2 = 9999998400000064$. Now subtract the former from the latter: $9999998400000064 - 9999998200000081 = 199999983$. On a typical desktop econometric package, executing the command $99999992^2 - 99999991^2$ produces 199999984. The squaring of these large numbers has just barely used up the computer's finite precision. To see this, simply drop the leading nines and perform the following subtraction on your desktop computer: $8400000064 - 8200000081 = 199999983$, which does not exhaust a desktop computer's precision. Think of what would happen if nine-digit numbers were used instead of eight-digit numbers! Using the calculator formula to compute the sample variance of the variable BIG yields 2.424 instead of the correct 2.738. This is an example of what was described in the first section as an algorithm simply not being up to the task. The calculator formula contrasts sharply with the usual formula:

$$\hat{\sigma}^2 = \frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{n-1}, \tag{28.2}$$

which squares much smaller numbers, and so it is more difficult for this formula to exhaust the computer's finite precision.

The calculator formula, often presented in textbooks in the pre-computer era, was designed for use on toy problems found in textbooks, not for real-life problems. This fact was known in the statistical computing literature at least as far back as Ling (1974), and in one of the two classic texts on statistical computing that every competent statistical programmer would have read, i.e., Thisted (1988) (the other classic text is Kennedy and Gentle, 1980). Nonetheless, the calculator formula appeared in many statistical and econometric software packages. What this tells us is that the people who designed these programs were not versed in the basics of

statistical computing, one of the primary tenets of which is this: do not program the formula from statistics texts. The fact that allegedly competent programmers would implement the calculator formula underscores the need for users to test their software.

Calculating the correlation coefficient is conceptually simple, especially since it is bounded between +1 and −1. Yet some packages returned a correlation between BIG and HUGE, or LITTLE and ROUND, or X and BIG, that was bigger than unity! The developers of these packages never revealed why their packages were unable to compute correctly a correlation coefficient. Also of interest, the correlation between ZERO and any other variable should be undefined by definition because ZERO is a constant so its standard deviation $\sigma_Z = 0$ and:

$$\rho_{ZX} = \frac{cov(z, x)}{\sigma_Z \sigma_X}. \tag{28.3}$$

The 0 in the denominator means that the value of the ratio is undefined, yet some packages computed $\rho_{ZX} = 0$, and one package even managed to compute $\rho_{ZZ} = 1$.

Plotting BIG against LITTLE obviously should produce a straight line. Some packages were unable to do this. In one case, the software produced a single point in the middle of the graph, dropping all the other points. Again, the developers did not reveal the reasons for the failure.

Performing operations that involved the MISS variable revealed that not all packages correctly handled missing values.

Regressing X on a constant, BIG and LITTLE should produce an error, since BIG and LITTLE are linear transforms of each other, i.e., the matrix of independent variables is singular. If a package does not recognize the singularity, then it can grind through all the calculations and produce an answer – an incorrect answer, but an answer nonetheless. Not all packages passed this test.

Wilkinson tests have been applied to many statistic and econometric software packages, almost invariably revealing flaws of one sort or another. The only mystery is why software developers don't apply these tests themselves and fix the errors before someone writes an article or software review about it. These tests are quick and easy, taking less than an hour, and every user should make sure his package passes all these tests – or if it doesn't, have the developer fix the problem. If he or she doesn't fix it fast enough, a well-placed software review will convince him or her to do so.

28.4 Intermediate tests

McCullough (1998a) proposed an intermediate set of tests covering three areas: coefficient estimation based on the then recently released National Institute of Standards and Technology's (NIST) Statistical Reference Datasets (StRD), random number generation, and statistical distributions (e.g., the functions used to determine critical values for various distributions). This methodology has been applied by McCullough (1999a, 1999b), Vinod (2000), Sall (2002), Altman and McDonald

(2002), Kitchen, Drachenberg and Symanzik (2003), Teyssiere (2005), Keeling and Pavur (2004, 2007), Yalta and Yalta (2007), and Yalta (2008), among others.[1]

28.4.1 StRD

The StRD presents estimation problems in four suites: univariate summary statistics, one-way analysis of variance, linear regression, and nonlinear least squares. Each suite contains test problems at three levels of difficulty: lower, average, and higher. The primary discussions for understanding and applying the StRD are found in McCullough (1998a, 2000b). For the linear problems, NIST computed accurate solutions by carrying 500 digits through all calculations, effectively eliminating rounding error, and then rounding the final answer to 15 digits. Nonlinear problems were solved using different algorithms in quadruple precision, and rounding the final solution to 11 digits. For each nonlinear problem there are two sets of starting values: Start I and Start II. The former is far from the solution, which makes it harder for a solver to find the solution. The latter is closer to the solution, making it easier for a solver to find the solution.

One of the nine univariate problems (six lower, two average, one higher difficulty) require the calculation of three summary statistics: mean, standard deviation, and first-order autocorrelation coefficient. One of the lower-difficulty problems, NumAcc1, consists of just three observations: 10000001, 10000003, 10000002. A program that employs the "calculator formula" will fail this test starkly, even in double precision. It is a bit easier to diagnose a failure with these data than with the similar data in Wilkinson tests. Many packages fail to get good accuracy when calculating the first-order autocorrelation coefficient because they use bad algorithms.

The ANOVA suite has four lower-, four average-, and three higher-difficulty problems. Even a good ANOVA algorithm that does not recenter the data will return a completely inaccurate answer for the most difficult problem. If a package returns four digits of accuracy on this problem, then it is safe to conclude that the package recenters the data (to reduce the effect of squaring) before calculating all the relevant sums of squares. It is not uncommon to see packages, especially those that have been around for a long time, fail even on the average difficulty tests. The reason is that the packages use legacy code left over from the days of single-precision computers. After the StRD is applied to such packages, the developers usually update the code.

The linear regression suite has 11 test problems, two of lower difficulty, two of average, and seven of higher difficulty. One of the higher-difficulty test problems is the Longley benchmark, which most packages can handle easily these days. A problem that many packages cannot handle is the Filip dataset, which is a tenth-order polynomial that is nearly singular. A good package will either produce accurate coefficients or detect the singularity and refuse to produce a solution. This latter result is *not* a failure, because the user has not been misled. A package that fails this test, e.g., Excel 2000 and earlier (McCullough and Wilson, 2005), is capable of producing completely inaccurate coefficients when confronted with collinear data. A package that directly solves the normal equations, e.g., that calculates

$\hat{\beta} = (X'X)^{-1}X'y$ will fail many of the linear regression tests. The reason is that computing the inverse of $(X'X)$ is like a squaring operation that produces a great deal of cumulated rounding error, sometimes enough cumulated rounding error to completely ruin the estimate $\hat{\beta}$. A better method is to use what is called the QR decomposition, which avoids the squaring in the computation of $\hat{\beta}$. If a package fails many of these linear problems, it is safe to say that the package does not use a good QR decomposition, and almost certainly calculates the least squares coefficients by inverting $(X'X)$.

Most nonlinear solvers offer various options to the user: different algorithms, convergence tolerance, etc. Two major lessons have been learned from the early application of the StRD nonlinear suite. First, the default options for most nonlinear solvers will not find the correct answer. One primary example is the convergence tolerance. Suppose the solver is set, at default, to stop when the difference between the sum of squares on two successive iterations changes by less than 0.001. This might not be tight enough and the solver might give a "failure to converge" message; it might be necessary to set the tolerance at 0.000001. For a nonlinear least squares problem, changing the tolerance by this amount may well dramatically alter the coefficients and markedly reduce the sum of squares. Do not rely on the default options for nonlinear solvers!

Normally, this first problem would not be of much consequence; simply change the options until convergence is declared. However, there is a common second problem that greatly complicates the matter: many packages have a tendency to stop at a point that is not a solution and claim that they have found a solution. (How is a user to know whether his/her solver has this second problem? See whether anyone has applied the StRD nonlinear suite to his/her software package!) If a user happens to have such a defective solver, then a reasonable strategy is to keep decreasing the convergence tolerance – getting a "convergence achieved message" every time – until the user verifies that the coefficients have stopped changing, that the solver really has achieved a stationarity point. For a detailed example of applying this strategy, see McCullough (2004b). For extended discussion of using nonlinear solvers to find solutions to nonlinear problems, see McCullough and Renfro (2000) and McCullough and Vinod (2003a, 2004).

To belabor this important point, almost any nonlinear problem solved using a package that has this second problem will produce an incorrect answer. The user simply accepts the default options, the solver produces an incorrect answer, and the user accepts the incorrect results. The literature is filled with results from such packages, and because journals typically do not even compel authors to identify their software packages, let alone make their data and code available, there is little hope of purging these incorrect results from the literature. As will be discussed in the conclusions, replication of published results and software accuracy are intimately connected.

One interesting aspect of the nonlinear StRD suite that has yet to be published in the literature is the following. The StRD nonlinear suite is for nonlinear least squares problems. Nonlinear least squares solvers make use of the special structure of nonlinear least squares problems. Reformulating these problems as maximum

likelihood problems and giving them not to the package's nonlinear least squares solver, but instead to its maximum likelihood solver, would produce a method for testing the efficacy of maximum likelihood solvers. To date, there has been no such systematic testing of the maximum likelihood solver of any econometrics package. Preliminary examination of this topic by the author suggests that many packages have maximum likelihood solvers that tend to stop at points that are not solutions but nonetheless declare that a solution has been found. The implications of this line of research for applied econometrics would be enormous.

28.4.2 Random number generators

Random numbers form the basis of many econometric estimators, e.g., simulation and bootstrapping. Yet the efficacy of these methods depends on the random numbers being truly random. In fact, the random number generator (RNG) in an econometrics package does not produce random numbers, but deterministic numbers. However, they are nonlinearly deterministic and can give the appearance of being truly random. For a short primer see McCullough (2001) or McCullough and Vinod (1999, sec. 5). The physics literature is filled with stories of bad simulation results due to bad RNGs (see, e.g., Coddington, 1994, 1996). The economics literature has no such examples because there is practically no replication in economics. When was the last time one economist took another economist's simulation code and swapped out one RNG for another RNG to see if the results would change? Nonetheless, the literature on testing econometric software has found bad RNGs, and the usual response by a developer is to put in a good RNG.

The primary method for determining whether an RNG produces "random" numbers is to take the numbers and apply a statistical test of some sort. As a simple example, take 1,000 random numbers, compute the first-order autocorrelation coefficient, and test the null that the coefficient equals zero. Rejecting the null constitutes evidence that the numbers are not random; they are correlated. There are many, many types of tests because there are many, many ways for a sequence of numbers not to be random. One of the first standard collections of such tests was given by the eminent computer scientist Donald Knuth in the 1981 first edition of his classic text (Knuth, 1998). Coding these many tests and applying them was time-consuming and tedious. The random-number specialist George Marsaglia (1996) collected several tests and coded them as "DIEHARD: a battery of tests of randomness." DIEHARD has been used to uncover bad RNGs in many statistical and econometric software packages.

As the scale of computing has grown since then, the DIEHARD tests are no longer up to the task of validating RNGs for the huge simulations that are run today. The RNG testing program TESTU01 has been the new standard since its first release in 2002. The program is reviewed by McCullough (2006) and described in more detail in L'Ecuyer and Simard (2007). Using TESTU01 requires a passing knowledge of C, and is available freely. It comes with three batteries of tests pre-programmed, Small Crush (which can take a few minutes), Crush (which can take a few hours), and Big Crush (which can take a day or more). By contrast, on a modern PC, DIEHARD takes several seconds. If an RNG passes Small Crush, then give it to Crush. If it

passes that, then give it to Big Crush. If it passes that, then it is fit to use. There are too many good RNGs to use one that fails any reasonable test of randomness. There are many bad RNGs, even ones published in journals, so testing is imperative.

It is not enough that the underlying uniform RNG passes tests. Often the need for random normal variates, or random variables with other distributions, arises. These are usually obtained from the uniform RNG via transformation. However, the process of turning seemingly good uniforms into normals, e.g., requires not just good uniforms, but also a good transformation. The transformations from uniformity to another distribution, e.g., standard normal, can be flawed. The Marsaglia Multicarry RNG, which passed all the DIEHARD tests and was popular for some years, does not play well in the tails with the Kinderman–Ramage transform to normality. So if your econometric software package uses the Multicarry, and it produces random normals via the Kinderman–Ramage, then the tails of the so-called random normals actually deviate substantially from true random normals. For a graphical depiction of this phenomenon, see Figure 28.1. Note the slight gap at about 3.4 and a pronounced gap at about 3.6. These gaps would wreak havoc upon any simulation that focused on the tails of the standard normal.[2]

Further, the Multicarry fails both Small Crush and Crush batteries in TESUT01 (there was no need to apply Big Crush). Testing random normals, random-t's, and random chi-squares needs to be done. As this time, such testing is in its infancy. A common approach is to back transform the random normals (say) to uniformity, and then apply tests for uniformity to the backtransformed uniforms. This approach was used successfully by Tirler *et al.* (2004). Do you think it safe to trust the random normals in your software package?

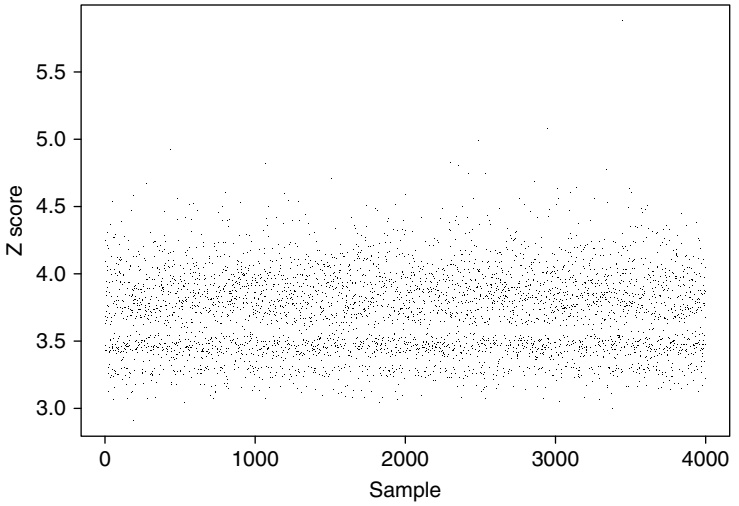

Figure 28.1 The extreme tails of 4,000 samples of random normals from Marsaglia Multicarry and Kinderman–Ramage

Generally speaking, econometric discussions of simulation simply assume a high-quality RNG the same way that econometrics texts discussing nonlinear estimation assume a high-quality solver. For example, the text on simulation in econometrics by Gouieroux and Montfort (1997) makes no mention of testing RNGs.

28.4.3 Statistical Distributions

Bai and Perron (2003) (henceforth BP) published an article in the *Journal of Applied Econometrics* about structural change models, and used an econometric software package to write software for their method. Zeileis and Kleiber (2005) (henceforth ZK) attempted to port the code to R. We first note that the *Journal of Applied Econometrics* has a data-only mandatory archive, i.e., BP were under no obligation to supply their code to would-be replicators, but they did so. While ZK were able to reproduce much of what BP did, they were unable to match some confidence intervals for break-points. As one example, both packages estimated a break-point at the third quarter of 1972, 1972:3, but the BP interval was [1970:3, 1972:4] while the ZK interval was [1969:1, 1972:4]. After much numerical detective work, ZK finally ascertained that the BP software package had a function for the Normal CDF (cumulative distribution function) that was inaccurate in the tails, while the R package had a Normal CDF that was accurate in the tails. The accuracy of statistical distributions matters.

On a related note, there is a definite need for the profession to find every article using the Normal CDF function in the package used by BP, and check to see if the results are wrong. Of course, since journals largely do not require authors even to identify what package they use, let alone supply the code, there is no hope of ever accomplishing this task. This example shows how replication can uncover errors not only in published articles, but in software, too.

To test statistical distributions, one needs an accurate source for the desired quantities – not just any software package will do. For years the primary sources were Knüsel's (1989) ELV package and Brown's DCDFLIB (available in C and Fortran). McCullough (2000c) showed that the program Mathematica was at least as good as ELV and, lately, Yalta (2008) showed that Mathematica produces results more accurate than ELV. One simply compares the output from one of these three programs to the output produced by the econometric software in question. Naturally, one cannot assess all possible outputs, so one examines a carefully chosen subset. For the normal distribution, one might first test the following percentiles: $\{0.0001, 0.001, 0.01, 0.1, 0.2, \ldots 0.9, 0.99, 0.999, 0.9999\}$ and check the extreme tails to find out where the algorithm in the econometric software breaks down; it might be completely inaccurate for the 0.9999999999 percentile. A similar approach might be undertaken for the t-distribution, except it has to be done for different degrees of freedom. The process gets more complex for distributions with two or more parameters, e.g., the F-distribution. Complete details for testing can be found in McCullough (1998a, sec. 6). Most packages are able to compute these distributions for simple hypothesis testing, but methods that require distributions to be evaluated in the extreme tails, e.g., value-at-risk testing or saddle-point approximation, should only be undertaken with packages that have very accurate distributions.

28.5 Advanced tests

Look at the table of contents of an advanced econometrics text, or the list of functions in any econometrics software package, and you will see many familiar names: Kalman filtering, multinomial logit, ARMA, etc. Just as in the case of multivariate GARCH, with which this chapter opened, different packages will give different answers to the same problem, and no one has any idea which package, if any, is correct. This is because there are no benchmarks for any of these procedures.

We have already alluded to different packages giving different answers to the same FIML problem. In fact, a benchmark was worked out for this problem by Calzolari and Panattoni (1988). Not many software developers were aware of this, because it was not advertised as a benchmark. Silk (1996) recognized that it was benchmark-quality work, and used it as a benchmark for his comparison of software packages.

When Bollerslev (1986) published the first GARCH article, he did not completely describe his method, leaving developers to guess at important details. Consequently, while every package soon had a GARCH command, they all gave different answers. McCullough and Renfro (1999) (henceforth MR) documented this fact, but also sought to alleviate the problem. Fiorentini, Calzolari and Panattoni (1996) published an article entitled "Analytic derivatives and the computation of GARCH estimates." Recognizing that two of the remaining three authors had already written benchmark-quality code, MR suspected that this might be code of a similar quality. Indeed, it was, and MR offered the "FCP GARCH benchmark" on which many developers quickly converged. MR analyzed seven packages, and found that four of them could not estimate the FCP GARCH model, and only one of the remaining three was reasonably accurate. When Brooks, Burke and Persand (2001) reassessed the situation only two years later, they found that most packages could estimate the model and do so with reasonable accuracy (but see McCullough and Vinod, 2003b, for another example of many packages giving different answers to the same GARCH problem). Developers will converge on a benchmark *if* one is available.

Bruno and De Bonis (2004) wrote a benchmark for a garden-variety panel data estimator, for both fixed and random effects. They then gave the data to three software packages. All packages agreed on the fixed effects estimation, but disagreed on the random effects. Investigation of the matter required correspondence with the developers because the user guide and reference manuals did not provide much information on the algorithms employed (which is typical of econometric software packages). As Bruno and De Bonis (2004, p. 281) discovered, "it is clear that all the numerical differences produced by the random-effects estimates are caused by the differences in the small-sample formulas for the computation of the between-regression variance." All three packages used consistent estimators, so there was no theoretical reason to prefer one over the other. The literature provided no guidance, so Bruno and De Bonis conducted a Monte Carlo study to determine which of the three estimators had the better finite-sample properties.

The Yule–Walker equations are often used to compute partial autocorrelation coefficients; the method is presented in most econometrics texts, and most econometric software packages offer the method. What is not presented is that it is the

least reliable method for such computation. The classic time series text by Priestley (1981) presents four methods for computing partial autocorrelation coefficients, and he presents them in *decreasing* order of reliability: the Yule–Walker method is presented fourth. The Yule–Walker equations are, from a computational standpoint, easy to implement, and they might have been justified back in the days when computing power was expensive; in the present day, they cannot be justified. Very few econometric packages offer better methods. One such method is the Burg algorithm. However, there was no benchmark for the method, so McCullough (1998b) computed one. Now some econometrics time series packages offer the Burg method as an improvement over the Yule–Walker equations.

There are not many advanced benchmarks for econometric software, and there is precious little tangible evidence that any econometric software package is giving the correct answer for any moderately complicated problem.

28.6 Benchmarks for ARMA models

In an important article, Newbold, Agiakloglou and Miller (1994) (henceforth NAM) observed: "fitting the same model to the same data will yield more or less identical results whatever software is used for multiple regression. That is not the case for the estimation of the parameters of an ARIMA model." In part, this may be due to the fact that NAM placed themselves in the position of a novice user, i.e., "though many programs allow the user a range of optional modifications, we generally ran them in default mode." If one thing has been learned from the literature on statistical and econometric software accuracy, it is that default options for nonlinear estimation procedures typically do not produce accurate answers. Such matters as choice of algorithm, convergence criterion, convergence tolerance, and initial conditions, can all greatly affect the quality of the answer produced by a nonlinear estimation procedure. For example, in the case of autoregressive integrated moving average (ARIMA) procedures, some packages conduct preliminary estimations to determine starting values, while others simply use zeros. This fact alone could account for much variation between packages. Therefore, it may seem entirely possible that the packages examined by NAM would have exhibited little variation in the range of results produced if only they had adopted the posture of an experienced user. Such, however, turns out not to be the case, as will be shown.

Given that the differences are not due to the use of default options, the notion that algorithmic differences may be responsible comes to mind. In the case of unconditional least squares (ULS) with backcasting, there is no one preferred method of backcasting, so perhaps this may account for the differences. NAM (1994, p. 580) pointedly address this notion in the discussion of their conditional least squares (CLS) results, for which no such difference is possible. Even in the cases when point estimates agree, NAM note substantial variation in the estimates of standard errors.

Thus, the only means to resolve the discrepancies between packages is the production of a benchmark. The production of a benchmark typically requires the use of extended precision computation, i.e., more than double precision. One

common method of achieving this level of accuracy is to use FORTRAN with a multiple precision pre-processor (e.g., Bailey, 1993). An alternative is to employ the software package Mathematica, which can combine symbolic calculation with extended precision computation to produce benchmark-quality results. For example, on the NIST StRD ANOVA tests, 32-bit word double precision can do no better than four or five digits of accuracy. Mathematica can, on these problems, return a full 15 digits of accuracy (McCullough, 2000c). For this analysis, we therefore employ Mathematica.

Here we consider only Box and Jenkins (1976) (henceforth BJ) methods based on least squares for two reasons. First, these are by far the most widely-used methods; only two of the packages considered by NAM offered exact maximum likelihood. Second, there is a definitive reference for the procedures – BJ. There exist many alternative methods for computing maximum likelihood methods, and computing a maximum likelihood benchmark for ARIMA estimation constitutes a project in itself.

This is not an unimportant topic. ARMA estimation and forecasting is a mainstay of applied time series analysis. Note that forecasts have not been benchmarked: this needs to be done, too. Recently, Yalta and Jenal (2009) attempted to double-check, by hand, the forecasts coming from an ARMA procedure. They could not reproduce the program's results. On further investigation, they found that not only were the forecasts incorrect, even the ARMA coefficients were incorrect. (For a benchmark, they used the approach of having several packages give the same answer to the same problem – the package in question did not agree with all the other packages.)

Sub-section 28.6.2 describes definitions and notations. Sub-section 28.6.3 presents CLS results; analytic derivatives are employed for the ARMA(1,1) case, and comparison with numerical derivatives sheds light on the choice of the differencing interval for the computation of numerical derivatives. Then, using extended precision computation, a benchmark for CLS is presented. Sub-section 28.6.4 presents a benchmark for ULS.

28.6.1 Definitions and notation

The ARMA(p,q) model can be written as:

$$a_t = \tilde{w}_t - \phi_1 \tilde{w}_{t-1} - \phi_2 \tilde{w}_{t-2} - \ldots - \phi_p \tilde{w}_{t-p} + \theta_1 a_{t-1} + \theta_2 a_{t-2} + \ldots \theta_q a_{t-q}, \quad (28.4)$$

where $w_t = \nabla^d z_t$ and $\tilde{w}_t = w_t - \mu$ with $E[w_t] = \mu$. In general, when $d > 0$ it is assumed that $\mu = 0$. However, we take $\mu \neq 0$ as an additional parameter to be estimated. The form in which the equation is written affects the intercept term in an ARMA model. For example, BJ write $(1 - \Phi(B))y_t = c + (1 - \Theta(B))a_t$, while an alternate formulation, adopted here, takes $(1 - \Phi(B))(y_t - \mu) = (1 - \Theta(B))a_t$. Comparing the two formulations, it is obvious that $\mu = c/(1 - \sum_{j=1}^{p} \phi_p)$. In the sequel, only the case $p = 1, q = 1$ is treated.

The variation on the Marquardt algorithm proposed by BJ, and which is implemented in several packages, is extremely simple, and focuses on minimizing a sum

of squares. In the case of CLS, the relevant quantity is:

$$S_*(\boldsymbol{\phi}, \boldsymbol{\theta}) = \sum_{t=1}^{n} a_t^2(\boldsymbol{\phi}, \boldsymbol{\theta} | \boldsymbol{w}_*, \boldsymbol{a}_*, \boldsymbol{w}), \tag{28.5}$$

where the subscript asterisks emphasize conditioning on the choice of starting values. The problem, obviously, is in the choice of pre-sample values for w and a, i.e., how to define $\boldsymbol{w}_*$ and $\boldsymbol{a}_*$.

BJ (1976, p. 211) consider two approaches. The first involves setting $\boldsymbol{w}_*$ and $\boldsymbol{a}_*$ equal to their unconditional expectations, which are μ and 0, respectively. In the event that $\mu \neq 0$, $\bar{w}$ can be substituted for each element of $\boldsymbol{w}_*$. This preserves the full sample. However, due to potential instabilities when the roots of $\phi(B)$ are near the unit circle, this method is not much used. A more reliable method is to discard observations so that actual values of w are used for all calculations. This implies that the sum of squares can be taken only over observations $p+1$ through n. (Clearly, when $p = 0$ this method is equivalent to the previous method.) Thus, the second approach sets $a_t = 0$ for $t = 1, \ldots, p$ and calculates the a's from a_{p+1} onward; observations must be dropped from the sample. It is the second approach that BJ adopt for CLS, and which is considered here.

Setting to zero values that might vary substantially from zero may induce a transient effect that can adversely affect the quality of the final estimates. BJ (1976, p. 211) notes that CLS is "not satisfactory" for seasonal models.

To derive the ULS method, BJ introduce the unconditional sum of squares:

$$S(\boldsymbol{\phi}, \boldsymbol{\theta}) = \sum_{t=-Q}^{n} [a_t | (\boldsymbol{\phi}, \boldsymbol{\theta}, \boldsymbol{w}]^2, \tag{28.6}$$

where the $a_t, t \leq 0$ are computed recursively by taking expectations of equation (28.4). The values necessary to compute these $a_t, t \leq 0$, are the $[w_t], t \leq 0$, which can be calculated via the procedure known as *backcasting*.

In the usual fashion, the backward and forward representations are given by:

$$e_t = (w_t - \mu) - \phi(w_{t+1} - \mu) + \theta e_{t+1} \tag{28.7}$$

$$a_t = (w_t - \mu) - \phi(w_{t-1} - \mu) + \theta a_{t-1}. \tag{28.8}$$

Given initial estimates of the parameters, μ_0, ϕ_0 and θ_0, setting $e_{n+1} = 0$ allows equation (28.7) to be executed from $t = n$ to $t = 1$. At $t = 0$ the value $e_t = 0$, and so the equation can be rewritten as an expression for w_t, from which $[w_t], t \leq 0$ can be calculated back to some $t = -Q$, the quantity $(w_t - \mu)$ being neglible for $t < -Q$. These backcasted values of w_t can then be used to start the recursion equation (28.8) from $-Q$ upon setting $a_{-Q-1} = 0$.

Exactly when the quantity $w_t - \mu$ becomes neglible is not explicitly stated in BJ. Their example in their Table 7.4 (1976, p. 218) suggests that $w_t - \mu < 0.01$ is an appropriate stopping rule. Other stopping rules for backcasting have been described in the literature. For example, Granger and Newbold (1977, p. 88) suggest stopping when the magnitude of three successive values of $E_c(Y_t)$ is less than 1% of the standard deviation of y_t.

In whatever way it is determined, the choice of Q, the number of observations to backcast, will affect the final estimation results. What is surprising is that many packages that offer the ULS method do not mention the stopping rule employed. Even more surprising, when this researcher contacted many such developers, they refused to reveal their stopping rules. Not only is this tantamount to refusing to reveal the method of computation, but it also makes provision of a benchmark impossible for these packages. Thus, users of such packages are in the unenviable position of relying on unproven and unverifiable code.

The variation of the Marquardt algorithm proposed by BJ for estimating CLS and ULS models is the essence of simplicity. Given initial estimates of the coefficients, μ_0, ϕ_0 and θ_0, compute the vector of residuals a, which will have length $n - p$ in the case of CLS and length $n + Q + 1$ in the ULS case. Compute the derivative of a with respect to the parameters, denoted $a^{(\mu)}$, $a^{(\phi)}$ and $a^{(\theta)}$, and run the regression:

$$a = b_\mu a^{(\mu)} + b_\phi a^{(\phi)} + b_\theta a^{(\theta)}, \tag{28.9}$$

to obtain estimates $\hat{b}_\mu, \hat{b}_\phi$ and $\hat{b}_\theta$. Compute the coefficient estimates at the end of the first iteration as $\mu_1 = \mu_0 + \hat{b}_\mu$, $\phi_1 = \phi_0 + \hat{b}_\phi$ and $\theta_1 = \theta_0 + \hat{b}_\theta$. To commence the second iteration, based on μ_1, ϕ_1 and θ_1, compute a (note that the value of Q on this iteration may well not be equal to the value of Q on the previous iteration) and repeat the process until a termination criterion is achieved (e.g., successive sum of squared residuals is less than ϵ, etc.). Suppose the termination test is successful at the end of the cth iteration. Then the procedure is said to have terminated after c iterations. Note, though, that the gradients currently in the computer's memory are computed based on μ_{c-1}, ϕ_{c-1} and θ_{c-1}.

Computation of the standard errors is effected in the usual fashion. First, the gradients must be recomputed using μ_c, ϕ_c and θ_c, and each gradient will have length $n-p$ (CLS) or $Q+1+n$ (ULS). In the latter case, drop the first $Q+1$ elements of each vector. Form the matrix with three columns and either $(n - p)$ (CLS) or n (ULS) rows: $g = [a^{(\mu)}\ a^{(\phi)}\ a^{(\theta)}]$. The covariance matrix is given by $(g'g)^{-1}$ which, when multiplied by $\sum a_i^2/n$, has as its trace the variances of the coefficients.

28.6.2 Calculation of derivatives

Given the general superiority of analytical derivatives over numerical derivatives, no benchmark for a nonlinear procedure should be attempted on the basis of numerical derivatives alone, except in exceptional circumstances (e.g., when calculation of the derivatives is nearly impossible). Comparing the performance of numerical and analytic derivatives in a benchmark setting can determine whether it is safe for a user to rely on numerical derivatives or whether, as Fiorentini, Calzolari and Panattoni (1996) found in the case of GARCH models, analytic derivatives are necessary to achieve decent accuracy.

Computation of numerical derivatives is easy. Consider computing $a^{(\phi)}$ on the ith iteration. Compute the residuals based on μ_i, ϕ_i and θ_i, and call this vector a_i. Now for some differencing interval h, compute a_i^h based on $\mu_i, \phi_i + h$ and θ_i. Then the numerical estimate of $a^{(\phi)}$ is given by $a_i - a_i^h$. The choice of differencing interval

can greatly affect the quality of the numerical derivatives. For example, in the days when single precision was common, $h = 0.01$ or $h = 0.001$ were common choices. In the present day, when double precision is standard, smaller values of h are used.

It is well known that analytic derivatives are generally more accurate than numerical derivatives. It is also well known that there exist some problems for which implementing analytic derivatives is too difficult, and there is no recourse to numerical differentiation. ARIMA estimation is just such a case. For CLS, analytic derivatives are not difficult to implement. Backcasting, however, is another case. BJ (1976, p. 235) provide the analytic derivatives for an ARMA(1,1) model, where $a_t^{(\phi)}$ denotes $\partial[a_t]/\partial\phi$:

$$e_t^{(\phi)} = w_t^{(\phi)} - \phi w_{t+1}^{(\phi)} + \theta e_{t+1}^{(\phi)} - [w_{t+1}] \tag{28.10}$$

$$a_t^{(\phi)} = w_t^{(\phi)} - \phi w_{t-1}^{(\phi)} + \theta a_{t-1}^{(\phi)} - [w_{t-1}] \tag{28.11}$$

$$e_t^{(\theta)} = w_t^{(\theta)} - \phi w_{t+1}^{(\theta)} + \theta e_{t+1}^{(\theta)} + [e_{t+1}] \tag{28.12}$$

$$a_t^{(\theta)} = w_t^{(\theta)} - \phi w_{t-1}^{(\theta)} + \theta a_{t-1}^{(\theta)} + [a_{t-1}], \tag{28.13}$$

where:

$$[w_t] = w_t, \ t > 0 \tag{28.14}$$

$$w_t^{(\phi)} = w_t^{(\theta)} = 0, \ t > 0 \tag{28.15}$$

$$[e_{-j}] = 0, \ j \geq 0. \tag{28.16}$$

These derivatives are tedious but straightforward to implement, and are similar to the previous use of backward and forward equations. Setting $e_{n+1}^{(\phi)} = 0$, equation (28.10) can be solved from n to 1. For $t = 0$, $e_t^{(\phi)} = 0$ and so this equation can be re-expressed to solve for values of $w_t^{(\phi)}, t \leq 0$. Then, setting $a_{-Q-1}^{(\phi)} = 0$ and using the backcasted values of $w_t^{(\phi)}, t \leq 0$, equation (28.11) can be solved from $t = -Q$ to $t = n$, and similarly for equations (28.12) and (28.13).

By comparison, the analytic derivatives for an ARIMA(1,0,1) are much more difficult to implement. Then differentiating equations (28.7) and (28.8) yields:

$$e_t^{(\phi)} = w_t^{(\phi)} - (w_{t+1} - \mu) - \phi w_{t+1}^{(\phi)} + \theta e_{t+1}^{(\phi)} \tag{28.17}$$

$$a_t^{(\phi)} = w_t^{(\phi)} - (w_{t-1} - \mu) - \phi w_{t-1}^{(\phi)} + \theta a_{t-1}^{(\phi)} \tag{28.18}$$

$$e_t^{(\theta)} = w_t^{(\theta)} - \phi w_{t+1}^{(\theta)} + e_{t+1} + \theta e_{t+1}^{(\theta)} \tag{28.19}$$

$$a_t^{(\theta)} = w_t^{(\theta)} - \phi w_{t-1}^{(\theta)} + a_{t-1} + \theta a_{t-1}^{(\theta)} \tag{28.20}$$

$$e_t^{(\mu)} = (w_t^{(\mu)} - 1) - \phi(w_{t+1}^{(\mu)} - 1) + \theta e_{t+1}^{(\mu)} \tag{28.21}$$

$$a_t^{(\mu)} = (w_t^{(\mu)} - 1) - \phi(w_{t-1}^{(\mu)} - 1) + \theta a_{t-1}^{(\mu)}, \tag{28.22}$$

and programming these, of course, is more difficult than the ARMA(1,1) case.

More sophisticated BJ models are much more difficult. Were it the case that the most estimated ARIMA model was an ARIMA(1,0,1) then it would be worthwhile for a developer to implement analytic derivatives. For example, the FCP GARCH benchmark (Fiorentini, Calzaroli and Panattoni 1996; McCullough and Renfro, 1999; Brooks, Burke and Persand, 2001) is based on a GARCH(1,1) model, with analytic first and second derivatives because most applications of GARCH involve the GARCH(1,1). The same is not true of ARIMA models.

Nonetheless, it is of interest to know what price is paid for the use of numerical derivatives instead of analytic derivatives. Moreover, the use of analytic derivatives can shed light on the appropriate choice of h, the differencing interval. Since analytic derivatives are easily implemented in CLS, this will be done in the next section.

28.6.3 Conditional least squares

We are now in a position to create a CLS benchmark. We use the 197 observations from Box–Jenkins Series A. In the CLS case, the analytic derivatives given by equations (28.17)–(28.22) reduce to:

$$a_t^{(\phi)} = (w_{t-1} - \mu) + \theta a_{t-1}^{(\phi)} \tag{28.23}$$

$$a_t^{(\theta)} = a_{t-1} + \theta a_{t-1}^{(\theta)} \tag{28.24}$$

$$a_t^{(\mu)} = -1 - \phi + \theta a_{t-1}^{(\mu)} \tag{28.25}$$

which can be calculated recursively after setting $a_0^{(\phi)} = a_0^{(\theta)} = a_0^{(\mu)} = 0$.

Carrying 50 digits through all calculations,[3] using the maximum of the relative change in the coefficients as the convergence criterion, setting the convergence tolerance to 1E-13, and rounding to 11 digits produced the benchmark. To determine what we can expect from ordinary double-precision calculation, we also re-ran the program using ordinary double precision. As can be seen in Table 28.4, double precision delivers the benchmark answer for the first seven digits of the constant, five digits of ϕ, and four digits for θ. The standard errors are computed on division by n, not $n - k$.

Recall that the benchmark was produced with analytic derivatives. We can use some capabilities of Mathematica to obtain this level of accuracy without

Standard error (MLE)	0.10520938686	0.045388753586	0.086811221485

Note: MLE = maximum likelihood estimation.

the trouble of implementing analytic derivatives. Issuing the commands: "$MinPrecision=50," rationalizing the input data, setting h = 1E-12 and using the "Rationalize" command on the input data series enabled numerical differentiation to recover the full eleven digits of the benchmark. Thus, without using analytic derivatives, Mathematica is capable of producing the same accuracy as if analytic derivatives were employed. This information will be useful in producing the benchmark for ULS – it will save us the trouble of implementing analytic derivatives.

Next we investigate the accuracy that can be attained with numerical derivatives with varying sizes of the forward differencing parameter, h. The forward difference derivative is computed by $f'(x) = (f(x+h) - f(x))/h$. We do not consider numerical derivatives via central differences, because the software packages in question do not offer such an option for estimation.

Though obviously the desired degree of accuracy depends on the particular problem at hand, based on the limits of achievable accuracy in this situation as discussed above, we take as our desideratum that the ARMA estimation procedure should produce at least three accurate digits for the coefficients and standard errors. Table 28.5 shows the effect of various choices of h on the accuracy of the estimates.

Recall that we ran analytic derivatives two ways: at regular double precision, and also carrying 50 digits; the former agreed with the latter to about five digits. Clearly, we cannot expect more than five digits of agreement when using numerical derivatives. We see that this level of accuracy is attained in the bottom row, and almost in the penultimate row. Hence, we see that, for best accuracy, the differencing parameter h should be set to at most 0.00001. (Very few packages even permit users to control this feature, so this information is mostly for the benefit of software developers rather than users.)

Programming analytic derivatives, especially recursive ones, can leave the programmer wondering whether he/she did it correctly. A useful device in this

situation is to compare the difference between the numeric and analytic derivatives (which should be close to zero) for different values of h (it should get smaller as h gets smaller). Both these conditions can be seen in Figure 28.2.

Having determined the benchmark coefficients and standard errors, we are now in a position to see whether our packages can hit the benchmark. In Table 28.6 we present default estimation for three packages that offer CLS.

Package X is the most accurate, followed by Package Y, followed by Package Z. The first two seem to provide about four accurate digits, and the third about three

Table 28.7 How close to the benchmark?

Package	ϕ	θ
Benchmark	0.045388753586	0.086811221485
Package X	0.0457	0.0874
Package Y	0.0547	0.1186
Package Z	0.0433	0.0894

digits. How much more accuracy can be squeezed out of a package by varying the default options? We consider only the case of Package X.

The primary option in this case is the convergence tolerance which, by default, is set to 0.00001, i.e., 1E-5. What this tolerance controls is unknown, because the package's extensive documentation does not say! (This is typical of econometric software packages.) Let us vary this convergence tolerance nonetheless.

As can be seen in Table 28.7, tightening up to 1E-6 yields a small improvement in about the sixth digit (which is negligible since the difference between the benchmark with 50 digits and the benchmark with double-precision occurs in about the same place), and no further improvement occurs with more tightening.

We now turn to the question of standard errors. Since all packages do not use the same parameterization for the constant term, the standard errors thereof are not directly comparable and are omitted. NAM noted that even when the parameters were the same, different standard errors could be observed, and we find the same with our three packages, as seen in Table 28.8. There are many possible sources for this (see McCullough and Renfro, 2000, for a discussion); here we mention just one. There is no single method for computing standard errors for nonlinear estimators; the product of the gradient (recommended by BJ, as discussed at the very end of sub-section 28.2.2), which is used in our benchmark program, the inverse of the Hessian, and the information matrix are all prime candidates.

Though the documentation for Package X gives no indication of how its standard errors are computed, we can see that Package X probably uses the product of the gradient method. Similarly, the documentation for both Packages Y and Z are silent on this important point. We have no idea whether these standard errors are incorrect or based on some other approach, e.g., inverse of the Hessian or the

information matrix. The users of these packages will just have to trust that these standard errors – whatever type they are – are correctly programmed.

28.6.4 Unconditional least squares

We have seen that an important part of ULS is the determination of Q, the number of observations to backcast. Many packages claim to use backcasting and offer only BJ as a reference. Given the atrocious state of software documentation, it is not surprising that most packages that offer backcasting do not give the rule used to determine the number of backcasts. What is perhaps surprising is that, when this author contacted the developers who did not mention the rule in their documentation, only one of them would reveal its rule.

This is either pathetic or amusing, depending on your point of view, because the text does not give the rule used to determine the number of backcasts. The backcasts in an example in BJ (1976, pp. 217–18) "die out quickly and to the accuracy with which we are working are equal to zero" for backcasts number 4 and greater. Confusingly, BJ do not declare the accuracy to which they are working! In their code in the back of the book, BJ (*ibid*., p. 502) recommend stopping backcasts when $w_t - \hat{\mu}$ becomes negligibly small, but they do not state what constitutes "negligibly small": is it 0.1, 0.01, 0.001, or even smaller? For this benchmark we backcast until $w_t - \hat{\mu} < 0.01$. Decreasing this tolerance to 0.001 changes the estimates of ϕ and θ in the third decimal.

Analytic derivatives are not used here, as mentioned in the previous section; yet we can be confident that we are achieving the same level of accuracy as if we were implementing analytic derivatives. The benchmark is presented in Table 28.9.

Note that this result comports with BJ's Table 7.13, the BJ results for estimation of Series A. BJ report (with standard errors in parentheses) a constant of 1.45, a ϕ of 0.92(0.04) and a θ of 0.58(0.08). The BJ constant is consistent with our benchmark constant because $17.066 \approx 1.45 \times 1/(1 - 0.9149...)$. Note that our standard errors agree with those of BJ. Further, BJ give the residual variance as 0.097 while that from the benchmark, to four decimals, is 0.0974. So it seems that we are estimating the same model for which BJ present results.

Of interest is whether any of the three packages that offer backcasting come close to the benchmark. These results are presented in Table 28.10.

Overall, no package comes close to the benchmark. As mentioned, this is because they use different, secret methods for determining Q that, for some reason, they will not reveal to their users. There is no point in checking the standard errors.

Table 28.9 ULS benchmark

Parameter	μ	ϕ	θ
Coefficient	17.065547663	0.91494836959	0.58268097638
Standard error (MLE)	0.10808561791	0.042209513625	0.083811338527

Table 28.10 Packages that backcast

Package	μ	ϕ	θ
Benchmark	17.065503687	0.91492053108	0.58262567074
Package U	17.11392	0.917600	0.607982
Package V	17.08580	0.919264	0.595042
Package W	17.06372	0.884730	0.530030

28.6.5 Final thoughts on ARMA benchmarking

We have used analytic derivatives and extended precision calculation in Mathematica to produce much-needed benchmarks for ARMA least squares models. Generally, packages can hit the point estimates for the CLS benchmark, but the method of standard error calculation for most packages is unknown. Packages offer disparate answers for the ULS benchmark because each uses its own specialized, undocumented algorithm for backcasting.

While this is a damning indictment of customary practice in econometric and statistical software practice, what can we hope for the future? Should we expect developers to fix these problems? Generally, no. To rewrite the CLS and ULS code would be very time-consuming and of little benefit. CLS is an approximation to ULS which, in turn, is an approximation to maximum likelihood. Everybody should be using exact maximum likelihood instead of CLS or ULS (Choudhury, Hubata and St. Louis, 1999). There is currently no exact maximum likelihood benchmark. Someone should develop it, and all packages should converge on it. A package that does not offer exact maximum likelihood should either implement it, or better document its existing CLS/ULS code, and ensure that it hits the benchmark presented in this section.

28.7 Conclusions

We have seen that it is not safe to assume that econometric software is accurate, and we have reviewed methods of testing econometric software, of which there are far too few. While this chapter has primarily concerned itself with the "known inputs – known outputs" approach to testing, it was mentioned that there is another approach: two independently developed methods producing the same answer. The former approach is very time-consuming and requires some knowledge of numerical methods. The latter approach simply requires two (or more) software packages, and the ability to use them correctly. This latter method has not been much employed simply because of the dearth of replication in economics. However, it is reasonable to expect that there will be much more replication in economics in the future, and the relation between the accuracy of econometric software and replication merits exposition here in the concluding section.

Over 20 years ago, Dewald, Thursby and Anderson (1986) attempted to replicate many articles from the *Journal of Money, Credit and Banking*. Dewald, Thursby and Anderson advised against the adoption of an honor system, whereby publishing

authors pledge to provide their data and code to researchers wishing to replicate the published results, due to the obvious incentive-compatibility problems. They recommended a mandatory data/code archive, whereby authors would have to deposit their data and code prior to publication. The *American Economic Review*, which published the article, nevertheless adopted an honor system. McCullough and Vinod (2003a) attempted to replicate every article in a single issue of the *American Economic Review* and discovered that half the authors would not honor their pledges; the percentage of compliant authors at other journals with honor systems was much less.

Under the then editor, Ben Bernanke, in direct response to McCullough and Vinod (2003a), the *American Economic Review* adopted a mandatory data/code archive (Bernanke, 2004). Many journals followed suit: *Econometrica*, 2005; *Review of Economic Studies*, 2005; *Journal of Political Economy*, 2006; *Spanish Economic Review*, 2007; *Canadian Journal of Economics*, 2008; and the *Review of Economics and Statistics*, 2009. More can be expected to follow. It should be noted that simply having a mandatory data/code archive is no guarantee of replicable research being published (see McCullough, McGeary and Harrison, 2006, 2008, for details). The topic of replication in economics, including its relation to software, is covered in great detail in Anderson *et al*. (2008).

As more data code and published results (read "inputs and alleged outputs") are available, more and more code will be run on more than one econometric software package, both uncovering discrepancies that need to be resolved as well as verifying that two different programs give the same answer to the same problem (increasing our confidence that both programs are correct). In the case of uncovered discrepancies, software developers are generally willing to fix these problems. The net result will be more accurate software, as evidenced by some cases we have discussed here: Drukker and Guan (2003), Zeileis and Kleiber (2005) and Bruno and De Bonis (2004).

While some journals have always been willing to publish software reviews that address accuracy issues, software reviews carry little professional credit, and until recently practically no journal would publish articles on accuracy. *Computational Statistics and Data Analysis*, *Computational Statistics*, the *International Journal of Forecasting* and the *Journal of Statistical Software* have all published such articles in recent years. So there are outlets for persons willing to do the computational work of creating benchmarks. And there will be a much greater need for it as progress on the replication of economic research leads to the identification of fruitful areas for developing such benchmarks.

Acknowledgments

The author would like to thank Houston Stokes for useful comments on this chapter.

Notes

1. Because using the StRD is much more interesting than, and not nearly so tedious as testing random number generators or statistical distributions, some of these authors only apply the StRD.

2. The R code to produce this graph is two lines: f <- function(n)max(rnorm(n)), and plot(sapply(rep(5000,4000),f)).
3. In Mathematica, this is effected by issuing the command "$MinPrecision=50."

Trends in Applied Econometrics Software Development 1985–2008: An Analysis of *Journal of Applied Econometrics* Research Articles, Software Reviews, Data and Code[1]

Marius Ooms

Abstract

Trends in software development for applied econometrics emerge from an analysis of the research articles and software reviews of the *Journal of Applied Econometrics* (*JAE*) appearing since 1986. The data and code archive of the journal provides more specific information on software use for applied econometrics since 1995. GAUSS, Stata, MATLAB and Ox have been the most important software since 2001. I compare these higher-level programming languages and R in somewhat more detail. An increasing number of packages are being used. A surprisingly low number of products have been discontinued since 1987. I put the time series count data on the number of articles using different software and on the number of reviews discussing different products in a historical perspective, where I distinguish several software types. Two waves of new products showed up in the period under study, the first associated with the introduction of the personal computer and new graphical interfaces, the second with the appearance of the internet. The *JAE* has reviewed 77 packages. In this chapter I discuss 13 other relevant packages. A table with all mentioned packages, their authors and latest versions provides a comprehensive overview of the relevant software as in June 2008.

29.1 Introduction

In this chapter I provide an overview of academic applied econometrics software development, deriving time series count data from the *JAE* software reviews (1987–2008), *JAE* research articles and the *JAE* data archive (1995–2008). The *JAE* has promoted documentation and indexing of softwares and codes for applied econometrics by publishing software reviews and replication studies. Most importantly, James MacKinnon has patiently, successfully and consistently added the software codes of *JAE* authors to the *JAE* data archive.

I first provide a contingency table of used data type versus year of publication. The types of data used indicate a gradual shift from traditional macroeconometrics and time series analysis to microeconometric applications and panel data research. Second, I present the distribution of reviews per software category per two years, and I check which software still existed in June 2008. Third, I present the yearly distribution of software use over the 25 specifically mentioned software packages.

During the observation period, the *JAE* reviewed the usefulness of 77 different packages for applied econometrics research and education. Surprisingly, only a handful of these products have been discontinued before June 2008 and a large majority have recently been updated. Trends in general and individual applied econometric software development emerge from the corresponding tables. In recent years the range of effective specific softwares in applied econometric research has increased. GAUSS, Stata and MATLAB dominate. Freely downloadable alternatives like R and Ox have not had a similar impact as yet.

Econometric programs such as LIMDEP, SHAZAM, TSP, RATS and Ox are also used for scientific research outside applied econometrics, not only in the traditionally related areas of econometric theory, applied statistics and applied economics, but also in marketing, finance, management science, accounting, regional science and transportation science. For example, Altman and McDonald (2001) survey the use of software in Political Science, including many econometrics packages. My analysis is therefore admittedly very focused. Many interesting applied econometrics articles have been published outside the *JAE*, but data on software use and development for other journals are not easy to obtain and results are therefore difficult to check.

This chapter implicitly defines applied econometrics as the econometrics that leads to publication in the *JAE*. Cleaning and preparing complicated empirical datasets, writing code for advanced estimation procedures or new types of inference, and presenting and interpreting results for *JAE* articles involves expert knowledge that distinguishes applied econometrics from both applied economics and econometric theory.

The remainder of this chapter is organized as follows. The *JAE* research articles, software reviews, data archive and software use are discussed in sections 29.2–29.5, respectively. The most intensively used high-level programming languages are treated in more detail in section 29.6.

A deeper understanding of the tables is obtained by a selective description of the history and characteristics of the packages, given in section 29.7. This section

draws heavily on Ooms and Doornik (2006) and on the extensive account of Renfro (2004b), who corresponded with many econometric software developers in preparing his article and in editing Renfro (2004a). It also reflects my experience as editor of the Econometric Software Links of the *Econometrics Journal* at http://www.econometriclinks.com. Section 29.8 discusses the combination of software and the concluding section 29.9 looks into future aspects of econometric modeling software.

29.2 *JAE* research articles

The *JAE* is an important source of information on trends in software development. The founding editor, Hashem Pesaran, has been based at the Cambridge (UK) Department of Applied Economics (DAE) for most of the time since 1986. Richard Stone, the founder of the DAE, wrote the first *JAE* article, this being his Nobel Prize lecture on national accounts (Stone, 1986). Stone's methods still underpin the basic data source for applied macroeconometric research today. Whereas Stone pioneered mainframe econometric software development in Cambridge, Pesaran was one of the first to produce user-friendly software for the PC, Data-Fit and Microfit, as reviewed in Ericsson (1988). He initiated the software review section and a replication section for the *JAE*. He has written influential publications in theoretical and applied time series econometrics, and in theoretical and applied microeconometrics for cross-section and panel data.

The *JAE* publishes applied econometric research in all important areas in the field. Special issues of the journal indicate the wide range of topics and methods: time series and cross-section model specification as in McAleer (1989) and Magnus and Morgan (1997); event counts as in Trivedi (1997); nonlinear dynamics as in Pesaran and Potter (1992); simulation-based inference (frequentist and Bayesian) as in Brown *et al*. (1993), macro time series as in Pagan (1994), Diebold and Watson (1996), Hendry and Pesaran (2001) and Franses *et al*. (2005); microeconometric structural dynamics as in Kapteyn *et al*. (1995) and Christensen *et al*. (2004); semiparametric microeconometrics as in Horowitz *et al*. (1998); statistical decision making (Bayesian and frequentist, macro, micro and finance) as in Geweke *et al*. (2000); financial time series analysis as in Franses and McAleer (2002); social and spatial interactions as in Durlauf and Moffitt (2003); and, finally, empirical industrial organization as in Bauwens *et al*. (2007).

The *JAE* co-editors have worked on both sides of the Atlantic and the Pacific and represent the major fields and schools of applied econometrics. Table 29.1 also illustrates this point. It shows the frequency distributions of the dataset types over three main categories, panel data, time series data and cross-section data, for the years 1995–2008, although with only four issues of 2008 covered. The basic source of these counts were the *JAE* authors' readme files on the *JAE* data archive. If these were unclear I checked the corresponding articles on the JSTOR archive and on Wiley Interscience. The gradual shift from traditional macroeconometrics and time series analysis to microeconometric applications and panel data research emerges. Time series articles are overrepresented in the years with corresponding

Table 29.1 Research articles in *JAE* per data type per year

special issues: 1996, 2001 and 2005. Four articles are based on simulated (Monte Carlo) data, reflecting the research interest of James MacKinnon. Two articles use data from economic experiments and four from auctions, new fields for serious applied econometrics. One article uses cross-section meta-data in a traditional way, and Baltagi (1999) uses bibliographical panel meta-data to construct rankings of authors and departments in applied econometrics. Finally, Meddahi (2002) is the only pure econometric theory *JAE* article I have come across. In computing the total number of research articles, I have included articles from the *JAE*'s replication section, edited by Badi Baltagi.

29.3 *JAE* software reviews

The *JAE* software reviews have been edited by Pravin Trivedi (1988–92) and James MacKinnon. The reviews vary greatly in length. Most reviews concentrate on one package, others compare up to six different packages on many features (data management, model formulation, simulation, availability of procedures, speed, help functions and documentation), as in Brillet (1989) and Cribari-Neto (1997). Other reviews compare specific functions like survival modeling, as in Goldstein *et al*. (1989); GARCH modeling, as in Brooks *et al*. (2003); or properties like numerical reliability, as in McCullough (1999).

Many packages have been reviewed only once, but dedicated widely used (inside and outside the *JAE*) econometric packages show up several times in these 20 years. Table 29.2 details the reviews of dedicated econometric software since 1987, split into two-year periods to show the distributions over time for each package. Repeated reviews of the same product occur because the package receives a major

Notes: Software: in alphabetical order within type categories; review counts per two-year periods, 88: 1987–88,. . .; 08: 2007–08; old names in parentheses; Tot.: total number of reviews per software package; . for unreviewed software; V.08: last version in June 2008; Y.: year of last update; Author: name of producing company/author(s) (not all authors mentioned); Type descriptions as S: statistics package; SCA: statistics computer algebra package; SCS: statistical cross-section package; SG: statistical graphics package; SDT: statistical data transfer package; SPD: statistical panel data package; SMC: statistical simulation (random number generator testing) package; SMC2: econometrics Bayesian Markov chain Monte Carlo package; SPL: statistical programming language; SSS: Social Sciences Statistics package; STS: Statistical Time Series package. Reviews in *JAE* often discuss multiple packages, so that total reviews (Tables 29.2–29.4) exceeds total articles.

Sources: JAE in JSTOR: http://www.jstor.org, and in http://www3.interscience.wiley.com; ISSN code JAE: 08837252; URLs for softwares available via the econometric links of the *Econometrics Journal*, http://www.econometriclinks.com.

update (in the beginning of its life) or because it is interesting, important and accessible enough to include in a comparison. JSTOR provides extensive bibliographical information on archived *JAE* articles in database entries like "Reviewed work(s)," but so far, this information is inaccurate and incomplete for the *JAE* reviews, so the numbers in Table 29.2 are based on the full text of the 92 articles.

I also checked the latest update and version number to make the table interesting as a reference for the state of relevant software in June 2008. I was first surprised to find recent updates for most of the packages. This may have been caused by the introduction of Windows Vista and Excel 2007, which made updating necessary for users who are not able to choose between operating systems. Table 29.2 also shows the current software companies and main author names. This entry is not relevant for the modern freely downloadable "team" software and these are therefore missing. The last column gives the country code of the workplace of the company and main authors. Most companies and software developers work in the US; some are in the UK, and nearly all others are in Canada and mainland Europe. None are in South America and Asia, although econometrics is now a well established field of (social) science in those continents. Irregular updates of internet links to the packages will be provided on the Econometric Software links of the *Econometrics Journal*.

The popular econometrics package Eviews (formerly Micro-TSP) has been discussed most often. LIMDEP, SHAZAM, PcGive and Microfit received most attention in the twentieth century. Gretl is the latest general econometrics package to appear on the *JAE* pages, and S-PLUS-FinMetrics is the latest time series econometrics package that has been reviewed. Three reviewed econometrics packages have been discontinued, or at least I could no longer trace them on the internet: ESP, PERM and SIMPC. All other packages have been updated since the first review. I have included three unreviewed packages in the list. TSM for GAUSS was mentioned in the code archive. Dynare, by Michel Juillard, is widely used in modern applied macroeconomics. Juillard (1996) is often cited. The 2008 version is available as a stand-alone program, but also in the form of GAUSS, MATLAB and Scilab packages. JMulti is a teaching package for multivariate time series analysis (see Lütkepohl and Krätzig, 2004); it previously required GAUSS to run. Markus Krätzig developed a graphical user interface (GUI), JStatCom (see also Table 29.3, and Krätzig, 2006). Using this GUI and GRTE (the GAUSS RunTime Engine), JMulti is now also available as a free stand-alone package.

Table 29.3 shows the corresponding review counts of programs and two packages for Bayesian econometrics (Micro-EBA and BACC), specific panel data econometrics (Frontier, DPD and ExPEnd), the econometric programming language Ox, and other packages used for scientific word processing, mathematics and computer science. I added the DPD package for dynamic panel data analysis. This code, by Manuel Arellano and Stephen Bond, has been instrumental for the breakthrough of dynamic panel data econometrics, catering for large unbalanced panels as encountered in practical applications. The fundamental article, Arellano and Bond (1991), has the exceptional econometrics citation scores of 900+ in the ISI Web of Knowledge and 4,000+ in Google Scholar. Their procedures have now been implemented in most econometric packages, both in the original time series-oriented packages

(PcGive) and in the original cross-section packages (LIMDEP). FORTRAN in Table 29.3 and BIOGEME, Excel and SPSS in Table 29.4 have been included to keep consistency with Table 29.5 below. BIOGEME and SPSS are discussed later in this chapter. Stat/Transfer has not been reviewed, but it is referred to on the *JAE* data archive. It allows for user-friendly transfer of datasets between statistics packages and LIMDEP, GAUSS, MATLAB and Excel.

Finally, Table 29.4 considers the statistical software reviews and provides summary statistics. Here I also added BUGS by Lunn *et al*. (2000), because it is widely used in Bayesian econometrics teaching; WinBUGS is a popular version for Windows. The preferred version is called OpenBUGS. The summary shows that 77 different packages have been reviewed 128 times in 92 articles. Thirteen packages have not been reviewed. The number of "reviews" in the table equals or exceeds the number of "articles" by definition. As explained above, a large difference between these two numbers indicates the discussion of several packages in single articles. This phenomenon occurred in 1989–90 when many PC packages for econometrics became fit for review, and in 1999–2000 when the first "GNUwares" came into use among econometricians.

29.4 The *JAE* data and code archive and reproducibility

The data (and code) archive of *JAE*, http://www.econ.queensu.ca/jae/, consistently coordinated by James MacKinnon, contains detailed references of all articles published since 1995. Most authors (85%) have complied with the policy to provide their data in a well documented human-readable format, fit for different operating systems and econometric software, and usable for many years to come. This is a high success rate, compared to journals in economics or statistics who intend to have a similar policy. Authors who do not provide data for no reason whatsoever receive the remark: "Contrary to the policy of the Journal, the author has failed to submit the data used in this paper."

In recent years a growing number of microeconometric datasets and even some software codes are confidential for reasons of privacy, so the overall coverage of the data archive will go down in the coming years. On the other hand, the number of articles providing details on used software and codes has been high and increasing. This is the main motivation for choosing *JAE* articles, data and code as the main sources of information for this chapter.

The existence of a carefully managed and indexed data and code archive is an essential prerequisite for the scientific ideal of effortless reproducibility of key results in applied econometrics. Anderson *et al*. (2008) set the *JAE* data and code archive as an example. William Greene is a leading econometric software developer, and Bruce McCullough and Hrishikesh Vinod are influential reviewers. They discussed the disappointing compliance rates for leading American economics journals for a recent American Economic Association meeting. The situation is hardly better for leading statistics journals, like the *Journal of Business and Economic Statistics*, where the latest instructions for the FTP (file transfer protocol) data archive are now eight years old.

Of course, thanks to automatic indexing by Google and free specific internet aggregators of economic and econometric research (papers, articles, books, citations, data and software) like RePEc (http://www.repec.org), it is relatively easy to find properly documented econometric source code outside official peer-reviewed archives. Unsurprisingly, given the working environment of most econometricians, robust, high-quality econometric procedures seldom come free. Here, the situation in computer science and statistics seems to be much better as the (much larger) programmer communities are funded in a different way.

Buckheit and Donoho (1995) gave a lively discussion of the difficulties in reproducing (even) one's own computer intensive results in computer science. Koenker and Zeileis (2007) elaborate on the difficulties in reproducing exact econometric results using codes from data archives. This is a nontrivial exercise, even using the original econometric software and a similar operating system. They advocate the use of internet-based tools for subversion control (SVN) for programmer communities and recent R applications to consistently develop reproducible econometric results. Roger Koenker is the father of quantile regression in econometrics (see Koenker, 2005). Achim Zeileis is a key R developer.

The good news to derive from Tables 29.2–29.4 is that it is now unlikely that the current software and code will become completely useless because of the discontinuation of products.

29.5 Software used in *JAE* research articles

Table 29.5 details the time-varying impact of the main software in applied econometrics research since 1995. The software packages are ordered by first-mentioned use to get a clear picture of the growing range of products used. Up to three software packages were mentioned per article; for example, S-PLUS, FORTRAN and Stata for a cross-section study. The basic sources of the counts were the readme files on the data archive. If these were unclear I checked the corresponding articles on the JSTOR archive and on Wiley Interscience.

The "Range" indicates the number of different products per year, which reached a maximum of 14 in 2006. The row labeled "Missing" counts the number of articles that don't mention specific software. This number has increased in absolute terms, but it has decreased compared with the number of (research) "Articles" mentioned in the bottom row. Twenty-five packages have been used. I have distinguished seven general econometrics packages (E), four statistical programming languages (SPL), three econometric time series packages (ETS), two mathematical matrix programming languages (MPL), two third-generation numerical programming languages (NPL), Ox as an econometric matrix programming language (EMPL), BACC as an econometric MCMC (Markov chain Monte Carlo) package (EMC2), and finally, SPSS and Excel.

GAUSS is number one and consistently mentioned over time. In addition, two specific GAUSS applications figure once. Stata and MATLAB have only become attractive for applied econometrics since 2000. SAS and Ox (in later years) appear regularly. RATS has been the most important econometrics package for time series applications. FORTRAN has been consistently more important than C. Other

packages appear less than five times. S-PLUS appears four times and R appears three times. SHAZAM, Xplore and PcGive do not reappear after 2001. The other packages cannot be written off as tools for applied econometrics software development. They may well have been used in the preparation of the articles, but the authors did not develop new programs or procedures that they wanted to publish.

In sum, Table 29.5 shows that the programming languages GAUSS, MATLAB, Stata and Ox are the most important tools for applied econometrics software development. GAUSS, MATLAB and Stata are apparently widely available in economics and econometrics departments all over the world.

29.6 High-level programming languages in econometrics

Table 29.6 illustrates some characteristics of the dominating languages GAUSS, MATLAB, Stata and Ox. The table displays very short programs that load a simple dataset from a human-readable ASCII file, estimate regression coefficients using ordinary least squares (OLS) and show these on screen. The examples are adapted from first lessons of course notes available on the internet. The table also includes code for R (and S-PLUS) as this is an increasingly important alternative, as discussed below.

The codes for the matrix programming languages GAUSS and MATLAB are very similar. Beginning is easy, because variables don't have to be declared. The "default type" is a matrix (of double-precision floating-point numbers); and statements end with a semicolon. MATLAB uses square brackets for concatenation, GAUSS has special concatenation operators. GAUSS uses square brackets for indexing, MATLAB indexes with parentheses. Indexing in GAUSS and MATLAB starts at one. Fortunately, arguments in clear function calls are in parentheses. GAUSS provides the least squares solution for the coefficients by the "divide symbol" `/`, which looks a bit weird and mathematically incorrect, but is easy to use; MATLAB uses the more sensible \ operator instead. Neither GAUSS nor MATLAB use a formal print function to show the regression coefficients.

The Stata code is totally different and is reminiscent of many command-line-driven packages in the early 1980s. Stata is, as Baum (2002) put it, "on the middle ground" between econometric packages and matrix languages. The default regression method requires variable names (of columns of dataset, rather than a matrix) to read the data. OLS is the default estimator of the easy-to-read-and-remember regress command, which also adds a constant term and computes standard errors and *p*-values by default. The `matrix` command extracts the regression coefficients in vector format. The mathematical structure is hidden from the programmer. The standard output of regress (not shown in the table) is in the ANOVA format, rather than the standard regression output of econometrics programs. Stata recently introduced the matrix language Mata. So far, Mata has not explicitly been used for *JAE* publications.

Like Stata, R starts with a dataset rather than a matrix. In the R example we assume that the variable names are on the first line of the data file, so that "header=T(rue)". OLS is performed using a challenging call of `lm()` (linear model). This function creates a model object, and the corresponding function `coefficients` extracts the coefficient estimates from the model. The model is specified with the names of the variables and the dataset. The operator ~ separates regressand and regressor, the operator + separates the regressors. The "dollar" operator makes sure we use the coefficients from the linear model object.

Table 29.6 OLS in programming languages for applied econometrics

Software	*Type*	*How to*	*Statements/commands*
GAUSS	MPL	begin, declarations	not necessary
		read data	`load myX[4,3]=yX.asc;`
		select y	`y=myX[.,1] ;`
		add constant to X	`X=ones(rows(myX),1)~myX[.,2:3];`
		get b	`b=y/X;`
		show b	`print b;`
MATLAB	MPL	begin declarations	not necessary
		read data	`myX=load('-ascii','yX.asc');`
		select y	`y=myX(:,1);`
		add constant to X	`X=[ones(size(myX,1), myX) myX(:,2:3)];`
		get b	`b=X\y;`
		show b	`b`
Stata	SPL	begin, declarations	not necessary
		read data	`infile y x1 x2 using yX.mat`
		add constant to X	added by default
		get b	`regress y x1 x2`
		show b	`matrix list e(b)`
R and S-PLUS	SPL	begin, declarations	not necessary
		read data	`myX<-read.table("yX.dat", header=T)`
		add constant to X	added by default
		get b	`b=lm(y1~x1+x2,data=myX)$coefficients`
		show b	`b`
		extra line in `yX.dat`	`y1 x1 x2 \\ variable names`
Ox	EMPL	begin main program	`main()`
			`{`
		declarations	`decl myX, mX, vy, vb, vyhat;`
		read data	`myX=loadmat("yX.mat");`
		select y	`vy=myX[][0];`
		add constant to X	`mX=1 So just a one: mX=1~myX[]1:2];` is the total command;
		get b	`olsc(vy, mX, &vb);`
		fit y: $\widehat{y} = Xb$	`vyhat=mX*vb;`
		show b	`println("b: ",vb);`
		end	`}`
		extra line in `yX.mat`	`4 3 \\ dimensions`

Notes: MPL: matrix programming language; SPL: statistical programming language; EMPL: econometric matrix programming language. Computation 3×1 regression coefficient vector b in linear model $y = X\beta + u$, where X is a 4×3 matrix starting with a column of ones. y and X are read from file. myX: 4×3 matrix with numerical data read from human-readable data file yX.asc. For R we read yX.dat, and for Ox we read yX.mat, starting with an extra line as indicated.

Ox has a syntax similar to C++ (and Java), so all statements are executed in a `main()` function, square bracket pairs index a matrix, and indexing starts at zero. Doornik (2002) discusses differences and similarities of C++ and Ox. Variables have to be declared, but they automatically get a type (double, matrix) when they are assigned. Ox uses the same matrix concatenation operator as GAUSS. A dedicated least squares function `olsc()` is provided, but the (slower and less robust) explicit matrix formula for OLS could have been used instead. The ampersand (reference) is used to deliver the coefficients directly at the memory address of the vector variable `b`. This reduces memory use. I added a statement for computing fitted values $\widehat{y}$ to clarify the matrix programming nature of Ox. I use slightly adapted Hungarian notation, where vector names start with `v` and matrix names with `m`, but this is not required. The Object Oriented (OO) nature of Ox does not appear in this example, but a Modelbase class, derived from a Database class, is standard. Both classes are extendible. Unlike R and S-Plus, Ox does not force the OO features upon novice users.

Table 29.6 shows that Stata code is probably the most easy to use for students and researchers with limited programming experience. GAUSS and MATLAB require knowledge of matrix algebra and numerical programming, but this should not be a problem for econometricians. R is harder to get into as it requires a profound knowledge of statistical terminology and object-oriented programming. Ox is easy to learn if a basic programming language and matrix algebra are known.

Readability and complexity are not the only selection criteria for high-level programming languages. Large models require an extendible modeling language (like Stata and R), and new models require an efficient programming language in which to code new algorithms to estimate and evaluate new model types (like GAUSS and Ox). The programming language should also cater for effective data management, robust optimization methods, state-of-the-art stochastic simulation, and decent, easily adaptable, graphical and textual output facilities.

For maintenance and reproducibility one requires explicit documentation facilities that can transform comments in the code into context-sensitive, clearly structured and indexed help functions for existing and new procedures. One should be able to integrate existing numerical procedures from low-level languages. For business use, the econometric programming language should be applicable as an engine within other software, so that econometric procedures can be called by, and feed results to, programs like Excel, Access, or commercial front-office and back-office applications written in lower-level languages like C++ or Perl. In computing intensive simulation-based methods, one wants to automatically optimize code for parallel computing or for specific hardwares at a low level to increase speed. Multiprocessor computers are now standard. Efficient computing will probably return as a very important issue as electricity prices go through the roof.

The econometric language should have an interface to the Structured Query Language (SQL), a standard language that provides an interface to many relational database systems, and to specific economic, financial, and energy data management software, like FAME (http://www.fame.com), or HAVER (http://www.haver.com). For example, none of the above-mentioned languages can be used to manipulate and select data from the vast datasets on the WRDS (Wharton Research

Data Service), which is now the leading academic archive for econometric time series data. Only SAS, C and FORTRAN can be used on the WRDS server.

The next section discusses other important aspects of a large array of packages and adds a historical perspective, concentrating on the period since 1980. This discussion should help the reader in interpreting the preceding tables on the historical impact of the different products.

29.7 The historical development of econometric software

Over the last 50 years, econometric software development has developed from writing complicated sets of computer specific instructions into coding in structured purpose built programming languages and into interactive GUI-based model development. Increased backward compatibility, cross-platform and cross-operating system applicability of new software, and low cost of maintaining existing software, has increased the lifetime of packages and procedures. Less than 10% of the 77 packages reviewed in the *JAE* have been discontinued.

Econometric software development started around 55 years ago. Renfro (2004b) gives a detailed account of the history of econometric software development in the English-speaking world. Early econometric software development was labor-intensive and served only a few institutions that could manage and pay the substantial capital input for the required programmable computers. Today, this situation has completely changed. Modern econometric software is written by a few individuals and thousands of users perform econometric estimations, forecasts and tests on thousands of machines. The joint cost of standard econometric software and hardware is low and dropping. Thanks to a concentration in hardware and software development, a few developers now serve an entire community. However, expert support and tailored innovative development of user-friendly platform-independent applications is still expensive.

Three structural changes affected econometric software development in a major way in the period 1985–2008. The first was the breakthrough in hardware development: the onset and subsequent quick improvement in computer power and graphical displays of personal computers (PC or Micro computer) during the 1980s opened opportunities for new developers. Many textbook authors wrote their own packages. Cheap standard storing devices for the PC (floppy disks) made distribution (and copying) of econometric software easy. This change is reflected in the large number of different software packages reviewed in 1990, as detailed in the summary statistics of Table 29.4.

The second change was the introduction and standardization of effective GUIs for data analysis, programming and operating systems. Graphing became easy, and it was no longer necessary to memorize a list of basic commands and options.

The third change was the development and widespread use of the internet since the 1990s, more specifically the WWW standard and the later development of powerful search engines like Google. This led to the development of "free" products in mathematics, statistics and computer science. These products have now become powerful, stable and easier to use so that they are effectively applied in econometric

software development and in innovative research in econometrics, leading to *JAE* publications.

The interfaces of many computer programs for data input, programming, text processing, formula and graph editing became more and more similar, due to the worldwide concentration in operating systems and standardization of other scientific applications like LaTeX. Only three operating systems remain important: MS-Windows (Microsoft), Mac OS X (Apple) and Linux (many distributions; Ubuntu/Linux is the most popular version of late). Products developed on one platform can be ported or recompiled on other platforms, although this is far from trivial for most econometricians. Racine (2000) discusses some aspects of Cygwin ports of basic Unix tools to Windows.

Hendry and Doornik (2000) discuss and illustrate the necessary changes of the time series econometric program PcGive during the 1980s and 1990s: from command interaction to menu interaction and IDE (Integrated Development Environment); from text menus to mouse-pointer-driven drop-down menus and dialogs of a WIMP (Windows, Icons, Menus, Pointing) GUI; from black-and-white text graphs to colored bitmap, to high-quality, adjustable, publication-ready figures; from a static manual to a context-sensitive help system, from static presentation to live presentations of simulation exercises; from basically one program code in FORTRAN, and later in C++, to a modular object-oriented architecture allowing user-built extensions with an up-to-date user interface with the same look and feel as the standard applications. PcGive was extended with an independent Windows interface, GiveWin. Jurgen Doornik (1998) also developed the object-oriented econometric matrix programming language Ox, which allowed independent development of new packages and was later integrated within OxMetrics (Doornik, 2007), together with PcGive and the time series programs STAMP and G@RCH. The new interface for OxMetrics was built with the free cross-platform GUI wxWidgets. Other software packages have provided similar updates in order to keep old users and get new customers. For example, Stata introduced object-oriented features and GUI programming in Stata 8 and the matrix language Mata in Stata 9.

In the remaining sub-sections I make a distinction between five admittedly overlapping categories of software: macroeconometric software, (pure) time series econometric software, microeconometric software, statistical software for econometrics and mathematical software for econometrics. I treat each in turn.

29.7.1 Macroeconometric software

Back in the 1960s, Robert Hall laid the foundations of TSP (Time Series Processor) software. At the end of the 1970s, TSP already had many of the characteristics of a modern econometric software package: it read and wrote a variety of data formats, it included a matrix language, it made use of symbolic differentiation, it contained good nonlinear solvers, a powerful optimizer and simulation procedures. In this sense TSP can be considered as the most original econometric software on the market.

In the PC era of the 1980s, TSP was split into two separate programs, Micro-TSP, headed by David Lilien, and PC-TSP, headed by Bronwyn Hall. Micro-TSP later became the Windows program Eviews, Econometric Views, whereas PC-TSP is now

simply called TSP (see Hall and Cummins, 2005; Eviews, 2004). TSP retained the numerical and algebraic programming features. Eviews later introduced its own object-oriented programming language. One of the main attractions of Micro-TSP and Eviews was the timely interface for the first univariate econometric time series models: ARCH (autoregressive conditional heteroskedasticity), and GARCH (generalized autoregressive conditional heteroskedasticity). This user-friendly implementation of GARCH models was developed in close cooperation with Robert Engle, the father of ARCH. A special issue of the *JAE* (Franses and McAleer, 2002) was published to celebrate Engle's seminal ARCH article (Engle, 1982).

Ken White started the package SHAZAM at Wisconsin and is now at UBC in Vancouver, where SHAZAM is updated by a small team. Whistler *et al*. (2004) describe the latest version. Nobel Laureate Lawrence Klein founded the Wharton Econometric Forecasting Association (WEFA) at the University of Pennsylvania: WEFA is now part of Global Insight and markets the econometric software AREMOS, which was strongly influenced by Klein's modeling methodology. AREMOS is not frequently updated, but is still being used.

In the UK, at the Department of Applied Economics of the University of Cambridge, Hashem and Bahram Pesaran used their expertise in econometric estimation and testing for the development of Data-FIT, later called Microfit, for the PC. At the Department of Statistics at the London School of Economics, econometric software development was inspired by the hands-on tradition of Denis Sargan. David Hendry, a student and later a colleague of Sargan, developed the programs AUTOREG and GIVE. In Oxford, Hendry developed PcGive (generalized instrumental variable estimator) and PCFIML (full information maximum likelihood) on the IBM PC. Jurgen Doornik modernized and extended PcGive, as explained in the first part of this section.

More recently, Michel Juillard developed a stand-alone version of Dynare, previously only available for GAUSS and MATLAB. Dynare implements modern, small-scale, but very computer-intensive DSGE (dynamic stochastic general equilibrium) modeling. These highly nonlinear structural models are difficult to solve and estimate and require Bayesian econometric techniques to do inference. DSGE models are introduced and used at central banks throughout the world.

On the educational side of the spectrum, Gretl, by Allin Cottrell and Ricardo Lucchetti, is an international GNU (GNU's Not Unix: a free, open source Unix-like operating system) econometrics program, with menus in French, Italian, Spanish, Polish and German as well as English. It is based on code for a textbook by Ramu Ramanathan. As in other packages mentioned in this section, the traditional macroeconometric procedures are being supplemented with microeconometric functions, DPD and procedures in particular.

29.7.2 Time series econometric software

One can no longer imagine applied econometrics without implementations of ARMA (autoregressive moving average), VAR (vector autoregression) and GARCH (generalized autoregressive conditional heteroskedasticity) time series models. The Box–Jenkins methodology is a standard procedure in many fields of science. Under the direction of George Box, the first special software for ARMA analysis was

written by David Pack, and David Reilly turned this into AutoBox. He also coded the Multivariate Time Series (VARMA) program MTS. AutoBox and MTS are now marketed by Reilly's company AFS.

Chris Sims developed SPECTRE at the end of the 1970s. This was one of the first econometric programs offering spectral analysis. Subsequently, Sims' 1980 VAR modeling methodology was made available in RATS (Regression Analysis of Time Series) by Thomas Doan (see Doan, 2004). CATS in RATS was (shortly after PcGive) one of the first widely available software packages for Søren Johansen's likelihood-based analysis of the concept of cointegration, eventually published as Johansen (1991).

The Census Bureau in Washington, DC, produced the first reliable software for seasonal adjustment of economic time series, Census X-11, implementing a methodology (updated to X-12 ARIMA) that is now an international standard and available in most time series econometrics softwares (see Ladiray and Quenneville, 2001).

At the London School of Economics, Andrew Harvey initiated the development of STAMP, for structural time series modeling, implementing an econometric methodology which serves as an alternative both to Box–Jenkins forecasting models and to Census X-11 seasonal adjustment. Siem Jan Koopman now develops the (multivariate) STAMP software at the VU University in Amsterdam (see Koopman *et al.*, 2007).

At the Bank of Spain, Victor Gómez and Augusín Maravall developed the second influential alternative software for seasonal adjustment: TRAMO/SEATS. Their procedures are also available in many time series programs.

Herman Bierens is the independent author of EasyReg International, a free software package (developed in visual Basic), primarily developed for econometrics education but equipped with many advanced procedures in Bierens' area of research (nonparametric methods, first for time series and later for cross-sections), and therefore also featuring in a recent *JAE* research article.

29.7.3 Microeconometric software

This sub-section is short as there is only one surviving dedicated econometric software for nonstandard econometric models for cross-section data, LIMDEP. Microeconometricians have mainly been using lower-level programming languages and statistical packages, discussed below.

William Greene based the first versions of LIMDEP, for LIMited DEPendent variable econometrics on code for multinomial logit models by Marc Nerlove and James Press at the University of Wisconsin. Greene (2007) describes the current features of the program. Previous versions of Greene's influential and popular textbook, now in its sixth edition (Greene, 2008), contained a special student edition, EA/LIMDEP, of the software. Over the last 20 years, most standard econometric procedures (time series and panel data) have been added. Greene also authored the packages ET and NLOGIT. Greene is now at New York University.

29.7.4 Statistical software for econometrics

In the last 25 years, several statistical programs have become more geared towards econometrics and subsequently widely used by econometricians. The general

statistics package SAS (SAS, 2004) has a long tradition (starting in the 1960s) of implementing macroeconometric and microeconometric procedures for large datasets. In academic research and education in econometrics, SAS/ETS has lost ground from its strong position at the end of the 1980s, though its econometrics features are still being developed, recently in state space procedures, in generalized maximum entropy estimation and in automatic model selection for forecasting. Of course, SAS is widely used in official institutions and in business applications, but few modern econometrics textbooks continue to use SAS examples.

SPSS, dating back to the 1970s, is not particularly suited for econometrics, but it is used for handling large and complicated datasets. Interesting third party packages for SPSS exist, like Jeroen Vermunt's LATENT GOLD for Latent Class models and event history modeling in marketing and social sciences. It is also suitable for modern microeconometrics problems (as other packages which were primarily developed for the social sciences).

The beginning of the PC era saw the birth of the "Data Analysis and Statistical Software" Stata. Stata, by William Gould, was not an instant success among econometricians, whereas it was for statistics in medicine. At first, it did not have extensive programming facilities and specialized in applications for survival data (see Goldstein *et al.*, 1989). It was not suited for dynamic econometric modeling. Peterson (1991) correctly predicted: "this shortcoming could be mitigated substantially in future versions." Later Stata introduced more programming tools and eventually a matrix language and it was completed with more and more econometric models. Stata's data management features made it well suited for the econometric analysis of complicated panel data like event histories. Time series procedures have been added. Stata is now a popular package in applied economics and econometrics and a large number of introductory econometric textbooks present examples using Stata. Kit Baum maintains a large Statistical Software Components (SSC) archive within RePEc with over 1,000 free open-source Stata procedures and programs for statistics, economics and econometrics. Baum (2006) also wrote an applied econometric textbook for Stata.

S-PLUS and corresponding packages cater for financial econometrics and operations research: financial time series analysis, modeling credit risks and optimizing asset allocation. S-PLUS, originally a product of StatSci, founded by R. Douglas Martin in Seattle, Washington, is a commercial version of the object oriented statistical programming language S, which Martin learned at Bell Laboratories in Murray Hill, New Jersey, now Lucent Technologies. The software was primarily developed for statistical data analysis of many types (see Venables and Ripley, 2002), with excellent graphs. Martin added robust estimation procedures, inspired by John Tukey, inventor of the term "bit," FFT (fast Fourier transform) and EDA (exploratory data analysis). The current owner of S-PLUS, Insightful, focuses on data mining and risk management. Zivot and Wang (2005), also in Seattle, Washington, developed the S-PLUS FinMetrics software for financial econometric time series analysis. The package also includes financial engineering procedures developed by Carmona (2004) and efficient Kalman filter state-space procedures by Siem Jan Koopman (see Koopman *et al.*, 1999). The popular financial time series textbook by Tsay (2005) makes intensive use of S-PLUS FinMetrics.

The popularity of the internet motivated the start of the statistical software Xplore in the later 1990s. There was great optimism about online cooperative development and use of software for advanced statistical computations. Härdle and Horowitz (2000) envisaged that the establishment of well-documented method archives, central common platform independent compilers and new web user interfaces would give easy access to the most advanced nonparametric methods. One of their suggested method and data technology centers was created and a (Java-based) web interface, Xplore Quantlet Client (XQC), was realized. Online electronic books with econometric and financial time series applications were provided for educational purposes, but online web-based econometric computing has not caught on yet. Xplore is now freely downloadable from http://www.xplore-stat.de.

In recent years, Michel Bierlaire has developed BIOGEME, an open source package (in C++ and Python) for modern random coefficient (or mixed) discrete choice modeling; he cooperates with Moshe Ben-Akiva and Nobel Laureate Daniel McFadden. Train (2003) treats this important topic in a textbook.

Young and old econometricians are switching from S-PLUS and other packages to the freely-available statistical system R, an open source statistical system that was initiated by statisticians Ross Ihaka and Robert Gentleman from Auckland, New Zealand. R has the S syntax (and is also known as GNU S). Graphs in R are provided via Gnuplot (which is also used in SHAZAM, discussed above, and TSMod, discussed below). R is part of the free GNU operating system (OS) and is part of all standard installations of this OS and therefore of many Linux installations. Officially, Gnuplot does not belong to GNU. Over 1,200 packages are available for R at the CRAN (Comprehensive R Archive Network) at http://www.r-project.org. Cribari-Neto and Zarkos (1999) reviewed an early version of R from an econometric research point of view, and Racine and Hyndman (2002) took a teaching perspective. Shumway and Stoffer (2006) provided up-to-date R code for their time series textbook. Rossi *et al*. (2005) developed an R package (`bayesm`) for their marketing statistics textbook. Li and Racine (2007) wrote the `np` package for a text on nonparametric econometrics. Modern statistical methods are often made available in R. For example, Hastie *et al*. (2001) discuss their well-known automatic model selection methods for regression and classification implemented in R.

Most R developers seem to work under the Linux OS and choose short, Unix-style package names. Many R packages are not difficult to use under Windows and Mac OS. Developing R packages under MS Windows has not been too easy, though as Rossi (2006) reports in his 15-page tutorial on this topic: "There is a sense in which the Windows R environment is a house of cards that must be carefully assembled or it won't work!" A specialized archive of R for econometrics does not exist. A comprehensive package for financial engineering, http://www.rmetrics.org, which encompasses many econometric time series functions, has been built by Diethelm Würtz at the ETH in Zürich.

29.7.5 Mathematical software for econometrics

The beginning of the PC era also witnessed the start of the matrix programming language GAUSS developed by Lee Edlefsen and Sam Jones in Washington State.

GAUSS did not offer a new econometric methodology, but it did have a very appealing combination of price and features for econometricians and economists (see GAUSS, 2005). It soon became popular and has remained popular ever since. It has a simple language with short matrix expressions (as illustrated in Table 29.6), decent graphs, fast numerical algorithms, tools to handle large datasets with limited memory, and a wide range of free and powerful packages implementing econometric applications for cross-section models and time series. Ron Schoenberg (1997), affiliated with Washington University, developed early procedures for constrained maximum likelihood for GAUSS, which found widespread application in the estimation of GARCH models. Schoenberg also wrote FANPAC, a financial time series analysis package with early applications of multivariate GARCH models.

The matrix programming language and signal processing tools of MATLAB (MATLAB, 2004), of the Mathworks, founded by Clive Moler, are used by many econometricians to implement model solvers and estimation methods. Econometricians use the free and comprehensive archive of econometric tools, at http://spatial-econometrics.com, administered by James P. LeSage at the university of Toledo, Ohio. Although the archive is set up for spatial econometrics procedures (LeSage and Pace, 2004), it contains many "estimation functions that provide printed and graphical output similar to that found in RATS, SAS or TSP."

Table 29.3 lists seven other mathematical programming languages which have not been used for *JAE* research articles so far, but code for these languages is provided by prominent econometricians. For example, Scilab code can be obtained for Dynare. Christopher Sims provides recent Octave code for solving rational expectations models on his own (Ubuntu/Linux) web server: http://sims.princeton.edu. Octave is a free alternative for MATLAB, but Sims points out that procedures with the same names can have different effects in the two languages.

Computer algebra packages like Mathematica and Maple are now also used for fast numerical computations, and are therefore more suited for applied econometrics, but they haven't had a big impact yet. The recently developed package MathStatica for Mathematica, by Colin Rose and Murray Smith, can save applied econometricians work in the analytical derivations of complicated likelihoods.

29.8 Simultaneous use of different software

As the tables and the discussion in the previous sections illustrate, many econometric techniques can now be implemented using existing mathematical and statistical software packages. No single software can serve all purposes, which explains why more and more packages coexist and why many researchers use several products next to each other.

Thanks to the search engine Google and free specific internet aggregators of economic and econometric research (papers, articles, books, citations, data and software) like RePEc, it is now easy to find properly documented econometric source code written for one of the main econometric softwares on the web. However, it is still difficult to assess the quality of this code if one does have access to the software for which it was originally developed. As most of these codes for academic

research papers are available free of charge, authors cannot be expected to set up a helpdesk, and one has to resort to mailing lists and internet forums, which also may be unreliable. Unsurprisingly, given the background of most econometricians, robust, high-quality econometric procedures seldom come free.

The modular structure of econometric and statistical software makes it possible to use codes outside their original environment. This helps the reproducibility required in academic econometrics. For example, Laurent and Urbain (2003) provide an interface called `M@ximize` for Ox, based on OxGauss, so that the wide range of econometric GAUSS programs available on the internet can be run without a licence for GAUSS or constrained maximum likelihood for GAUSS. Markus Krätzig developed a GUI for econometric modeling, JStatCom (see Kräetzig, 2006), which he built on top of GAUSS code and the GRTE (Gauss run time engine) to create JMulti as a stand-alone program. JStatCom can also be used in combination with MATLAB and Ox. John Breslaw of Econotron software introduced Symbolic Tools, which extends GAUSS and the GRTE with the infinite precision computer algebra of Maple. Cameron Rookley wrote the free GTOML (GAUSStoMATLAB) scripts which translate GAUSS code into MATLAB. This requires the free powerful OO programming language Perl (see http://www.perl.com, and http://www.cameronrookley.com).

Diethelm Würtz, author of Rmetrics, provided an interface in R for the G@RCH package that Laurent and Peters (2005) developed for Ox, but this still requires the availability of Ox. Many statistical packages have been ported to R; for example, BRugs, which embeds OpenBUGS in R. Robert Henson (2004) introduced a MATLAB R-link with functions for calling R from within MATLAB; Bengtsson (2005) increased the communication possibilities between MATLAB and R.

Integrating codes from different applications can save time, but has its dangers. Evaluation and improvement of existing implementations for nontrivial procedures should be a constant concern (see, for example, the discussion of numerical precision of econometric packages by McCullough and Vinod, 1999, which generated a series of changes in testing procedures). Note also the evaluation of random number generators (RNGs) as in McCullough (2006) and Doornik (2006). Reliability of RNGs is now extremely important as simulation-based inference starts to dominate both macroeconometrics and microeconometrics. Even if the RNG is right, and expert econometric knowledge is available, there is plenty of room for undetected mistakes. The home page of the BUGS project (Bayesian inference using Gibbs sampling) phrases this as follows: "Independent corroboration of MCMC results is always valuable!"; "MCMC is inherently less robust than analytic statistical methods. There is no in-built protection against misuse." Even before econometric modeling starts, one should apply Hendry's (1980) "three golden rules of econometrics: test, test and test" to the freshly developed or imported software.

29.9 New econometric modeling features and conclusions

Pagan and Wickens (1989) surveyed applied econometric methods 20 years ago. Four estimation methods were discussed: maximum likelihood, GMM (generalized

method of moments), M-estimators and nonparametric estimation, and different types of inference: frequentist and Bayesian, large sample asymptotics and the bootstrap for tests in small samples. They concluded: "when it comes to an area such as econometrics. Gone are the days when a single individual could have a detailed knowledge of all divisions of the subject. Just twenty years ago this might have been possible"; "the years since then have witnessed a fragmentation of econometrics. The biggest division has been between micro and macro econometrics." As indicated in section 29.2, many new data types, estimators, inference methods and diagnostic procedures have been analyzed by applied econometricians since 1989. The fragmentation now also applies to software development, with dozens of procedures published on the internet for the same purpose.

Although applied nonparametric econometrics has been on the rise, model-based econometrics still dominates the field of applied econometrics. A key aspect that distinguishes model-based econometric software is the standard availability of features for the interactive modeling cycle: models not only are easily specified and estimated, but diagnostic tests, easy respecification, and re-estimation facilities are provided in order to make the interpretation of parameter estimates and forecasts as credible as possible. Today, this requires a graphical (WIMP) interface that is sufficiently intuitive and easy to learn and remember for new users.

This recursive modeling is especially relevant for the econometric analysis of time series, where new observations become available in a natural order, with associated testing possibilities and possible adaptations of existing models. In the context of dynamic linear regression models, PcGive was the first program to cater for the influential general-to-specific methodology of econometric model selection. A "Progress" menu in PcGive simplifies the interactive model selection process. Although this feature *per se* has not been copied in other packages, a wide range of standard specification tests and diagnostics for estimated models has now become a crucial ingredient of every econometric software.

The model selection process can be automated. Successful automated model selection has long been available for pure Box–Jenkins time series modeling for forecasting in the AutoBox software by David Reilly and in the Census X-11-ARIMA program for seasonal adjustment of the US Census. Automated linear dynamic model selection for economic analysis, based on a wide range of robust diagnostic tests and multiple-path general-to-specific modeling, is available in the PcGive procedure Autometrics (Doornik, 2008).

However, automated model selection methods, even if they encompass generalized linear models of "Statistical Learning," as in Hastie *et al*. (2003), or fractional instead of zero-one model weights of Bayesian model averaging (BMA), as in Raftery *et al*. (1997), still require a "most general" adequately specified model, for which extensive tests should be available.

Stochastic simulation and bootstrap analysis of econometric models should be available as a matter of course, both for the interpretation of nonlinear models and for associated statistical inference. James Davidson's (nonlinear) time series modeling package TSMod, reviewed by Fuertes *et al*. (2005), has this feature for all models in the package: "Bootstrap *p*-values for diagnostic and significance tests, using the

simulation module to generate bootstrap draws." If the inference is simulation-based, one also needs diagnostics on the efficacy and reliability of the associated simulation methods.

User interfaces will have to be updated. Following Google and Gretl, users will expect econometric software to deal with labels and numbers in their native language and application menus to use their own character sets. The graphical interface will also need reconstruction as customers adapt to modern graphical interfaces. New interfaces will help to make better use of the many options that programs and procedures have, both on the user's own computer and on internet archives. Many procedures are ineffective because they are hard to find in the current menu structures. Based on a user history, the menus will "automatically" select the best options for the user.

The market for specific econometric software is too small for one program to keep up with all recent scientific developments in econometrics, mathematics and statistics, to keep advanced knowledgeable customers interested in buying updates, and to implement lessons from human–computer interaction (HCI) research to keep attracting new customers.

The presence of trends implies some predictability of future developments. The pattern that has emerged in the last 25 years does not make it likely that new, fully-fledged, dedicated econometric software packages with high academic standards are going to be developed. Academic returns on high-quality, robust, versatile, and well-documented and supported econometric software development are low. Changing citation practices for software use, as exemplified by the *JAE* data and code archive, may increase these returns in the years ahead.

In this chapter I have discussed over 20 years of changing software use and software development for innovative applied econometrics. An increasing range of software has became relevant in this period. I also classified this large collection of programs and assessed the continuity of their use. Finally, I pointed out new direction for econometric modeling software development.

Acknowledgments

I would like to thank Christopher Baum, Jurgen Doornik, Bill Rising, Ronald Schoenberg and Christian Kleiber for helpful comments on this chapter. All errors are my own.

Note

1. Software: I used MS Excel 2000, Windows XP, 5.1 Service Pack 2, MikTeX 2.4, OxEdit 5.0, Firefox 3, OxMetrics 5.0, GAUSS 7, R 2.7, Google, Google Scholar, Google Books, JSTOR and Wiley Interscience to prepare this chapter.
